In allopatric speciation (from the Greek *alias*, other, and *patra*, homeland), gene flow is interrupted when a population is divided into geographically isolated subpopulations. For example, the water level in a lake may subside, resulting in smaller lakes that are home to separated populations (see Figure 24.5). A river may change course and split a population of animals that cannot cross it. Allopatric speciation can also occur without geologic remodeling, such as when individuals colonize a remote area, and their descendants become geographically isolated from the parent population. An example is the speciation that occurred on the Galapagos Islands following colonization by mainland organisms.

How formidable must a geographic barrier be to keep allopatric populations apart? The answer depends on the ability of the organisms to move about. Birds, mountain lions, and coyotes can cross hills, rivers, and canyons. Nor do such barriers hinder the windblown pollen of pine trees or the seeds of many flowering plants. In contrast, small rodents may find a deep canyon or a wide river a formidable barrier (Figure 24.6).

Once geographic separation has occurred, the separated gene pools diverge through any or all of the mechanisms described in Chapter 23: different mutations arise, sexual selection takes a different course in the respective populations, other selective pressures act differently on the separated organisms, and genetic drift alters allele frequencies. Because small, isolated populations are more likely than large populations to undergo a significant change in their gene pool in a relatively short time due to selection and drift, they are also more likely to experience allopatric speciation. In less than 2 million years, the few animals and plants from the South American mainland that colonized the Galapagos Islands gave rise to all the new species now found there. But for each small, isolated population that becomes a new species, many more perish in their new environment.

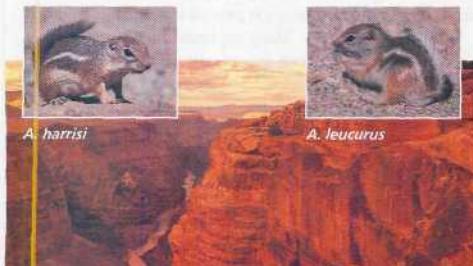

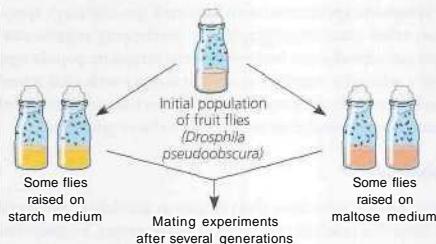

Figure 24.6 Allopatric speciation of antelope squirrels on opposite rims of the Grand Canyon. Harris's antelope squirrel (*Ammospermophilus harrisi*) inhabits the canyon's south rim (left). Just a few miles away on the north rim (right) lives the closely related white-tailed antelope squirrel (*Ammospermophilus leucurus*). In contrast, birds and other organisms that can disperse easily across the canyon have not diverged into different species on opposite rims.

To confirm a case of allopatric speciation, it is necessary to determine whether the allopatric populations have changed enough that they no longer have the potential to interbreed and produce fertile offspring. In some cases, researchers evaluate whether speciation has occurred by bringing together members of separated populations in a laboratory setting (Figure 24.7).

Figure 24.7

Inquiry Can divergence of allopatric fruit fly populations lead to reproductive isolation?

EXPERIMENT Dariel Dodd, of Yale University, divided a fruitfly population, raising some populations on a starch medium and others on a maltose medium. After many generations, natural selection resulted in divergent evolution: Populations raised on starch digested starch more efficiently, while those raised on maltose digested maltose more efficiently. Dodd then put flies from the same or different populations in mating cages and measured mating frequencies.

RESULTS

When flies from "starch populations" were mixed with flies from "maltose populations," the flies tended to mate with like partners. In the control group, flies taken from different populations that were adapted to the same medium were about as likely to mate with each other as with flies from their own populations.

| | | Female | |
|--|-----------------------|--------|---------|
| | | Starch | Maltose |
| Male | Starch | 22 | 9 |
| | Maltose | 8 | 20 |
| Mating frequencies in experimental group | | | |
| | | Female | |
| Male | Same population | 18 | 15 |
| | Different populations | 12 | 15 |
| Mating frequencies in control group | | | |

CONCLUSION

The strong preference of "starch flies" and "maltose flies" to mate with like-adapted flies, even if they were from different populations, indicates that a reproductive barrier is forming between the divergent populations of flies. The barrier is not absolute (some mating between starch flies and maltose flies did occur) but appears to be under way after several generations of divergence resulting from the separation of these allopatric populations into different environments.

Biologists can also assess allopatric speciation in the wild. For example, females of the Galapagos ground finch *Geospiza difficilis* respond to the song of males from the same island, but ignore the songs of males of the same species from other islands (allopatric populations) that they encounter. This finding indicates that different behavioral (prezygotic) barriers have developed in these allopatric *G. difficilis* populations, which may eventually become separate species.

We need to emphasize that geographic isolation, though obviously preventing interbreeding between allopatric populations, is not in itself a biological isolating mechanism. Isolating mechanisms—which are intrinsic to the organisms themselves—prevent interbreeding even in the absence of geographic isolation.

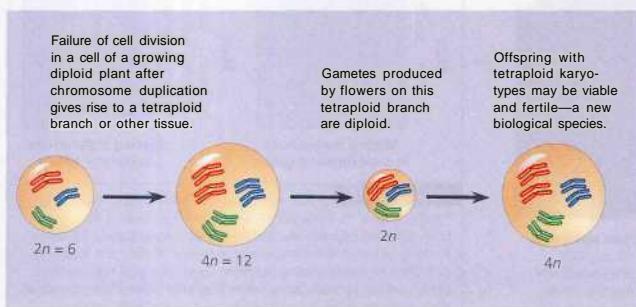

Next, let's turn to mechanisms that can produce a new species without geographic isolation from the parent population.

Sympatric ("Same Country") Speciation

In sympatric speciation (from the Greek *syn*, together), speciation takes place in geographically overlapping populations. How can reproductive barriers between sympatric populations evolve when the members remain in contact with each other? Mechanisms of sympatric speciation include chromosomal changes and nonrandom mating that reduces gene flow.

Folyploidy

Some plant species have their origins in accidents during cell division that result in extra sets of chromosomes, a mutational change that results in the condition called polyploidy. An autopolyploid (from the Greek *autos*, self) is an individual that has more than two chromosome sets, all derived from a single species. For example, a failure of cell division can double a cell's chromosome number from the diploid number ($2n$) to a tetraploid number ($4n$) (Figure 24.8). This mutation prevents a tetraploid from successfully interbreeding with diploid plants of the original population—the triploid ($3n$)

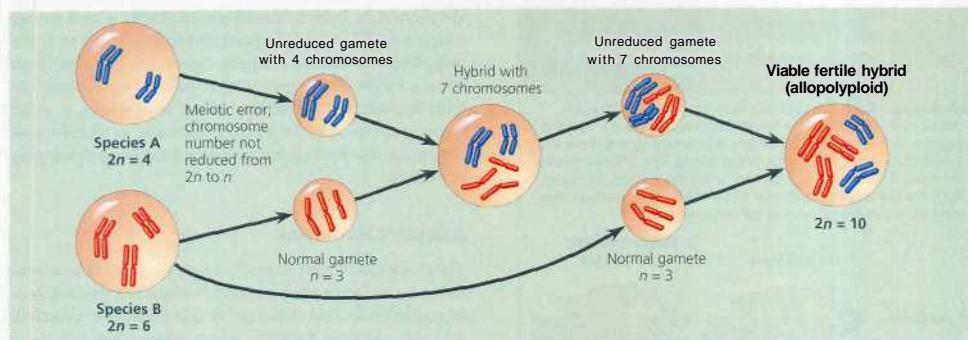

▲ Figure 24.8 Sympatric speciation by autopolyploidy in plants.

offspring of such unions are sterile because their unpaired chromosomes result in abnormal meiosis. However, the tetraploid plants can still produce fertile tetraploid offspring by self-pollinating or mating with other tetraploids. Thus, in just one generation, autopolyploidy can generate reproductive isolation without any geographic separation.

A much more common form of polyploidy can occur when two different species interbreed and produce a hybrid. Inter-specific hybrids are often sterile because the set of chromosomes from one species cannot pair during meiosis with the set of chromosomes from the other species. However, though infertile, the hybrid may be able to propagate itself asexually (as many plants can do). In subsequent generations, various mechanisms can change a sterile hybrid into a fertile polyploid known as an allopolyploid (Figure 24.9 illustrates one such mechanism). The allopolyploids are fertile with each other but cannot interbreed with either parental species—thus they represent a new biological species.

The origin of new polyploid plant species is common enough and rapid enough that scientists have documented several such speciations. For example, two new species of goatsbeard plants (genus *Tragopogon*) originated in the Pacific Northwest in the mid-1900s. Although the goatsbeard genus is native to Europe, humans had introduced three species to the Americas in the early 1900s. These species, *T. dubius*, *T. pratensis*, and *T. porrifolius*, are now common weeds in abandoned parking lots and other urban wastelands. In the 1950s, botanists identified two new *Tragopogon* species in regions of Idaho and Washington where all three European species are also found. One new species, *T. miscellus*, is a tetraploid hybrid of *T. dubius* and *T. pratensis*; the other new species, *T. mirensis*, is also an autopolyploid, but its ancestors are *T. dubius* and *T. porrifolius*. While the *T. minis* population grows mainly by reproduction of its own members, additional episodes of hybridization between the ancestral species are continuing to add to the *T. mirus* population—just one example of an ongoing speciation process that can be observed.

Many important agricultural crops—such as oats, cotton, potatoes, tobacco, and wheat—are polyploids. The wheat used for bread, *Triticum aestivum*, is an allohexaploid (six sets of chromosomes, two sets from each of three different species). The first of the polyploid events that eventually led to modern wheat probably occurred about 8,000 years ago in the Middle East as a spontaneous hybrid of an early cultivated wheat and a wild grass. Today, plant geneticists create new polyploids in the laboratory by using chemicals that induce meiotic and mitotic errors. By harnessing the evolutionary process,

A Figure 24.9 One mechanism for allopolyploid speciation in plants. A hybrid of two different species is usually sterile because its chromosomes are not homologous and cannot pair during meiosis. However, such a hybrid may be able to reproduce asexually. This diagram traces one mechanism that can produce fertile hybrids (allopolyploids) as new species. The new species has a diploid chromosome number equal to the sum of the diploid chromosome numbers of the two parent species.

researchers can produce new hybrid species with desired qualities, such as a hybrid combining the high yield of wheat with the hardiness of rye.

Habitat Differentiation and Sexual Selection

Polyplid speciation also occurs in animals, although it is less common than in plants. Other mechanisms can also lead to sympatric speciation in both animals and plants. For example, reproductive isolation can occur when genetic factors enable a subpopulation to exploit a resource not used by the parent population. Such is the case with the North American apple maggot fly, *Rhagoletis pomonella*. The fly's original habitat was native hawthorn trees, but about 200 years ago, some populations colonized apple trees introduced by European settlers. Apples mature more quickly than hawthorn fruit, and so the apple-feeding flies have been selected for rapid development. These apple-feeding populations now show temporal isolation from the hawthorn-feeding *R. pomonella*. Although the two groups are still classified as subspecies rather than separate species, speciation appears to be well under way.

One of Earth's hot spots of animal speciation is Lake Victoria in eastern Africa. This vast, shallow lake has filled and dried up repeatedly in response to climate changes. The current lake, which is only 12,000 years old, is home to more than 500 species of cichlid fishes. The species are so genetically similar that it is very likely that many have arisen since the lake last filled. The subdivision of the original fish population into groups adapted to exploiting different food sources was one factor contributing to this rapid speciation. But researchers from the University of Leiden in the Netherlands

have shown that an additional factor may have been nonrandom mating (sexual selection), in which females select males based on their appearance.

These researchers studied two closely related sympatric species of cichlids that differ mainly in coloration: *Pimelomilia pumila* has a blue-tinged back, and *Pimelomilia nyererei* has a red-tinged back. It is a reasonable hypothesis that a preference for mates of like coloration functions as a behavioral barrier to interbreeding. In an aquarium with natural light, females of each species mated only with males of their own species. But in an aquarium illuminated with a monochromatic orange lamp, which made the two cichlid species appear identical, females of each species mated indiscriminately with males of both species (**Figure 24.10**, on the next page). The hybrids from the *P. pumila* × *P. nyererei* matings were viable and fertile.

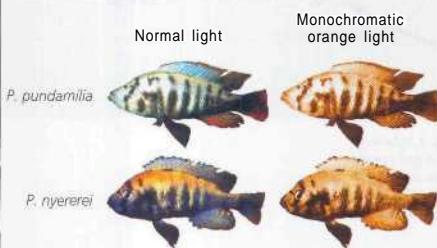

From the results of these experiments, we can infer that mate choice based on coloration is the main reproductive barrier that normally keeps the gene pools of these two species separate. And we can also infer from their ability to interbreed in the laboratory that, like the apple maggot flies, these species have only begun to diverge. It seems likely that the ancestral population was polymorphic for color and that divergence began with the appearance of two ecological niches that divided the fish into subpopulations. Genetic drift resulted in chance differences in their genetic makeup, with the result that females in one subpopulation favored red in their mates, while females in the other subpopulation preferred blue. Sexual selection then reinforced the color difference as females mated preferentially with males having genes for the least mistakesable coloration (see Chapter 23 to review sexual selection). Pollution is now clouding the waters of Lake Victoria, so perhaps the cichlids' divergence will be

Figure 24.10

Inquiry Does sexual selection in cichlids result in reproductive isolation?

EXPERIMENT

Researchers from the University of Leiden placed males and females of *Pundamilia pundamilia* and *P. nyererei* together in two aquarium tanks, one with natural light and one with a monochromatic orange lamp. Under normal light, the two species are noticeably different in coloration; under monochromatic orange light, the two species appear identical in color. The researchers then observed the mating choices of the fish in each tank.

RESULTS

Under normal light, females of each species mated only with males of their own species. But under orange light, females of each species mated indiscriminately with males of both species. The resulting hybrids were viable and fertile.

CONCLUSION

The researchers concluded that mate choice by females based on coloration is the main reproductive barrier that normally keeps the gene pools of these two species separate. Since the species can still interbreed when this prezygotic behavioral barrier is breached in the laboratory, the genetic divergence between the species is likely to be small. This suggests that speciation in nature has occurred relatively recently.

reversed. As it becomes more difficult for female cichlids to visually distinguish between the males, the gene pools of *Pundamilia* and *P. nyererei* may again blend together.

Allopatric and Sympatric Speciation: A Summary

Before continuing our discussion, let's recap the two main modes by which new species form. In allopatric speciation, a new species forms while geographically isolated from its parent population. As the isolated population evolves by natural selection and genetic drift, reproductive isolation from the ancestral species may arise as a by-product of the genetic change. Such reproductive barriers prevent interbreeding with the parent population, even if the populations come back into contact.

Sympatric speciation, in contrast, requires the emergence of a reproductive barrier that isolates a subset of a population without geographic separation from the parent population. A common mechanism, especially in plants, is

allopolyploidy: hybridization between closely related species coupled with errors during cell division that lead to fertile polyploid individuals. Sympatric speciation can also result when a subset of a population becomes reproductively isolated because of a switch to a habitat, food source, or other resource not used by the parent population. In animals, speciation can also result from sexual selection in a polymorphic population.

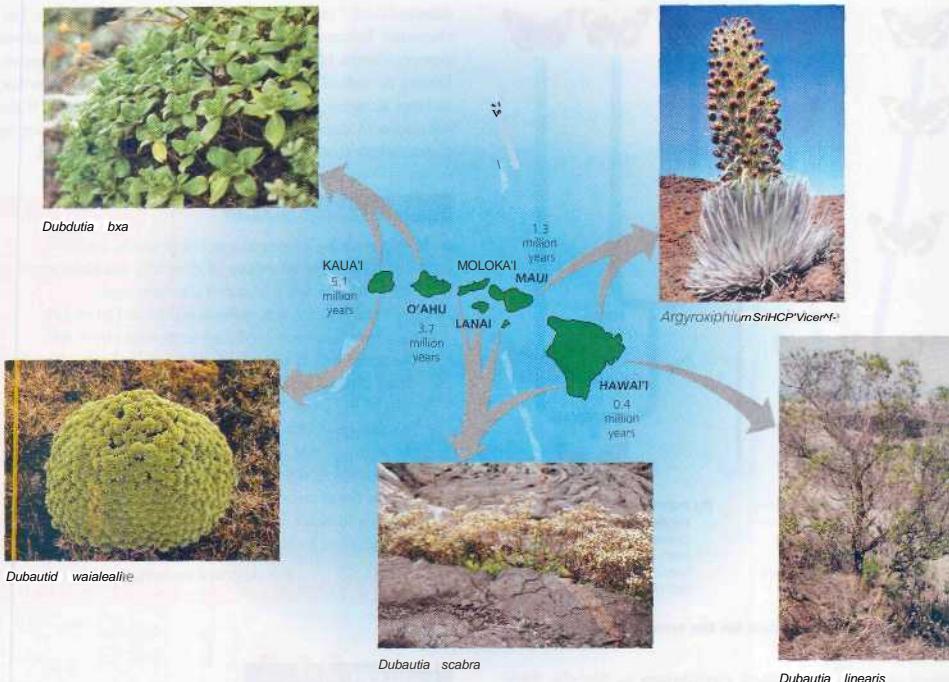

Adaptive Radiation

The evolution of many diverse adapted species from a common ancestor upon introduction to various new environmental opportunities and challenges is called **adaptive radiation**. Adaptive radiation typically occurs when a few organisms make their way to new, often distant areas (Figure 24.11) or when environmental changes cause numerous extinctions, opening up ecological niches for the survivors. For example, fossil evidence indicates that mammals underwent a dramatic adaptive radiation after the extinction of the dinosaurs 65 million years ago.

The Hawaiian archipelago is one of the world's great showcases of adaptive radiation, as Kenneth Kaneshiro explained in the interview on pages 436–437. Located about 3,500 km from the nearest continent, the volcanic islands are progressively younger as one follows the chain toward the southeast; the youngest island, Hawaii, is less than a million years old and still has active volcanoes. "Each island was born "naked" and was gradually populated by stray organisms that rode the ocean currents and winds either from far-distant land areas or from older islands of the archipelago itself. The physical diversity of each island—including immense ranges of altitudes and rainfall—provides many opportunities for evolutionary divergence by natural selection (Figure 24.12). Multiple

& Figure 24.11 Long-distance dispersal. Seeds of the plant *Pisonia* cling like Velcro to this migratory black noddy tern off the Australian coast. This mechanism enables the seeds to be transported over long distances. (In fact, studying how such seeds bind tightly but reversibly to feathers and fur inspired the inventors of Velcro.)

A Figure 24.12 Adaptive radiation. Molecular analysis indicates that these remarkably varied Hawaiian plants, known collectively as the “silversword alliance,” are all descended from an ancestral tarweed that arrived on the islands about 5 million years ago from North America. Members of the silversword alliance have since spread into many different habitats on the islands, evolving into distinct forms through allopatric and sympatric speciation.

invasions and allopatric and sympatric speciation events have ignited an explosion of adaptive radiation—most of the thousands of species that inhabit the islands are found nowhere else on Earth.

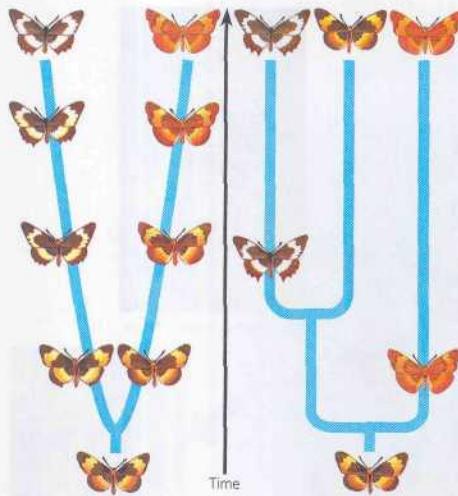

Studying the Genetics of Speciation

Rapid strides in genetics are enabling researchers to pinpoint genes that play a key role in particular cases of speciation. In one such study, Douglas Schemske and his colleagues at Michigan State University examined two species of monkey flower (*Mimulus*; see Figure 24.4f and g). *Mimulus lewisii* and *Mimulus cardinalis* are pollinated by bees and hummingbirds, respectively, keeping their gene pools separate through prezygotic isolation. But the species so far show no postzygotic isolation; they can be mated readily in the greenhouse. The resulting hybrids produce offspring with flowers

in a wide variety of colors and shapes. By observing which pollinators visit which flowers and then investigating the genetic differences among the plants, the researchers concluded that two gene loci are largely responsible for pollinator choice. One locus influences flower color and the other affects the amount of nectar that the flowers make. Thus, by determining the attractiveness of the flowers to different pollinators, allelic diversity at these loci has ultimately resulted in speciation.

The Tempo of Speciation

The fossil record includes many episodes in which new species appear suddenly in a geologic stratum, persist essentially unchanged through several strata, and then apparently disappear. Paleontologists Niles Eldredge of the American Museum of Natural History and Stephen Jay Gould of Harvard University

(a) Gradualism model. Species descended from a common ancestor gradually diverge more and more in their morphology as they acquire unique adaptations.

(b) Punctuated equilibrium model. A new species changes most as it buds from a parent species and then changes little for the rest of its existence.

A Figure 24.13 Two models for the tempo of speciation.

coined the term punctuated equilibrium to describe these periods of apparent stasis punctuated by sudden change.

Some scientists suggest that these patterns require an explanation outside the Darwinian model of gradual descent with modification. However, this is not necessarily the case. For one thing, such punctuations may have been less abrupt than they appear from the fossil record. Suppose that a species survived for 5 million years, but most of its morphological alterations occurred during the first 50,000 years of its existence—just 1% of its total lifetime. Because time periods this short often cannot be distinguished in fossil strata, the species would seem to have appeared suddenly and then lingered with little or no change before becoming extinct. Even though the emergence of this species actually took tens of thousands of years, this period of change left no fossil record (**Figure 24.13**).

In fact, Darwin himself noted this pattern in the fossil record. He anticipated the concept of punctuated equilibrium when he wrote, "Although each species must have passed through numerous transitional stages, it is probable that the periods during which each underwent modification, though many and long as measured by years, have been short in comparison with the periods during which each remained in an unchanged condition."

Stasis, too, can be explained. All species continue to adapt after they come into existence, but often in ways that cannot be

detected from fossils, such as small modifications in their biochemistry. By necessity, paleontologists base hypotheses about descent almost entirely on external anatomy and skeletons. During periods of apparent equilibrium, changes in behavior, internal anatomy, and physiology may go undetected. If the environment changes, however, the stasis will be broken by punctuations that leave visible traces in the fossil record.

Concept Check 24.2

- Explain why allopatric specialization would be less likely to occur on an island close to a mainland than on a more isolated island of the same size.
- Normal watermelon plants are diploid ($2n = 22$), but breeders have produced tetraploid ($4n = 44$) watermelons. If tetraploid plants are hybridized with their diploid relatives, they produce triploid ($3n = 33$) seeds. These offspring can produce triploid seedless watermelons and can be further propagated by cuttings. Are the diploid and tetraploid watermelon plants different species? Explain.
- In the fossil record, transitional fossils linking newer species to older ones are relatively rare. Suggest an explanation for this observation.

For suggested answers, see Appendix A.

Concept 24.3

Macroevolutionary changes can accumulate through many speciation events

Speciation can result from differences as seemingly small as the color on a cichlid's back. However, as species diverge and speciate again and again, these differences can accumulate and become more pronounced. Thus, speciation constitutes the beginning of macroevolutionary change. Macroevolutionary transformations, like the microevolutionary changes that take place within a single gene pool, accumulate through the processes that we examined in Chapter 23—natural selection, mutation, genetic drift, and gene flow. It is the cumulative change during thousands of small speciation episodes that accounts for sweeping evolutionary changes. We will now look at some of the ways in which these major transformations have taken place.

Evolutionary Novelties

The Darwinian concept of descent with modification can be extended to account for even major morphological transfor-

mations. In most cases, complex structures have evolved in increments from much simpler versions that performed the same basic function.

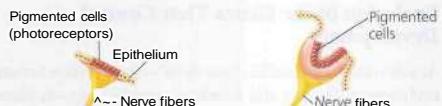

For example, consider the human eye, an intricate organ constructed from numerous parts that work together in forming an image and transmitting it to the brain. How could the human eye have evolved in gradual increments? If the eye needs all its components to function, how could a partial eye have been of any use to our ancestors?

The flaw in this argument, as Darwin himself noted, lies in the assumption that only complicated eyes are useful. In fact, many animals depend on eyes that are far less complex than our own (**Figure 24.14**). The simplest eyes that we know of are patches of light-sensitive photoreceptor cells. These simple eyes appear to have had a single evolutionary origin and are now found in a variety of animals, such as limpets, small molluscs (members of the phylum Mollusca). These eyes have no lenses or other equipment for focusing images, but they do enable the animal to distinguish light from dark. Limpets cling more tightly to their rock when a shadow falls on them—a behavioral adaptation that reduces the risk of being eaten. Since limpets have had a long evolutionary history, we can conclude that their "simple" eyes are quite adequate to support their survival and reproduction.

In the animal kingdom, complex eyes of various types evolved independently from such basic structures many times. Some molluscs, including the squids and octopuses.. have eyes as complex as those of humans and other vertebrates (see Figure 24.14). Although complex mollusc eyes evolved independently of complex vertebrate eyes, both evolved from an ancestral simple cluster of photoreceptor cells. This divergence took place through a series of incremental modifications that benefited the eyes' owners at every stage. Evidence for this evolutionary divergence comes from phylogenetic analysis of the genes that act as "master regulators" of eye development and are shared by all animals with eyes.

Throughout their evolutionary history, eyes retained their basic function of vision. But evolutionary novelty can also arise when structures that originally played one role gradually acquire a different one. Structures that evolve in one context but become co-opted for another function are sometimes called *exaptations* to distinguish them from the adaptive origin of the original structure.

Note that the concept of exaptation does not imply that a structure somehow evolves in anticipation of future use. Natural selection cannot predict the future; it can only improve a structure in the context of its *current* utility. For example, the lightweight, honeycombed bones of birds are homologous to the bones of birds' earthbound ancestors. However, honeycombed bones could not have evolved in the ancestors as an adaptation for future flight—they must have had another benefit. Fossils of some close relatives of

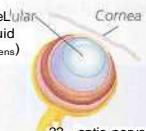

(a) Patch of pigmented cells. The limpet *Patella* has a simple patch of photoreceptors.

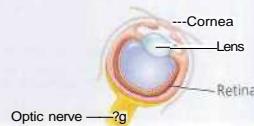

(b) Eyecup. The slit shell mollusc *Pleurotomaria* has an eyecup.

(c) Pinhole camera-type eye. The *Nautilus* eye functions like a pinhole camera (an early type of camera lacking a lens).

(d) Eye with primitive lens. The marine snail *Murex* has a primitive lens consisting of a mass of crystal-like cells. The cornea is a transparent region of epithelium (outer skin) that protects the eye and helps focus light.

(e) Complex camera-type eye. The squid *Loligo* has a complex eye whose features (cornea, lens, and retina), though similar to those of vertebrate eyes, evolved independently.

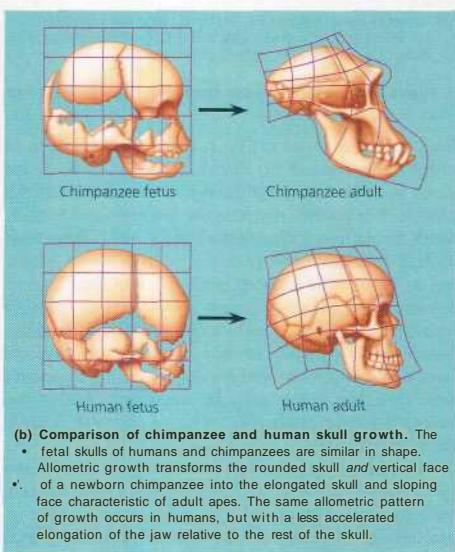

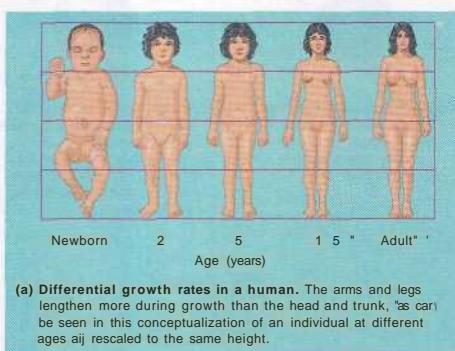

A Figure 24.14 A range of eye complexity among molluscs.

birds have been found in China. These small animals were unable to fly but had feet that enabled them to climb and perch in trees. Lightweight bones would have aided this lifestyle. It is possible that winglike forelimbs and feathers, which would have increased the surface area of these small animals' forelimbs, were co-opted for flight after functioning in some other capacity, such as courtship, thermoregulation, or camouflage (functions that feathers still serve today). The first flights might have been only short glides. Indeed, the first feathers to leave traces in the fossil record were short and downy; feathers adapted for flight appeared later. Over time, natural selection screening additional mutations remodeled feathers and wings in ways that better fit their new function.

The concept of exaptation offers one explanation for how novel features can arise gradually through a series of intermediate stages, each of which has some function in the organism's current context. In the words of Harvard University zoologist Karel Liem, "Evolution is like modifying a machine while it's running."

Evolution of the Genes That Control Development

As you read in Chapter 21, "evo-devo"—the interface between evolutionary biology and developmental biology—is illuminating how slight genetic divergences can be magnified into major morphological differences between species. Genes that program development control the rate, timing, and spatial pattern of changes in an organism's form as it develops from a zygote into an adult.

A Figure 24.15 Allometric growth. Different growth rates for different parts of the body determine body proportions.

Changes in Rate and Timing

Many striking evolutionary transformations are the result of heterochrony (from the Greek *hetera*, different, and *throws*, time) an evolutionary change in the rate or timing of developmental events. For example, an organism's shape depends in part on the relative growth rates of different body parts during development. This proportioning that helps give a body its specific form is called allometric growth (from the Greek *olios*, other, and *metron*, measure). **Figure 24.15a** tracks how allometric growth alters human body proportions during development. Changing these relative rates of growth even slightly changes the adult form substantially. For example, different allometric patterns contribute to the contrasting shapes of human and chimpanzee skulls (**Figure 24.15b**).

Heterochrony has also played a role in the evolution of salamander feet (**Figure 24.16**). Most salamanders live on the ground, but some species live in trees. The feet of the tree-dwelling species are adapted for climbing vertically rather

(a) Ground-dwelling salamander. A longer time period for foot growth results in longer digits and less webbing.

(b) Tree-dwelling salamander. Foot growth ends sooner. This evolutionary timing change accounts for the shorter digits and more extensive webbing, which help the salamander climb vertically on tree branches.

A Figure 24.16 Heterochrony and the evolution of salamander feet in closely related species.

tlim walking on the ground; for example, their shorter digits and more extensive webbing provide better traction. The basis for this adaptation was probably selection for alleles of genes that control the timing of foot development. According to this hypothesis, the foot of the ancestral salamander grew until the products of certain regulatory genes switched off growth, resulting in a foot of a certain size. A mutation in one or more of these regulatory genes could have switched off foot growth sooner, resulting in the stunted feet of tree-dwelling salamanders. In this way, a relatively small amount of genetic change can be amplified into substantial morphological change.

Heterochrony can also alter the timing of reproductive development relative to the development of somatic (nonreproductive) organs. If the rate of reproductive development accelerates compared to somatic development, the sexually mature stage of a species may retain body features that were juvenile structures in an ancestral species—a condition called paedomorphosis (from the Greek *paedos*, of a child, and *morphosis*, formation). For example, most salamander species have a larval stage that undergoes metamorphosis in becoming an adult. But some species grow to adult size and become sexually mature while retaining gills and other larval features (Figure 24.17). Such an evolutionary alteration of developmental timing can produce animals that appear very different from their ancestors, even though the overall genetic change may be small. Indeed, recent evidence indicates that a genetic change at a single locus was probably sufficient to bring about paedomorphosis in the axolotl salamander, although other genes may have contributed as well.

In summary, heterochrony affects the evolution of morphology by altering the rates at which various body parts

A Figure 24.17 Paedomorphosis. Some species retain as adults features that were juvenile in ancestors. This salamander is an axolotl, which grows to full size, becomes sexually mature, and reproduces while retaining certain larval (tadpole) characteristics, including gills.

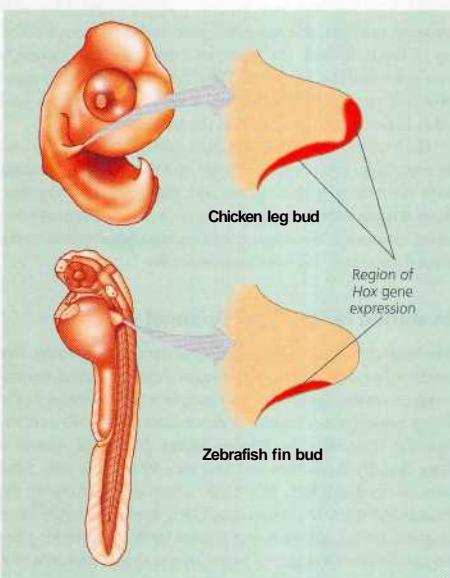

develop or by changing the timing of onset or completion of a particular part's development.

Changes in Spatial Pattern

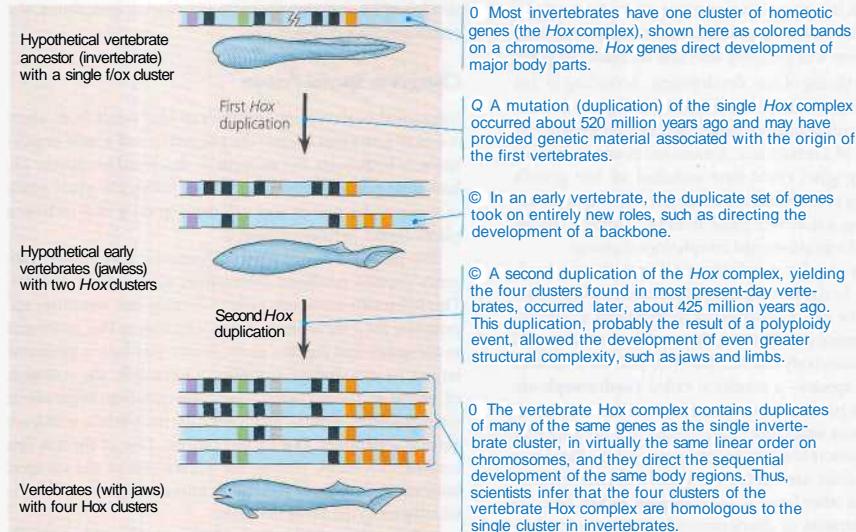

Substantial evolutionary changes can also result from alterations in genes that control the placement and spatial organization of body parts. For example, as described in Chapter 21, homeotic genes determine such basic features as where a pair of wings and a pair of legs will develop on a bird or how a plant's flower parts are arranged.

The products of one class of homeotic genes called *Hox* genes provide positional information in an animal embryo. This information prompts cells to develop into structures appropriate for a particular location. Changes in *Hox* genes and in the genes that regulate them in turn can have a profound impact on morphology. Consider, for example, the evolution of tetrapods (the terrestrial vertebrates including amphibians, birds and other reptiles, and mammals) from fishes, which are aquatic vertebrates. During this process, four of the fish fins evolved into limbs. Among the adaptations of the tetrapod limb are digits (fingers and toes in humans) that extend skeletal support to the tip of the limb.

In fish embryos, a *Hox* gene is expressed in a band of cells running along one edge of the fin bud (Figure 24.18). In

A Figure 24.18 Hox genes and the evolution of tetrapod limbs. The red zones indicate regions where a *Hox* gene involved in skeleton development is expressed.

4 Figure 24.19 *Hox* mutations and the origin of vertebrates.

tetrapod embryos, this same *Hox* gene is also expressed at the tip of the limb bud, the embryonic structure that develops into a forelimb or hind limb. The product of this *Hox* gene provides positional information about how far digits and other bones should extend from the limb.

The evolution of vertebrates from invertebrate animals was an even larger evolutionary change, and it, too, was associated with alterations in *Hox* genes and the genes that regulate them (Figure 24.19). In producing such morphological novelties, changes in developmental dynamics have undoubtedly played important roles in macroevolution.

Evolution Is Not Goal Oriented

The fossil record often shows apparent trends in evolution. For instance, some evolutionary lineages exhibit a trend toward larger or smaller body size. An example is the evolution of the living horse (genus *Equus*), a descendant of the 40-million-year-old *Hyracotherium* (Figure 24.20). About the size of a large dog, *Hyracotherium* had four toes on its front feet, three toes on its hind feet, and teeth adapted for browsing on bushes and trees. In comparison, living horses are larger, have only one toe on each foot, and possess teeth modified for grazing on grasses. Do these changes represent real trends, and if so, how do we account for them?

Extracting a single evolutionary progression from the fossil record can be misleading; it is like describing a bush as grow-

ing toward a single point by tracing only the branches that lead to that twig. For instance, by selecting certain species from the available fossils, it is possible to arrange a succession of animals intermediate between *Hyracotherium* and living horses that shows trends toward increased size, reduced number of toes, and modification of teeth for grazing (yellow line in Figure 24.20). However, if we include all fossil horses known today, this apparent trend vanishes. The genus *Equus* did not evolve in a straight line; it is the only surviving twig of an evolutionary tree that is so branched that it is more like a bush. *Equus* actually descended through a series of speciation episodes that included several adaptive radiations, not all of which led to large, one-toed, grazing horses. For instance, notice in Figure 24.20 that only those lineages derived from *Parahippus* include grazers; other lineages derived from *Miohippus*, all of which are now extinct, remained multi-toed browsers for 35 million years.

Branching evolution can result in an evolutionary trend even if some new species counter the trend. For example, one model of long-term trends proposed by Steven Stanley of Johns Hopkins University considers species to be analogous to individuals: Speciation is their birth, extinction is their death, and new species that diverge from them are their offspring. In this model, Stanley suggests that just as individual organisms undergo natural selection, species undergo species selection. The species that endure the longest and generate the most new offspring species determine the direction of major

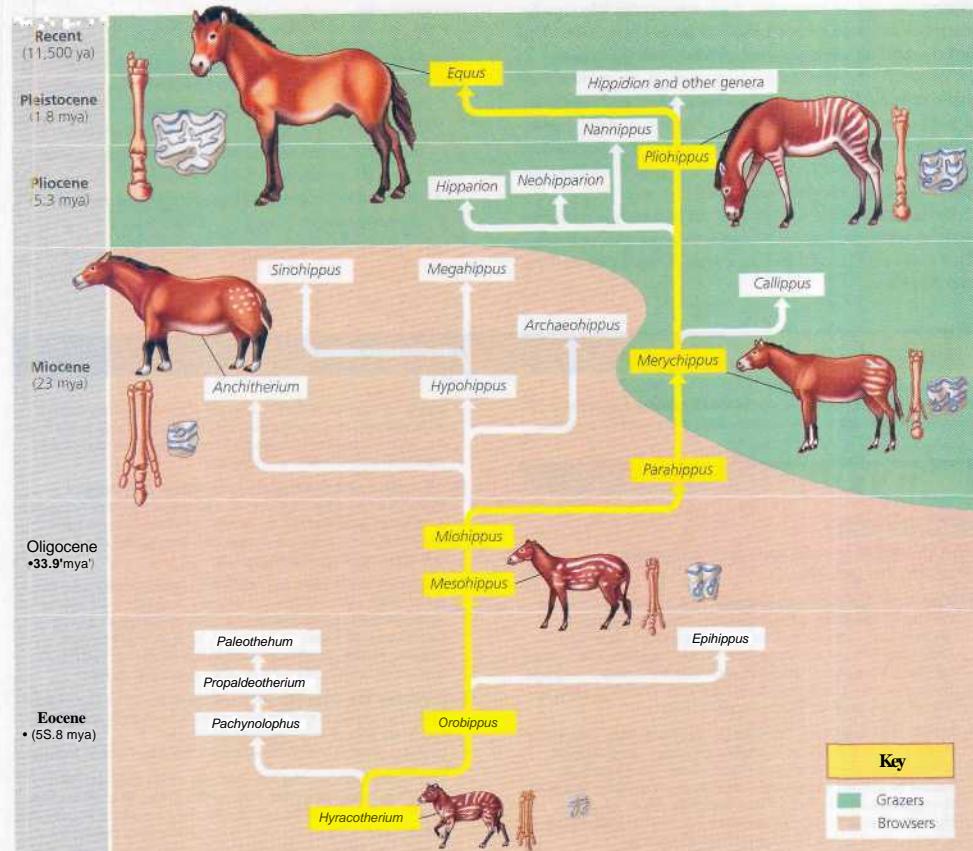

Figure 24.20 The branched evolution of horses. Using a yellow highlighter to trace the sequence of fossil horses that are intermediate in form between the living horse (*Equus*) and its Eocene ancestor *Hyracotherium* creates the illusion of a progressive trend toward larger size, reduced number of toes, and teeth modified for grazing. In fact, the living horse is the only surviving twig of an evolutionary bush with many divergent trends.

evolutionary trends. The species selection model suggests that "differential speciation success" plays a role in macroevolution similar to the role of differential reproductive success in microevolution.

To the extent that speciation rates and species longevity reflect success, the analogy to natural selection is even stronger. It is possible that qualities unrelated to the overall success of organisms in specific environments may become important when entire species are selected. For example, if a species is

able to disperse easily to new locations, it may give rise to a large number of "daughter species."

Whether or not the species selection model is valid, there are other possible sources of trends observed in the fossil record. For example, sexual selection in the Irish elk of northern Europe drove an immense increase in the size of their antlers—though this did not prevent the elk from becoming extinct because of changing vegetation and hunting by humans. And when horse ancestors invaded the grasslands that spread

during the Age of Mammals, there was strong selection for grazers that could escape predators by running faster. This trend would not have occurred without open grasslands.

Whatever its cause, the appearance of an evolutionary trend does not imply that there is some intrinsic drive toward a particular phenotype. Evolution is the result of the interactions between organisms and their current environments. If environmental conditions change, an apparent evolutionary trend may cease or even reverse itself.

In the next chapter, we will continue our study of speciation and the further divergence of organisms, with a more detailed look at the fossil record and the effects of significant environmental change.

Concept Check 24.3

- How can the Darwinian concept of descent with modification explain the evolution of such complex structures as the vertebrate eye or heart?
- Explain why the concept of exaptation does not mean that a structure evolves in anticipation of some future environmental change.
- How can heterochrony cause the evolution of different body forms?

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 24.1

The biological species concept emphasizes reproductive isolation

- The Biological Species Concept** (pp. 473–476) A biological species is a group of populations whose individuals have the potential to interbreed and produce fertile offspring with each other but not with members of other species. The biological species concept emphasizes reproductive isolation through prezygotic and postzygotic barriers that can result in separating the gene pools of different populations.
- Other Definitions of Species** (p. 476) Although particularly helpful in thinking about speciation processes, the biological species concept has some major limitations. For instance, it cannot be applied to organisms that are known only as fossils or to organisms that reproduce only asexually. Thus, scientists maintain alternative species concepts, such as the morphological species concept, that are useful in various contexts.

Activity *Overview of Macroevolution*

Concept 24.2

Speciation can take place with or without geographic separation

- Allotropic ("Other Country") Speciation** (pp. 477–478) Allotrophic speciation may occur when two populations of one species become geographically separated from each other. One or both populations may undergo evolutionary change during the period of separation. Should they come into contact once more, they may be separated by the prezygotic and postzygotic isolating mechanisms that have accumulated.
- Sympatric ("Same Country") Speciation** (pp. 478–480) A new species can originate while remaining in a geographically overlapping area with the parent species. In particular, many plant species have evolved sympatrically through polyploidy (multiplications of the chromosome number). Autopolyploids are species derived this way from one ancestral species. Allopolyp-

ploids are species with multiple sets of chromosomes derived from different species. Sympatric speciation can also result from the appearance of new ecological niches and from nonrandom mating in polymorphic populations.

- Allopatric and Sympatric Speciation: A Summary** (p. 480) In allopatric speciation, a new species forms while geographically isolated from its parent population. In sympatric speciation, a reproductive barrier isolates a subset of a population without geographic separation.
- Adaptive Radiation** (pp. 480–481) Adaptive radiation can occur when a population encounters a multiplicity of new or newly available ecological niches. This may happen during colonization of a new environment, such as newly formed volcanic islands, or after an environmental change that has resulted in mass extinctions of other species in an area.
- Studying the Genetics of Speciation** (p. 481) The explosion of genomics is enabling researchers to identify specific genes involved in some cases of speciation. Investigation *How Do New Species Arise by Genetic Isolation?*
- The Tempo of Speciation** (pp. 481–482) J. J. Gould and Niles Eldredge's punctuated equilibrium model draws on fossil evidence showing that species change most as they arise from an ancestral species, after which they undergo relatively little change for the rest of their existence. This model contrasts with a model of gradual change throughout a species' existence.

Concept 24.3

Macroevolutionary changes can accumulate through many speciation events

- Evolutionary Novelties** (pp. 482–483) Most novel biological structures evolve in many stages from previously existing structures. Some complex structures, such as the eye, have had similar functions during all stages of their evolution. The most important functions of others, such as feathers, have changed.
- Evolution of the Genes That Control Development** (pp. 484–486) Many large evolutionary changes may have been associated with mutations in genes that regulate development. Such changes can affect the timing of developmental events (heterochrony) or the spatial organization of body parts. Some of these changes result from mutational changes in homeotic genes and in the genes that regulate them.

Activity *Allometric Growth*

- **Evolution Is Not Goal Oriented** (pp. 486–488) Long-term evolutionary trends may arise because of adaptation to a changing environment. In addition, according to the species selection model, trends may result when species with certain characteristics endure longer and speciate more often than those with other characteristics.

TESTING YOUR KNOWLEDGE

Evolution Connection

In the margin of one of his notebooks, Darwin scrawled a note to remind himself never to apply the terms higher or *lower* to species. It was, and still is, very common for people to think of some species or species groups as more or less evolved than others. This probably stems from a notion of evolutionary "progress." Is there such a thing as evolutionary progress? Why or why not? Defend your position as if you were debating someone holding the opposite view.

Scientific Inquiry

Cultivated American cotton plants have a total of 52 chromosomes ($2n = 52$). In each cell, 13 pairs of chromosomes (26 chromosomes) are smaller than the other 13 pairs. Old World cotton plants have a total of 26 chromosomes ($2n = 26$), all large. Wild American cotton plants have 26 chromosomes, all small. Propose a hypothesis to explain how cultivated American cotton may have originated. How could you test your hypothesis?

Investigation *How Do New Species Arise by Genetic Isolation?*

Science, Technology, and Society

-What is the biological basis for assigning all human populations to a single species? Can you think of a scenario in which a second human species could arise in the future by cladogenesis?

Phylogeny and Systematics

A Figure 25.1 A dragonfly fossil from Brazil, more than 100 million years old.

Key Concepts

- 25.1 Phylogenies are based on common ancestries inferred from fossil, morphological, and molecular evidence
- 25.2 Phylogenetic systematics connects classification with evolutionary history
- 25.3 Phylogenetic systematics informs the construction of phylogenetic trees based on shared characters
- 25.4 Much of an organism's evolutionary history is documented in its genome
- 25.5 Molecular clocks help track evolutionary time

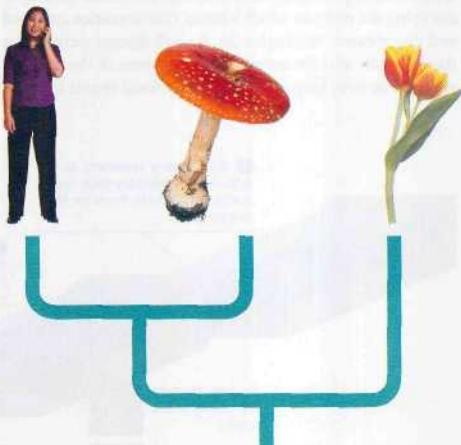

Overview

Investigating the Tree of Life

Evolutionary biology is about both process and history. In this unit, we have already examined the processes of evolution—natural selection and other mechanisms that change the genetic composition of populations (see Chapter 23) and that can lead to the origin of new species (see Chapter 24). But evolutionary biologists also seek to reconstruct the long-term results of these processes—the entire history of life on Earth.

This chapter describes how biologists trace phylogeny (from the Greek *phylon*, tribe, and *genesis*, origin), the evolutionary history of a species or group of species. In constructing phylogenies, biologists draw on the fossil record, which provides information about ancient organisms (Figure 25.1). They also utilize systematics, an analytical approach to understanding the diversity and relationships of organisms, both present-day and extinct. Systematists have traditionally studied morphological and biochemical resemblances among organisms as a basis for inferring evolutionary relationships. In

recent decades, systematists have gained a powerful new tool: molecular systematics, which uses comparisons of DNA, RNA, and other molecules to infer evolutionary relationships between individual genes and even between entire genomes (Figure 25.2). This information explosion is enabling evolutionary biologists to construct a universal tree of all life, which will continue to be refined as the database of DNA and RNA sequences grows.

A Figure 25.2 An unexpected family tree. What are the evolutionary relationships among a human, a mushroom, and a tulip? Molecular systematics has revealed that—despite appearances—animals, including humans, and fungi, such as mushrooms, are more closely related to each other than either are to plants.

Concept 25.1

Phylogenies are based on common ancestries inferred from fossil, morphological, and molecular evidence

In order to infer phylogenies, we must gather as much information as we can about the morphologies, development, and biochemistry of living organisms. But it is also essential to study fossils, the preserved remnants or impressions left by organisms that lived in the past. Fossils can help establish relationships between living organisms because they reveal ancestral characteristics that may have been lost over time in certain lineages.

The Fossil Record

Sedimentary rocks are the richest source of fossils. Sand and silt eroded from the land are carried by rivers to seas and swamps, where the minerals settle to the bottom along with the remains of organisms. Over millions of years, deposits pile up and compress the older sediments below into layers called strata (Figure 25.3). The fossil record is based on the sequence in which fossils have accumulated in such strata.

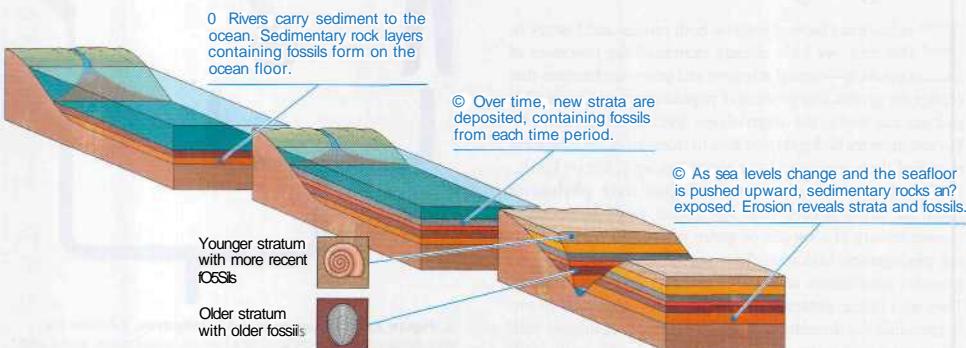

Though sedimentary fossils are the most common, paleontologists also study other types of fossils (Figure 25.4). But fossils inform phylogeny only if we can determine their ages, clarifying the order in which various characteristics appeared and disappeared. In Chapter 26, we will discuss methods for dating fossils and for assigning the divisions of the geologic record. For now, keep in mind that the fossil record is a sub-

stantial, but incomplete, chronicle of evolutionary change. A large number of Earth's species probably did not die in the right place at the right time to be captured in fossils; of those fossils that were formed, many were probably destroyed by later geologic processes; and only a fraction of existing fossils have been discovered. Rather than giving a true indication of the diversity of past life, the fossil record is biased in favor of species that existed for a long time, were abundant and widespread, and had hard shells, skeletons, or other hard parts that facilitated their fossilization. Even with its limitations, however, the fossil record is a remarkably detailed account of biological change over the vast scale of geologic time.

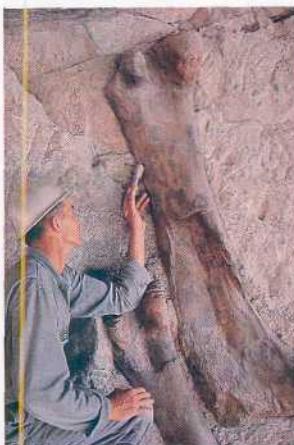

Morphological and Molecular Homologies

In addition to fossil organisms, phylogenetic history can be inferred from certain morphological and molecular similarities among living organisms. Recall that similarities due to shared ancestry are called homologies. For example, the similarity in the number and arrangement of bones in the forelimbs of mammals is due to their descent from a common ancestor with the same bone structure; this is an example of a morphological homology (see Figure 22.14). In the same way, genes or other DNA sequences are homologous if the nature of their similarity suggests that they are descended from the sequences carried by a common ancestor.

In general, organisms that share very similar morphologies or similar DNA sequences are likely to be more closely related than organisms with vastly different structures or sequences. In some cases, however, the morphological divergence between related species can be great and their genetic divergence small (or vice versa). For example, consider the Hawaiian silversword plants discussed in Chapter 24. These species vary dramatically in appearance throughout the islands: Some

A Figure 25.3 Formation of sedimentary strata containing fossils.

(a) Dinosaur bones being excavated from sandstone

(b) Petrified tree in Arizona, about 190 million years old

(c) Leaf fossil, about 40 million years old

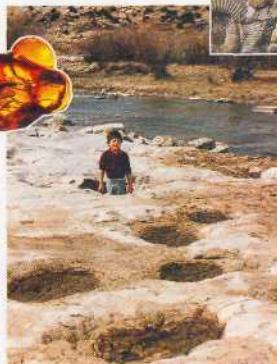

(d) Casts of ammonites, about 375 million years old

(e) Tusks of a 23,000-year-old mammoth, frozen whole in Siberian ice

(f) Insects preserved whole in amber

(g) Boy standing in a 150-million-year-old dinosaur track in Colorado

retain organic material from which scientists can extract molecules for analysis, (d) Buried organisms that decay may leave impressions that are filled by water containing dissolved minerals. The casts that form when the minerals harden are replicas of the organisms.

(e) Trace fossils are footprints, burrows, and other remnants of an ancient organism's activities, (f) Entire organisms are sometimes found preserved in amber (hardened resin from a tree), (g) Rarely, ice or an acid bog preserves the body of a very large organism.

are tall, twiggy trees, and others are dense, ground-hugging shrubs (see Figure 24.12). But in spite of these striking phenotypic differences, the silverswords' genes are very similar. Based on these small molecular divergences, scientists estimate that the silversword group began to diverge 5 million years ago, which is also about the time when the oldest of the current islands formed. We can infer that the morphological diversity of the silverswords is controlled by relatively few genetic differences.

Sorting Homology from Analogy

A potential red herring in constructing a phylogeny is similarity due to convergent evolution—called analogy—rather than to shared ancestry (homology). As you read in Chapter 22, convergent evolution occurs when similar environmental pressures and natural selection produce similar (analogous) adaptations in organisms from different evolutionary lineages (see Figure 22.17). For example, Australian and North American

burrowing moles are very similar in appearance (**Figure 25.5**). However, their reproductive systems are very dissimilar: Australian moles are marsupials (their young complete their embryonic development in a pouch outside the mother's body), whereas North American moles are eutherians (their young complete their embryonic development in a uterus within the mother's body). Indeed, genetic comparisons and the fossil record provide evidence that the moles' common ancestor lived 120 million years ago, about the time the marsupial and eutherian mammals diverged. This ancestor and most of its descendants were not mole-like, but similar characteristics evolved independently in these two mole lineages as they adapted to similar lifestyles.

Distinguishing between homology and analogy¹ is critical in reconstructing phylogenies. For example, both bats and birds have adaptations that enable them to fly. This superficial resemblance might imply that bats are more closely related to birds than they are to cats, which cannot fly. But a closer examination reveals that the complex structure of the bat's flight apparatus is far more similar to the forelimbs of cats and other mammals than to a bird's wing. Fossil evidence also documents that bat forelimbs and bird wings arose independently from walking forelimbs of different ancestors. Thus, we can state that the bat's forelimb is *homologous* to those of other mammals, but *analogous* in function to a bird's wing. Analogous structures that have evolved independently, such as bat forelimbs and bird wings, are also sometimes called homoplasies (from the Greek for "to mold in the same way").

Besides searching for corroborating similarities or fossil evidence, another clue to distinguishing between homology and analogy is to consider the complexity of the characters being

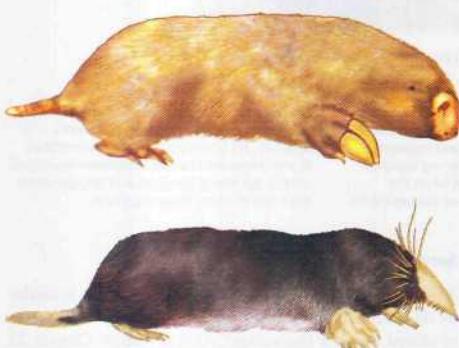

compared. The more points of resemblance that two complex structures have, the less likely it is that they evolved independently. For instance, the skulls of a human and a chimpanzee do not consist of a single bone but rather of many bones fused together. The compositions of the two skulls match almost perfectly, bone for bone. It is highly improbable that such complex structures, matching in so many details, have separate origins. More likely, the genes involved in the development of both skulls were inherited from a common ancestor. The same argument applies to comparing genes themselves, which are sequences of thousands of nucleotides. Each nucleotide position along a stretch of DNA or RNA represents an inherited character in the form of one of the four DNA bases: A (adenine), G (guanine), C (cytosine), or T (thymine). Thus, comparable regions of DNA that are 1,000 nucleotides long provide 1,000 points of similarity or difference between two species. Systematists compare long stretches of DNA and even entire genomes to assess relationships between species. If genes in two organisms share many portions of their nucleotide sequences, it is highly likely that the genes are homologous.

Evaluating Molecular Homologies

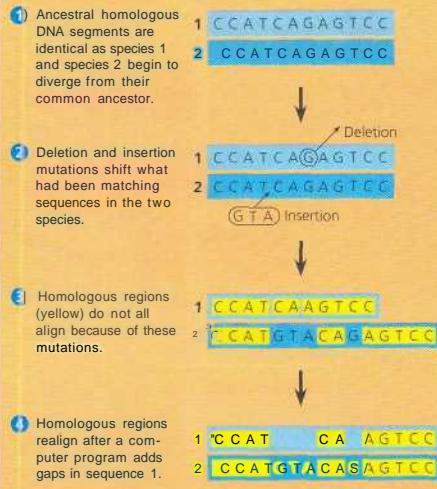

Molecular comparisons of nucleic acids often pose technical challenges. The first step is to align comparable nucleic acid sequences from the two species being studied. If the species are very closely related, the sequences likely differ at only one or a few sites. In contrast, comparable nucleic acid sequences in distantly related species usually have different bases at many sites and may even have different lengths. This is because, over longer periods of time, insertions and deletions accumulate, altering the lengths of the gene sequences (see Chapter 23). Suppose, for example, that certain noncoding DNA sequences in a particular gene in two species are very similar, but a deletion mutation has eliminated the first base of the sequence in one of the species. The effect is that the remaining sequence shifts back one notch. A comparison of the two sequences that does not take this deletion into account would overlook what in fact is a very good match. To avoid this problem, systematists use computer programs to analyze comparable DNA segments of differing lengths and realign them appropriately (**Figure 25.6**).

Such molecular comparisons reveal that a large number of base substitutions and other differences have accumulated between the comparable genes of the Australian and North American moles, indicating that their lineages have diverged greatly since their common ancestor; thus, we say that the living species are not closely related. In contrast, the high degree of gene-sequence similarity among the silverswords supports the hypothesis that they are all very closely related, in spite of their considerable morphological differences.

The fact that molecules have diverged between species does not in itself tell us how long ago their common ancestor lived.

A Figure 25.5 Convergent evolution of analogous burrowing characteristics. An elongated body, enlarged front paws, small eyes, and a pad of thickened skin that protects a tapered nose all evolved independently in the marsupial Australian mole (top) and eutherian North American mole (bottom).

A (Figure 25.6 Aligning segments of DNA. Systematists use computer software to find and realign similar sequences along DNA segments from two species. (In this example, no bases have changed and the comparable sequences are still identical once the length is adjusted.)

Sometimes, as in the case of the moles, the fossil record provides data about when their common ancestor probably lived. But in the case of the silverswords, few fossils have been found. For such species, researchers may be able to compare their molecular divergence with that found in other plant lineages that have more complete fossil records. These values can serve as a sort of molecular yardstick to measure the approximate time span of various degrees of divergence. (This is how researchers calculated that the silverswords' common ancestor lived approximately 5 million years ago, as we discussed earlier.) Just as with morphological characters, it is necessary to distinguish homology from analogy to determine the usefulness of molecular similarities for evolutionary studies. Two sequences that resemble each other at many points along their length are most likely homologous (see Figure 25.6). But in organisms that do not appear to be closely related, the bases that they otherwise very different sequences happen to share may simply be coincidental matches, or molecular homoplasy (Figure 25.7). Scientists have developed mathematical tools that can distinguish "distant" homologies from such coincidental matches in extremely divergent sequences. For example, such molecular analysis has provided evidence that, despite our lack of morphological similarity, we humans do indeed share a distant common ancestor with bacteria.

ACGGATAGTCCACTAGGCCTA
TCACCCGACAGGCTTGTGACTAG

A. Figure 25.7 A molecular homoplasy. These two DNA sequences from organisms that are not closely related coincidentally share 25% of their bases. Many tools have been developed to determine whether DNA sequences that share higher proportions of bases do so because they are homologous.

Scientists have so far sequenced more than 20 billion bases' worth of nucleic acid data from thousands of species. This enormous collection of data has fed a boom in the study of phylogeny clarifying many evolutionary relationships, such as those between the Australian and North American moles and those between the various silverswords. In the rest of this chapter and the next unit, you will see many examples of the tremendous impact of molecular systematics.

Concept Check 25.1

- Suggest whether each of the following pairs of structures more likely represents analogy or homology and explain your reasoning: (a) a porcupine's quills and a cactus's spines; (b) a cat's paw and a human's hand; (c) an owl's wing and a hornet's wing.
- Which of the following are more likely to be closely related: two species with similar appearances but very divergent gene sequences, or two species with very different appearances but nearly identical genes? Explain.

For suggested answers, see Appendix A.

Concept 25.2

Phylogenetic systematics connects classification with evolutionary history

The discipline of systematics dates to the 18th century. In 1748, Swedish botanist and anatomist Carolus Linnaeus published *Systema naturae* ("System of Nature"), his taxonomic classification of all plants and animals known at the time. Taxonomy is an ordered division of organisms into categories based on a set of characteristics used to assess similarities and differences. Although Linnaeus' classification was not based on evolutionary relationships but simply on resemblances,

many features of his system remain useful in phylogenetic systematics. Two of these are binomial designations for species and hierarchical classification.

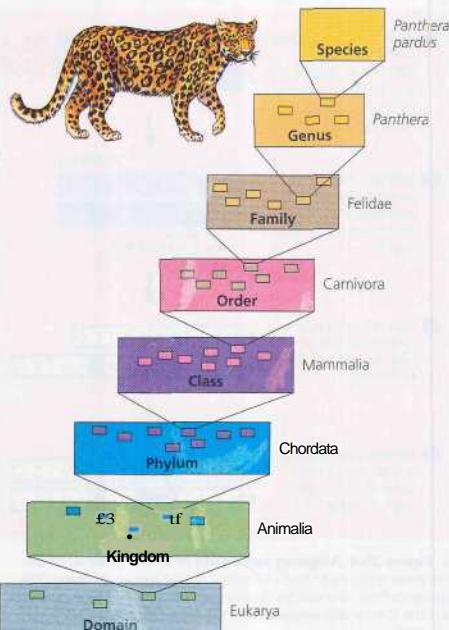

Binomial Nomenclature

Common names for organisms—such as monkey, finch, and lilac—convey meaning in casual usage, but they can also cause confusion. Each of these names, for example, refers to more than one species. Moreover, some common names do not accurately reflect the type of organism. Consider these three “fishes”: jellyfish (a cnidarian), crayfish (a small lobster-like crustacean), and silverfish (an insect). And of course, different languages have different words for various organisms.

To avoid ambiguity when communicating about their research, biologists refer to organisms by Latin scientific names. The two-part format of the scientific name, called a **binomial**, was instituted by Linnaeus. The first part of a binomial is the genus (plural, *genera*) to which the species belongs. The second part, the **specific epithet**, refers to one species within the genus. An example of a binomial is *Pantherapardus*, the scientific name for the large cat commonly called the leopard. Notice that the first letter of the genus is capitalized and the entire binomial is italicized. (Scientific names are also “latinized”; you can name an insect you discover after a friend, but you must add an appropriate Latin ending.) Many of the more than 11,000 binomials assigned by Linnaeus are still used today, including the optimistic name he designated for our own species—*Homo sapiens*, meaning “wise man.”

Hierarchical Classification

In addition to naming species, Linnaeus also grouped them into a hierarchy of increasingly broad categories. The first grouping is built into the binomial; species that appear to be closely related are grouped into the same genus. For example, the leopard (*Panthera pardus*) belongs to a genus that also includes the African lion (*Panthera leo*), the tiger (*Panthera tigris*), and the jaguar (*Panthera onca*). Beyond genera, systematists employ progressively comprehensive categories of classification (Figure 25.8). They place related genera in the same family, group families into orders, orders into classes, classes into phyla (singular, *phylum*), phyla into kingdoms, and, more recently, kingdoms into domains. The named taxonomic unit at any level is called a **taxon** (plural, *taxa*). For example, *Panthera* is a taxon at the genus level, and Mammalia is a taxon at the class level that includes all the many orders of mammals. Note that taxa broader than the genus level are not italicized, though they are capitalized. The resulting biological classification of a particular organism is somewhat like a postal address identifying a person in a particular apartment, in a building with many apartments, on a street with many apartment buildings, in a city with many streets, in a state with many cities, and so on.

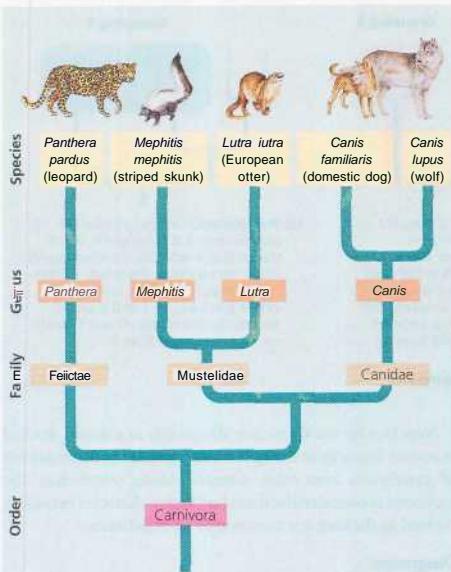

A **Figure 25.8 Hierarchical classification.** Species are placed into groups belonging to more comprehensive groups.

Classifying species seems to come naturally to humans—it is a way to structure our view of the world. We lump together several species of tree to which we give the common name of oaks and distinguish them from other species of trees we call chestnuts. Taxonomists have decided that oaks and chestnuts are different enough that they should belong to separate genera. Yet oaks and chestnuts are deemed similar enough to be grouped into the same family the Fagaceae. This decision was ultimately arbitrary because higher classification levels are generally defined by various morphological characters chosen by taxonomists rather than by some quantitative measurement applicable to all organisms. For this reason, the larger categories are often not comparable between lineages; that is, an order of snails does not necessarily exhibit the same degree of morphological or genetic diversity as an order of mammals.

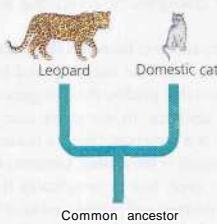

Linking Classification and Phylogeny

We saw earlier how systematists explore phylogeny by examining various characteristics in living and fossil organisms. They use branching diagrams called **phylogenetic trees** to depict their hypotheses about evolutionary relationships. Tie

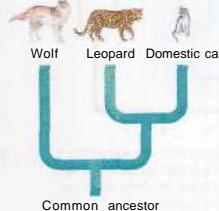

A figure 25.9 The connection between classification and phylogeny. Hierarchical classification is reflected in the progressively finer branching of phylogenetic trees. This tree traces possible evolutionary relationships between some of the taxa within the order Carnivora, itself a branch of the class Mammalia.

branching of such trees reflects the hierarchical classification of groups nested within more inclusive groups (**Figure 25.9**). A phylogenetic tree is often constructed from a series of dichotomies, or two-way branch points; each branch point represents the divergence of two species from a common ancestor. For example, we could represent a branch point within the cat family this way:

As in Figure 25.9, we can also diagram dichotomous branching of taxa that are more inclusive than species, such as families

and orders. Each of the "deeper" branch points represents progressively greater amounts of divergence:

Do not confuse the sequence of branching in a tree with the vintages (actual ages) of the particular species. The tree in Figure 25.9 does *not* indicate that the wolf evolved more recently than the European otter, but only that their common ancestor preceded the last common ancestor of the wolf and the domestic dog.

"Methods for tracing phylogeny began with Darwin, who, unlike Linnaeus, realized the evolutionary implications of hierarchical classification. Darwin introduced phylogenetic systematics in *The Origin of Species*, writing: "Our classifications will come to be, as far as they can be so made, genealogies."

Concept Check 25.2

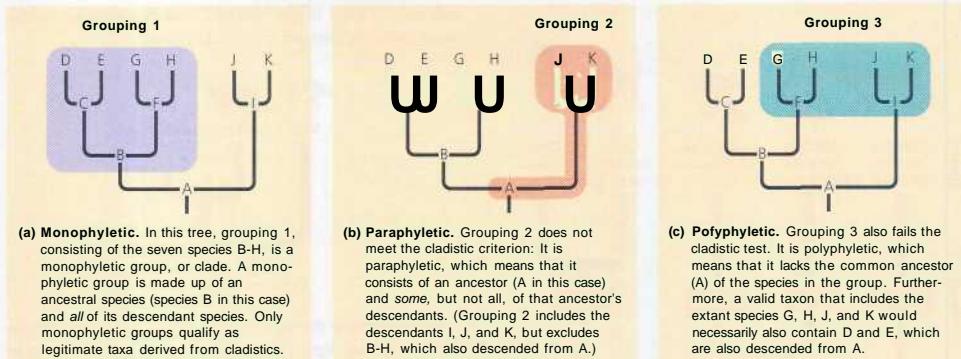

- Which levels of the classification in Figure 25.8 do humans share with the leopard?
- What does the phylogenetic tree in Figure 25.9 indicate about the evolutionary relationships of the leopard, striped skunk, and wolf?

For suggested answers, see Appendix A.

Concept 25.3

Phylogenetic systematics informs the construction of phylogenetic trees based on shared characters

Patterns of shared characteristics can be depicted in a diagram called a cladogram (see Figure 25.1b on p. 499). A cladogram by itself does not imply evolutionary history. But if the shared characteristics are due to common ancestry (that is, if they are homologous), then the cladogram forms the basis of a phylogenetic tree. Within the tree, a clade (from the Greek *klados*, branch) is defined as a group of species that includes an ancestral species and all its descendants. The analysis of how species may be grouped into clades is called cladistics.

A **Figure 25.10 Monophyletic, paraphyletic, and polyphyletic groupings.**

Cladistics

Clades, like taxonomic ranks, can be nested within larger clades. For example, the cat family represents a clade within a larger clade that also includes the dog family. But not all groupings of organisms qualify as clades. A valid clade is monophyletic (meaning "single tribe"), signifying that it consists of the ancestor species and all its descendants (**Figure 25.10a**). When we lack information about some members of a clade, the result is a paraphyletic grouping that consists of an ancestral species and some, but not all, of the descendants (**Figure 25.10b**). Or the result may be a polyphyletic grouping of several species that lack a common ancestor (**Figure 25.10c**). Such situations call for further reconstruction to uncover species that tie together these groupings into monophyletic clades.

Shared Primitive and Shared Derived Characters

After systematists have separated homologous from analogous similarities, they must sort through the homologies to distinguish between shared primitive and shared derived characters. "Character" here refers to any feature that a particular taxon possesses. The characters that are relevant to phylogeny of course, are the homologous ones. For example, all mammals share the homologous character of a backbone. However, the presence of a backbone does not distinguish mammals from other vertebrates because nonmammalian vertebrates such as fishes and reptiles also have backbones. The backbone is a homologous structure that predates the branching of the mammalian clade from the other vertebrates; it is a shared primitive character, a character that is shared beyond the taxon we are trying to define. In contrast, hair, a character shared by all mammals but not found in nonmammalian vertebrates, is a shared derived character, an evolutionary novelty unique to a particular clade—in this case, the mammalian clade.

Grouping 2

(b) **Paraphyletic.** Grouping 2 does not meet the cladistic criterion: It is paraphyletic, which means that it consists of an ancestor (A in this case) and some, but not all, of that ancestor's descendants. (Grouping 2 includes the descendants I, J, and K, but excludes B-H, which also descended from A.)

Grouping 3

(c) **Polyphyletic.** Grouping 3 also fails the cladistic test. It is polyphyletic, which means that it lacks the common ancestor (A) of the species in the group. Furthermore, a valid taxon that includes the extant species G, H, J, and K would necessarily also contain D and E, which are also descended from A.

Note that the backbone can also qualify as a shared derived character, but only at a deeper branch point that distinguishes *all* vertebrates from other animals. Among vertebrates, the backbone is considered a shared primitive character because it evolved in the ancestor common to all vertebrates.

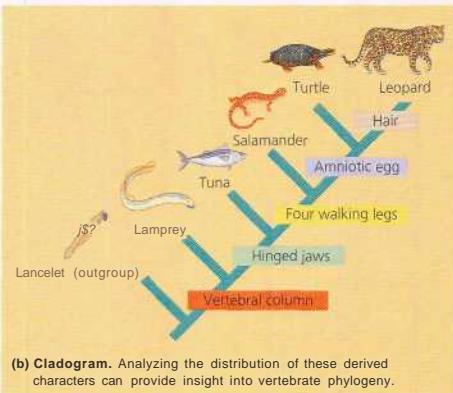

Outgroups

Systematists use outgroup comparison to differentiate between shared derived characters and shared primitive characters. To demonstrate this method, let's arrange five vertebrates—a leopard, turtle, salamander, tuna, and lamprey (a jawless aquatic vertebrate)—into a cladogram. As a basis of comparison, we need to designate an outgroup, which is a species or group of species that is closely related to the ingroup, the various species we are studying; the outgroup is known to be less closely related than any of the ingroup members are to each other based on other evidence (such as paleontology, embryonic development, and gene sequences). A good choice of an outgroup for our example is a lancelet, a small animal that lives in mudflats and (like vertebrates) is a member of the phylum Chordata, but does not have a backbone. We can begin building our cladogram by comparing the ingroup with the outgroup.

Outgroup comparison is based on the assumption that homologies present in both the outgroup and ingroup must be primitive characters that predate the divergence of both groups from a common ancestor. In our study case, an example of such a character is a structure called a notochord, a flexible rod running the length of the animal. Lancelets have notochords throughout their lives, but in vertebrates the notochord is present only in embryos and is replaced later in development by the backbone. The species making up the ingroup display a mixture of shared primitive and shared derived characters. The outgroup comparison enables us to focus on just these characters that were derived at the various branch points of

| CHARACTERS | TAXA | | | | | |
|--------------------------------|------------------------|---------|------|------------|--------|---------|
| | Lancelet (outgroup) | Lamprey | Tuna | Salamander | Turtle | Leopard |
| Hair | 0 | 0 | 0 | 0 | 0 | 1 |
| Amniotic (shelled) egg | 0 | 0 | 0 | 0 | 1 | 1 |
| Four walking legs | 0 | 0 | 0 | 1 | 1 | 1 |
| Hinged jaws | 0 | 0 | 1 | 1 | 1 | 1 |
| Vertebral column (backbone) | 0 | 1 | 1 | 1 | 1 | 1 |

(a) Character table. A 0 indicates that a character is absent; a 1 indicates that a character is present.

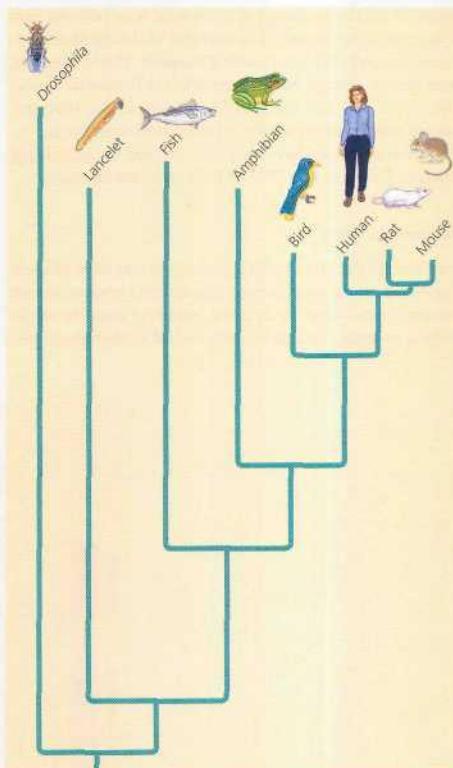

(b) Cladogram. Analyzing the distribution of these derived characters can provide insight into vertebrate phylogeny.

Figure 25.11 Constructing a cladogram.

vertebrate evolution. **Figure 25.11a** tabulates examples of these characters. Note that *all* the vertebrates in the ingroup have backbones; this is a shared primitive character that was present in the ancestral vertebrate, though not in the outgroup. Now note that hinged jaws are a character absent in lampreys but present in other members of the ingroup; this character helps us identify an early branch point in the vertebrate clade. **Figure 25.11b** illustrates how the data in our table of homologies can be translated into a cladogram.

Note that the cladogram in Figure 25.11b is *not* a phylogenetic tree. We may suspect that it tells an evolutionary story, but to convert it to a phylogenetic tree we would need more information—for example, from fossils, which can indicate when, and in which groups, the characters first appeared.

A Figure 25.12 Phylogram. This phylogram was constructed by comparing homologous *hedgehog* genes, employing the *Drosophila* gene as an outgroup. The *hedgehog* gene is important in development. The varying lengths of the branches indicate that the gene has evolved at slightly different rates in the different lineages.

Phylogenetic Trees and Timing

Any chronology represented by the branching pattern of a phylogenetic tree is relative (earlier versus later) rather than absolute (so many millions of years ago). But some kinds of tree diagrams can be used to present more specific information about timing: Phylogenograms present information about the sequence of events relative to one another, and ukralectic trees present information about the actual time that given events occurred.

Phylogenograms

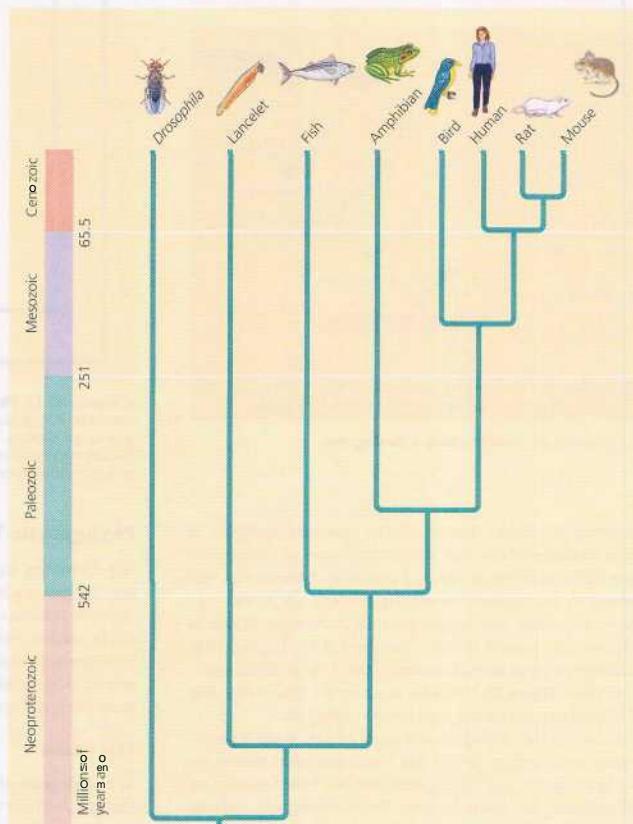

In a **phylogram**, the length of a branch reflects the number of changes that have taken place in a particular DNA sequence in that lineage (**Figure 25.12**). Note that in the phylogram in

Figure 25.12, the *total length* of the vertical lines from the base of the tree to the mouse is less than that of the line leading to the outgroup species, the fruit fly *Drosophila*. This implies that more genetic changes have occurred in the *Drosophila* lineage than in the bird and mammal lineages since they diverged. Later in this chapter you will read about how scientists can estimate the time that likely must have elapsed for a particular number of changes in a DNA or RNA sequence to occur.

Ultrametric Trees

Even though the branches in a phylogram may have different lengths, all the different lineages that descend from a common ancestor have survived for the same number of years. To take an extreme example, humans and bacteria had a common ancestor

that lived over 3 billion years ago. Evidence indicates that this ancestor was a single-celled prokaryote, and thus it must have been more like a modern bacterium than like a human. Even though bacteria have apparently changed little in their structure since that common ancestor, there have nonetheless been 3 billion years of evolution in the bacterial lineage, just as there have been 3 billion years of evolution in the eukaryote lineage that includes humans. These equal amounts of chronological time can be represented in an ultrametric tree. In an ultrametric tree, the branching pattern is the same as in a phylogram, but all the branches that can be traced from the common ancestor to the present are of equal length (**Figure 25.13**). While ultrametric trees do not contain the information about different evolutionary rates that can be found in phylogenograms, they can draw on data from the fossil record to place certain branch points in the context of geologic time.

• Figure 25.13 Ultrametric tree. This ultrametric tree was constructed from the same molecular data as the phylogram in Figure 25.12. These data were then fit to known branching events in the fossil record. In this ultrametric tree, all the branches now have the same total length from the base of the tree through the various vertical segments leading to the labels at the top. This reflects the evidence that all of these lineages have diverged from the common ancestor at the base for equal amounts of time. Note also that as you move up the tree, each branch point sprouts two lineages of equal length, representing the equal times of divergence from that common ancestor. Because the root of the tree is located at a time before a substantial fossil record begins, its date is less certain.

Maximum Parsimony and Maximum Likelihood

As available data about DNA sequences increase and it becomes possible to link more and more species, the difficulty of building the phylogenetic tree that best describes evolutionary history also grows. What if you are analyzing data for 50 species? There are 3×10^{70} different ways to arrange 50 species into a tree! And which tree in this huge forest reflects the true phylogeny? Systematists can never be sure of finding the single best tree in such a large data set, but they can narrow the possibilities by applying the principles of maximum parsimony and maximum likelihood.

According to the principle of **maximum parsimony**, we should first investigate the simplest explanation that is consistent with the facts. (The parsimony principle is also called "Occam's Razor" after William of Occam, a 14th-century English philosopher who advocated this minimalist problem-solving approach of "shaving away" unnecessary complications.) In the case of trees based on morphological characters, the most parsimonious tree is the one that requires the fewest evolutionary events to have occurred in the form of shared derived characters. For phylogenograms based on DNA sequences, the most parsimonious tree requires the fewest base changes.

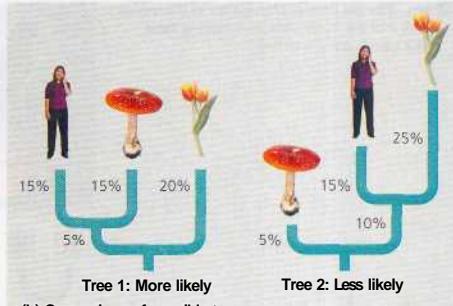

The principle of **maximum likelihood** states that, given certain rules about how DNA changes over time, a tree can be found that reflects the most likely sequence of evolutionary events. Maximum likelihood methods incorporate as much information as possible. As a simple example of more likely and less likely trees, let us return to the phylogenetic relationships between a human, a mushroom, and a tulip. **Figure 25.14** shows two possible, equally parsimonious trees for this trio. In tree 1, the human is more closely related to the mushroom, whereas in tree 2, the human is more closely related to the tulip. Tree 1 is more likely if we assume that DNA changes have occurred at equal rates along all the branches of the tree from the common ancestor. Tree 2 is also possible, but it requires assuming that the rates of evolution slowed greatly in the mushroom clade and sped up greatly in the tulip clade. Thus, assuming that equal rates are more common than unequal rates, tree 1 is more likely. We will soon see that many genes do evolve at approximately equal rates in different lineages. But note that if we find new evidence of unequal rates, tree 2 might be more likely! The likelihood of a tree depends on the assumptions on which it is based.

Many computer programs have been developed to search for trees that are parsimonious and likely. These include the following approaches:

1. "Distance" methods minimize the total of all the percentage differences among all the sequences.
2. More complex "character-state" methods minimize the total number of base changes or search for the most likely pattern of base changes among all the sequences.

| | Human | Mushroom | Tulip |
|----------|-------|----------|-------|
| Human | 0 | 30% | 40% |
| Mushroom | | 0 | 40% |
| Tulip | | | 0 |

(a) Percentage differences between sequences

(b) Comparison of possible trees

A Figure 25.14 Trees with different likelihoods. Based on percentage differences between genes carried by a human, a mushroom, and a tulip (a), we can construct two possible phylogenograms with the same total branch length (b). The sum of the percentages from a point of divergence in a tree equals the percentage differences as listed in (a). For example, in tree 1, the human-tulip divergence is $15\% + 5\% + 20\% = 40\%$. In tree 2, this divergence also equals 40% ($15\% + 25\%$). Assuming that the genes have evolved at the same rate in the different branches, tree 1 is more likely than tree 2.

Although researchers can never be certain precisely which tree truly reflects phylogeny if they have collected a large amount of accurate data, the various methods usually yield similar trees. As an example of one method, **Figure 25.15**, on the next two pages, walks you through the process of identifying the most parsimonious molecular tree for a four-species problem.

Phylogenetic Trees as Hypotheses

This is a good point at which to reiterate that any phylogenetic tree represents a hypothesis about how the various organisms in the tree are related to one another. The best hypothesis is the one that best fits all the available data. A phylogenetic hypothesis may be modified when new evidence compels systematists to revise their trees. Indeed, many older phylogenetic hypotheses have been changed or rejected since the introduction of molecular methods for comparing species and tracing phylogenies.

Figure 25.15

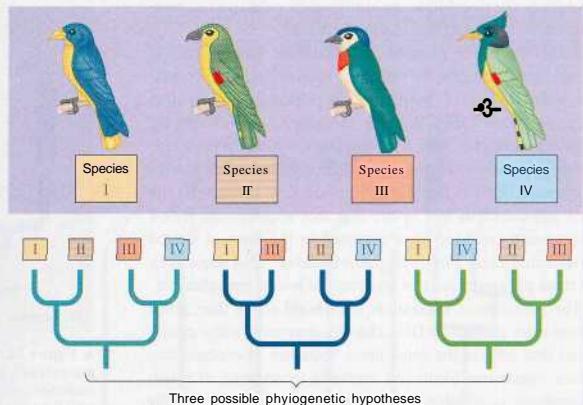

Research Method Applying Parsimony to a Problem in Molecular Systematics

APPLICATION In considering possible phylogenies for a group of species, systematists compare molecular data for the species. The most efficient way to study the various phylogenetic hypotheses is to begin by first considering the most parsimonious—that is, which hypothesis requires the fewest total evolutionary events (molecular changes) to have occurred.

TECHNIQUE

Follow the numbered steps as we apply the principle of parsimony to a hypothetical phylogenetic problem involving four closely related bird species.

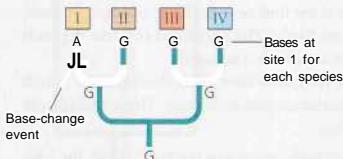

- O First, draw the possible phylogenies for the species (only 3 of the 15 possible trees relating these four species are shown here).

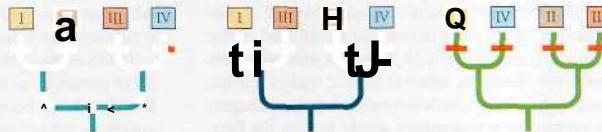

- ② Tabulate the molecular data for the species (in this simplified example, the data represent a DNA sequence consisting of just seven nucleotide bases).

| Species | Sites in DNA sequence | | | | | | |
|---------|-----------------------|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
| S3 | A | G | G | G | G | G | T |
| H | G | G | G | A | G | G | G |
| I | G | A | G | G | A | A | T |
| IV | G | G | A | G | A | A | G |

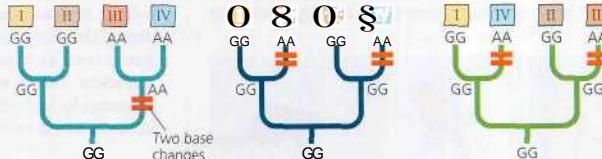

- ③ Now focus on site 1 in the DNA sequence. A single base-change event, marked by the crossbar in the branch leading to species I, is sufficient to account for the site 1 data.

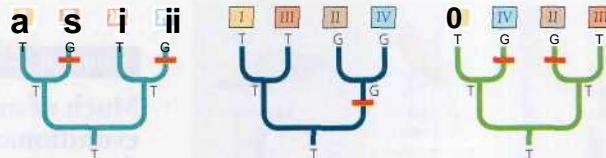

Continuing the comparison of bases at sites 2, 3, and 4 reveals that each of these possible trees requires a total of four base-change events (marked again by crossbars). Thus, the first four sites in this DNA sequence do not help us identify the most parsimonious tree.

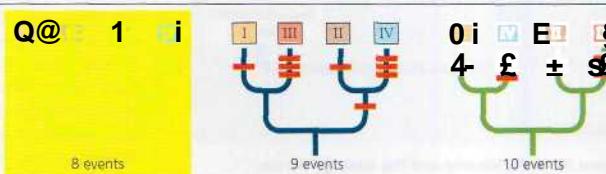

After analyzing sites 5 and 6, we find that the first tree requires fewer evolutionary events than the other two trees (two base changes versus four). Note that in these diagrams, we assume that the common ancestor had GG at sites 5 and 6. But even if we started with an AA ancestor, the first tree still would require only two changes, while four changes would be required to make the other hypotheses work. Keep in mind that parsimony only considers the total number of events, not the particular nature of the events (how likely the particular base changes are to occur).

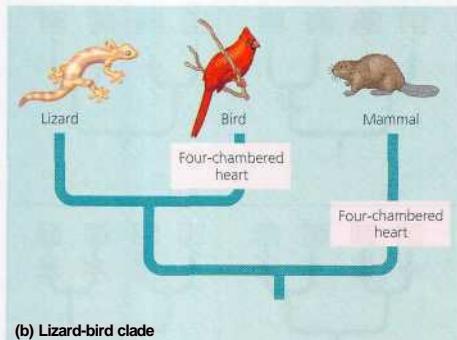

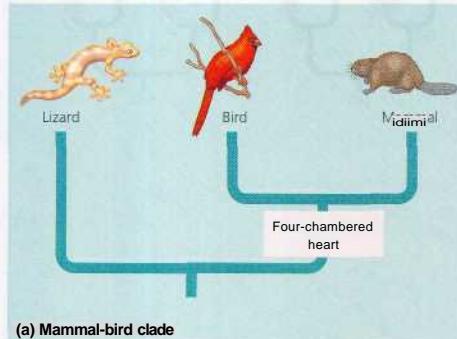

At site 7, the three trees also differ in the number of evolutionary events required to explain the DNA data.

IzX2Um To identify the most parsimonious tree, we total all the base-change events noted in steps 3-6 (don't forget to include the changes for site 1, on the facing page). We conclude that the first tree is the most parsimonious of these three possible phylogenies. (But now we must complete our search by investigating the 12 other possible trees.)

Often, in the absence of conflicting information, the most parsimonious tree is also the most likely. But sometimes there is compelling evidence that the best hypothesis is *not* the most parsimonious (**Figure 25.16**). Nature does not always take the simplest course. Perhaps the particular morphological or molecular character we are using to sort taxa actually did evolve multiple times. For example, both birds and mammals have hearts with four chambers, whereas lizards, snakes, turtles, and crocodiles have hearts with three chambers (see Chapter 42). The parsimonious assumption would be that the four-chambered heart evolved once and was present in an ancestor common to birds and mammals but not to lizards, snakes, turtles, and crocodiles. However, abundant evidence indicates that birds are more closely related to lizards, snakes, turtles, and crocodiles than they are to mammals. Thus, the four-chambered heart appears to have evolved independently in

A Figure 25.16 Parsimony and the analogy-versus-homology pitfall. If we interpret the four-chambered hearts of birds and mammals as homologous instead of analogous and use no other information, the tree in (a) appears to be the more parsimonious tree. In fact, abundant evidence supports the hypothesis that birds and lizards are more closely related than birds and mammals are and that four-chambered hearts evolved more than once, supporting the tree in (b).

birds and mammals. Indeed, studies have shown that the four-chambered hearts of birds and mammals develop differently; which supports the hypothesis that they evolved independently. The apparently parsimonious tree in Figure 25.16a is not consistent with these facts, while the tree in Figure 25.16b is consistent with the additional facts.

In this example, the problem is not so much with the principle of parsimony as it is with the analogy-homology issue. The four-chambered hearts of birds and mammals turn out to be analogous, not homologous. Matching changes of bases in DNA sequences in two species can also occur independently but the more bases that are involved, the less likely it is that the matching changes are coincidental. Applying parsimony in molecular systematics is more reliable for a data set of many long DNA sequences than for a smaller data set. Similarly, occasionally misjudging an analogous similarity in morphology as a shared derived (homologous) character is less likely to distort a phylogenetic tree if each clade in the tree is defined by several characters. The strongest phylogenetic hypotheses are those supported by multiple lines of molecular and morphological evidence as well as by fossil evidence.

Concept Check 25.3

- To distinguish a particular clade of mammals within the larger clade that corresponds to class Mammalia, would hair be a useful character? Why or why not?
- Why might the most parsimonious tree not necessarily be the most accurate in representing evolutionary relationships among a particular group of species?

For suggested answers, see Appendix A.

Concept 25.4

Much of an organism's evolutionary history is documented in its genome

You have seen throughout this chapter that molecular systematics—comparing nucleic acids or other molecules to infer relatedness—is a valuable tool for tracing organisms' evolutionary history. The molecular approach helps us to understand phylogenetic relationships that cannot be measured by non-molecular methods such as comparative anatomy. For example, molecular systematics helps us uncover evolutionary relationships between groups that have little common ground for morphological comparison, such as mammals and bacteria. It is possible to reconstruct phylogenies among groups of present-day bacteria and other microorganisms for which we have no fossil record at all. And molecular systematics enables scientists

to compare genetic divergence within a species. Molecular biology has helped to extend systematics to evolutionary relationships far above and below the species level, ranging from the major branches of the tree of life to its finest twigs. Still, its findings are often inconclusive, as in cases where taxa diverged at nearly the same time in the distant past. The differences may be apparent, but not the order of their appearance.

The ability of molecular trees to encompass both short and long periods of time is based on the fact that different genes evolve at different rates, even in the same evolutionary lineage. For example, the DNA that codes for ribosomal RNA (rRNA) changes relatively slowly, so comparisons of DNA sequences in these genes are useful for investigating relationships between taxa that diverged hundreds of millions of years ago. Studies of rRNA sequences, for example, indicate that fungi are more closely related to animals than to green plants (see Figure 25.2). In contrast, the DNA in mitochondria (mtDNA) evolves relatively rapidly and can be used to explore recent evolutionary events. One research team has traced the relationships among Native American groups through their mtDNA sequences. The molecular findings corroborate other evidence that the Pima of Arizona, the Maya of Mexico, and the Yanomami of Venezuela are closely related, probably descending from the first of three waves of immigrants that crossed the Bering Land Bridge from Asia to the Americas about 13,000 years ago.

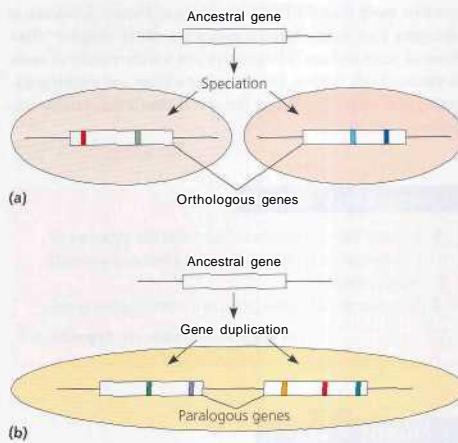

Gene Duplications and Gene Families

Gene duplication is one of the most important types of mutation in evolution because it increases the number of genes in the genome, providing opportunities for further evolutionary changes. The molecular phylogenies of gene duplications and the influence of these duplications on genome evolution can now be followed in detail. These phylogenies must account for repeated duplications that have resulted in gene families, which are groups of related genes within an organism's genome (see Figure 19.17). Like homologous genes in different species, these duplicated genes have a common ancestor. We distinguish these types of homologous genes by different names: orthologous genes and paralogous genes.

The term *orthologous genes* (from the Greek *orthos*, straight) refers to homologous genes that are passed in a straight line from one generation to the next but have ended up in different gene pools because of speciation (Figure 25.17a). The *P* hemoglobin genes in humans and in mice are orthologous.

Paralogous genes (from the Greek *para*, at the side of) result from gene duplication, so they are found in more than one copy in the same genome (Figure 25.17b). In Chapter 23 you encountered an example: the olfactory receptor genes, which have undergone many gene duplications in vertebrate animals. Humans and mice each have huge families of more than 1,000 of these paralogous genes.

It is possible to describe most of the genes that make up genomes as representing one of these two types of homology

A Figure 25.17 Two types of homologous genes. The colored bands mark regions of the genes where differences in base sequences have accumulated. Orthologous genes can only diverge after speciation, whereas paralogous genes can diverge within the same evolutionary lineage.

Note that orthologous genes can only diverge after speciation has taken place, with the result that the genes are found in separate gene pools. For example, humans and mice each have one functioning *Hb* hemoglobin gene. These genes serve similar functions, but their sequences have diverged since the time that humans and mice had a common ancestor. Paralogous genes, on the other hand, can diverge even while they are in the same gene pool, because they are present in more than one copy in the genome. The paralogous genes comprising the olfactory receptor gene family in humans have diverged from each other during our long evolutionary history. They now specify proteins that confer sensitivity to a wide variety of odors, ranging from various foods to sex pheromones.

Genome Evolution

Now that we can compare the entire genomes of different organisms, including our own, two remarkable facts have emerged. First, orthologous genes are widespread and can extend over huge evolutionary distances. Ninety-nine percent of the genes of humans and mice are detectably orthologous, and 50% of our genes are orthologous with those of yeast. This remarkable commonality demonstrates that all living organisms share many biochemical and developmental pathways.

And second, the number of genes seems not to have increased through duplication at the same rate as phenotypic complexity. Humans have only about five times as many genes as yeast, a simple single-celled eukaryote, even though—unlike yeast cells—we have a large, complex brain and a body that

contains more than 200 different types of tissues. Evidence is emerging that many human genes are more versatile than those of yeast and are able to carry out a wide variety of tasks in various body tissues. Before us lies a huge and exciting scientific challenge: unraveling the mechanisms that enable this genomic versatility.

Concept Check 25.4

1. Explain how comparisons between the proteins of two species can yield data about their evolutionary relationship.
2. Contrast orthologous genes with paralogous genes.

For suggested answers, see Appendix A.

Concept 25.5

Molecular clocks help track evolutionary time

As we stated at the beginning of this chapter, one of the goals of evolutionary biology is to understand the relationships between all living organisms, including those for which there are no fossils. When we extend molecular phylogenies beyond the fossil record, however, we must rely on an important assumption about how change occurs at the molecular level.

Molecular Clocks

Recall our statement earlier that researchers have estimated that the common ancestor of Hawaiian silverswords lived about 5 million years ago. How did they make this estimate? It relies on the concept of a molecular clock, a yardstick for measuring the absolute time of evolutionary change based on the observation that some genes and other regions of genomes appear to evolve at constant rates. The assumption underlying the molecular clock is that the number of nucleotide substitutions in orthologous genes is proportional to the time that has elapsed since the species branched from their common ancestor. In the case of paralogous genes, the number of substitutions is proportional to the time since the genes became duplicated.

We can calibrate the molecular clock of a gene that has a reliable average rate of evolution by graphing the number of nucleotide differences against the times of a series of evolutionary branch points that are known from the fossil record. The graph line representing the evolution rate of this molecular clock can then be used to estimate the date of evolutionary episodes that cannot be discerned from the fossil record, such as the origin of the silverswords.

Of course, no genes mark time with complete accuracy. In fact, some portions of the genome appear to have evolved in irregular fits and starts that are not at all clocklike. And even those genes that seem to have reliable molecular clocks are accurate only in the statistical sense of showing a fairly smooth *average* rate of change; over time, there may still be chance deviations above and below that average rate. Finally, even among genes that are clocklike, the rate of the clock may vary greatly from one gene to another; some genes evolve a million times faster than others.

Neutral Theory

The regularity of change that enables us to use some genes as molecular clocks raises the possibility that many of the changes in these sequences result from genetic drift, and the changes are mostly neutral—neither adaptive nor detrimental. In the 1960s, Jack King and Thomas Jukes, at the University of California, Berkeley, and Motoo Kimura, of the Japanese National Institute of Genetics, published papers supporting this **neutral theory**—that is, that much evolutionary change in genes and proteins has no effect on fitness and therefore is not influenced by Darwinian selection. Kimura pointed out that many new mutations are harmful and are removed quickly. But if most of the rest are neutral and have little or no effect on fitness, then the rate of molecular change should indeed *be* regular like a clock. Differences in the rate of the clock in different genes are a function of how important each gene is. If the exact sequence of amino acids a gene specifies is essential to survival, most of the mutational changes will be harmful and only a few will be neutral. As a result, such genes change only slowly. But if the exact sequence of amino acids is less critical, fewer of the new mutations will be harmful and more will be neutral. Such genes change more quickly.

Difficulties with Molecular Clocks

In fact, the molecular clock does not run as smoothly as neutral theory predicts. Many irregularities are likely to be the result of natural selection in which some DNA changes are favored over others. Consequently, some scientists question the utility of molecular clocks for timing evolution. Their skepticism is part of a broader debate about the extent to which neutral genetic variation can account for DNA diversity. Indeed, new evidence suggests that almost half of the amino acid differences in proteins of two *Drosophila* species, *D. simulans* and *D. yakuba*, are not neutral but have resulted from directional natural selection. Nonetheless, it is likely that over extremely long periods of time, fluctuations in evolutionary rate due to selective pressure will average out, so that even genes with irregular clocks can serve as approximate markers of elapsed time.

Another question arises when researchers attempt to extend molecular clocks beyond the time span documented by the

fossil record. Although some fossils date back as far as 3 billion years, these are very rare. An abundant fossil record extends back only about 550 million years, but molecular clocks have been used to date evolutionary divergences that occurred a billion or more years ago. These estimates assume that the clocks have been constant for all that time. Thus, such estimates are likely to have a high degree of uncertainty.

Applying a Molecular Clock: The Origin of HIV

Recently, researchers at Los Alamos National Laboratory in New Mexico used a molecular clock to date the origin of HIV infection in humans. Phylogenetic analysis shows that HIV, the virus that causes AIDS, is descended from viruses that infect chimpanzees and other primates. (The viruses do not cause any AIDS-like diseases in nonhuman hosts.) When did HIV jump to humans? There is no simple answer, because the virus has spread to humans more than once. The multiple origins of HIV are reflected in the variety of strains (genetic types) of the virus. HIV's genetic material is made of RNA, and like other RNA viruses, it evolves quickly.

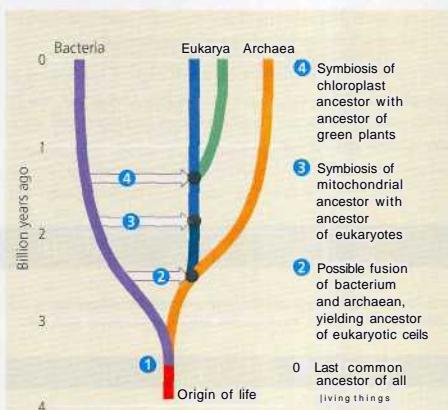

The most widespread strain in humans is HIV-1 M. To pinpoint the earliest HIV-1 M infection, the researchers compared samples of the virus from various times during the epidemic, including one partial viral sequence from 1959. The samples showed that the virus has evolved in a remarkably clocklike fashion since 1959. By extrapolating from their molecular clock, the researchers concluded that the first HIV-1 M invasion into humans took place during the 1930s.

The Universal Tree of Life

In the 1960s, researchers deciphering the genetic code found that it is universal in all forms of life. They inferred that all present-day organisms must therefore have a common ancestor. Today, researchers are applying systematics to link all organisms in a tree of life (Figure 25.18).

Investigators use two criteria to identify regions of DNA molecules that can demonstrate the branching pattern of this tree: The regions must be able to be sequenced, and they must have evolved so slowly that homologies between even distantly related organisms can still be detected. The rRNA genes, which code for the RNA parts of ribosomes, fit these requirements. Because rRNA genes are fundamental to the workings of the cell, their molecular clock runs so slowly that they can serve as the basis for a universal tree of life. We will examine this tree in greater detail in later chapters, but for the moment let us make two points:

1. The tree of life consists of three great domains: Bacteria, Archaea, and Eukarya. The domain Bacteria includes most of the currently known prokaryotes, including the bacteria closely related to chloroplasts and mitochondria (we'll examine the bacterial origins of these organelles in

A Figure 25.18 The universal tree of life. All living organisms are divided into three domains: Bacteria, Archaea, and Eukarya. The details of this tree will change as further information emerges, but its general outlines appear firm.

Chapter 26). The second domain, Archaea, consists of a diverse group of prokaryotic organisms that inhabit a wide variety of environments. Some archaea can use hydrogen as an energy source, and some were the chief source of the deposits of natural gas that are found throughout Earth's crust. Chapter 27 will explore bacteria and archaea in more detail. The third domain, Eukarya, consists of all the organisms that have cells containing true nuclei. This domain includes many groups of single-celled organisms as well as multicellular plants, fungi, and animals, and is the topic of Chapters 28–34.

2. The early history of these domains is not yet clear. Comparisons of complete genomes from the three domains show that, especially during the early history of life, there have been substantial interchanges of genes between organisms in the different domains. These took place through horizontal gene transfer, in which genes are transferred from one genome to another through mechanisms such as transposable elements, and perhaps through fusions of different organisms. The first eukaryote may have arisen through such a fusion between an ancestral bacterium and an ancestral archaean. Because phylogenetic trees are based on the assumption that genes are passed vertically from one generation to the next, the occurrence of such horizontal events means that universal trees built from different genes often give inconsistent results, particularly near the root of the tree. As a result, details of the tree are continually being revised. However, the division into three great

domains has remained secure since systematists first glimpsed the overall shape of the universal tree.

In the next unit of chapters, we will explore the history of biological diversity and its current variety. Our study will be illuminated by the concepts of evolution and systematics you have learned in this unit.

Concept Check 25.5

1. What is a molecular clock? What assumption underlies the use of a molecular clock?
2. Explain how numerous base changes could occur in DNA, yet have no effect on an organism's fitness.

For suggested answers, see Appendix A.

Chapter 25 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 25.1

Phylogenies are based on common ancestries inferred from fossil, morphological, and molecular evidence

- **The Fossil Record** (pp. 492-493) The fossil record is based on fossil organisms preserved in geologic strata of different ages and reveals ancestral characteristics that may have been lost.

Activity *A Scrolling Geologic Record*

- **Morphological and Molecular Homologies**

(pp. 492-495) Organisms that share very similar morphologies or DNA sequences are likely to be more closely related than organisms with very different structures and genetic sequences. But homology (similarity due to shared ancestry) must be sorted from analogy (similarity due to convergent evolution).

Concept 25.2

Phylogenetic systematics connects classification with evolutionary history

- **Binomial Nomenclature** (p. 496) Linnaeus's system gives organisms two-part names: a genus plus a specific epithet.

- **Hierarchical Classification** (p. 496) Linnaeus introduced a system for grouping species in increasingly broad categories.

- **Linking Classification and Phylogeny** (pp. 496-497) Systematists depict evolutionary relationships as branching phylogenetic trees, which may be based on various kinds of evidence.

Activity *Classification Schemes*

Concept 25.3

Phylogenetic systematics informs the construction of phylogenetic trees based on shared characters

- **Cladistics** (pp. 498-499) A clade is a monophyletic grouping of species that includes an ancestral species and all its descendants. In cladistic analysis, clades are defined by their evolutionary novelties, or shared derived characters. These are identified by comparing ingroup species with an outgroup species that does not have the shared derived character.

- **Phylogenetic Trees and Timing** (pp. 499-500) In phylogenograms, the length of a branch reflects the number of evolutionary changes in that lineage. Ultrametric trees place evolutionary branch points in the context of geologic time.

Investigation *How Is Phylogeny Determined by Comparing Proteins?*

Maximum Parsimony and Maximum Likelihood

(pp. 501-503) Among phylogenetic hypotheses, the most parsimonious tree is the one that requires the fewest evolutionary changes, and the most likely tree is the one based on the most likely pattern of changes.

Phylogenetic Trees as Hypotheses

(pp. 501-504) The best phylogenetic hypotheses are those that are consistent with the most data: morphological, molecular, and fossil.

Concept 25.4

Much of an organism's evolutionary history is documented in its genome

Gene Duplications and Gene Families

(p. 505) Orthologous genes, found in a single copy in the genome, can diverge only after speciation has taken place. Paralogous genes arise through duplication within a genome and can diverge within a clade, often adding new functions.

Genome Evolution

(pp. 505-506) Orthologous genes are often shared by distantly related species. The relatively small variation in total gene number in organisms of varying complexity indicates that genes in complex organisms are extremely versatile and that each gene can perform many functions.

Concept 25.5

Molecular clocks help track evolutionary time

Molecular Clocks

(pp. 506-507) The base sequences of some regions of DNA change at a rate consistent enough to allow dating of episodes in past evolution. These molecular clocks may result from the fixation of neutral mutations, but even when selection plays a role, many genes have tended to change in a clocklike fashion over long periods of time. Researchers have measured some molecular clocks and shown that they are remarkably constant. Other genes, however, change in a less predictable fashion.

The Universal Tree of Life

(p. 507) The tree of life has three great clades (domains): Bacteria, Archaea, and Eukarya.

TESTING YOUR KNOWLEDGE

Evolution Connection

Darwin suggested looking at a species' close relatives to learn what its ancestors may have been like. How does his suggestion anticipate the use of outgroups in cladistic analysis?

Biological Inquiry: A Workbook of Investigative Cases Explore the use of outgroups and other methods of modern cladistic analysis in "Tree Thinking."

Scientific Inquiry

Some nucleotide changes cause amino acid substitutions in the encoded protein (nonsynonymous changes), and others do not (synonymous changes). In a comparison of rodent and human genes, rodents were found to accumulate synonymous changes 2.0 times faster than humans, and nonsynonymous substitutions 1.3 times faster. What factors could explain this difference? How do such data complicate the use of molecular clocks to date evolutionary events?

Investigation How Is Phylogeny Determined by Comparing Proteins?

Science, Technology, and Society

The ability to compare genomes has opened up new avenues in medical research. Because humans and mice share so many orthologous genes, it is possible to infer gene function in humans by "knocking out" the corresponding orthologous genes in mice. What medical applications might such research lead to? What might be the consequences of these discoveries to society?

H E J. lie ELVUIULIULLdiy B nibLUiy ui DiuiuiiiLdi Diversity

An Interview with **Linda Graham**

Professor Linda Graham is a time traveler. By peering through microscopes at fossils of the earliest plants and their closest living relatives. Dr. Graham looks back a half-billion years to investigate a major breakthrough in the history of life: the origin of land plants from their aquatic algal ancestor. Those early plants were the first macroscopic creatures on land. In addition to her research on the origin and early diversification of land plants, Graham and her students study how plants, especially mosses, continue to have an enormous impact on the biosphere today. Dr. Graham, who is a professor of botany and environmental studies at the University of Wisconsin-Madison, is also a gifted teacher, and the interview that follows offers some sage advice for why the study of biological diversity is an important part of your education.

What is the ancestor of land plants?

Plants originated from a particular group of green algae known as charophyceans. The evidence is very strong that these ancestors had already acquired some degree of complexity in terms of being able to branch. They also had some reproductive complexities that were probably inherited by the earliest land plants as well.

How long ago did this origin of land plants from algae occur?

The origin of land plants is still somewhat controversial in terms of timeline. The consensus among the paleobotanical community is that there were plants on the terrestrial surface at about 475 million years ago. This conclusion is based on evidence from fossil spores and other types of fossilized plant material. However, some of my colleagues have found fossil spores that they believe to have originated from land

plants that lived as far back as 500 million years ago, in the mid-Cambrian period. I predict that in the future we will extend the origin of land plants back in time to at least the mid-Cambrian, perhaps even further back.

Which living plants do you think are most similar to the earliest land plants?

The molecular evidence indicates that the bryophytes—liverworts, hornworts, and mosses—are the oldest branches of the plant kingdom. And yet no one had found complete fossils of plants similar to bryophytes that were older than fossils of early vascular plants—plants with veins that transport water and nutrients—which the molecular data indicate diverged *after* bryophytes. That just didn't make sense. The standard explanation for the absence of early bryophyte fossils was that they just didn't preserve well. However, I knew that bryophytes produced spores and suspected that they produced other resistant materials as well. So, we wanted to test the idea that bryophytes have materials that could fossilize.

How did you do that?

We used two techniques to try to mimic the effects of degradation that would occur when a plant dies and falls into a water body and becomes partially degraded by microbial action. First, we treated living bryophyte material with an extreme technique known as acetolysis that combines high heat with strong acids. This is the same technique that the paleobotanists use to extract spores from rocks. We hypothesized that any plant material that would survive such an extreme treatment was fossilizable and should appear in a fossil record. Some of our colleagues argued that we might actually be generating resistant materials by such extreme treatment. So we added rotting techniques to our repertoire. We would

leave our living bryophyte material in moist soil for months, and then retrieve the material and see what was left. Amazingly, the same types of resistant bryophyte materials that stood up to acetolysis also survived the more gentle process of rotting. And amazingly, those bits and pieces that survived rotting and acetolysis looked like some scrappy fossils of very ancient origin that people simply didn't recognize as being plant material.

And some of those fossil fragments are older than vascular plants?

Yes. Those scrappy fossils consisting of spores, tubelike structures, and bits of cellular sheets were much older than the vascular plant fossils. So we think that our work helps cement the idea that bryophyte-like plants were indeed present prior to the origin of vascular plants, as is supported by the molecular data.

How did the spread of these early land plants change the biosphere?

First, they helped produce early soils. Even the earliest plants had some organic materials that weren't easily degraded by microbes. So these materials built up as an organic layer in the soil. Second, by this photosynthetic conversion of carbon dioxide to resistant organic materials, early plants began to lower the amount of CO₂ in the atmosphere. That started a trend that culminated in the lowest historic CO₂ level as a result of the early woody plants of the coal swamps during the Carboniferous period. In addition, by producing organic acids, early plants probably released phosphate from the soil, and the runoff of phosphate would have stimulated growth of photosynthetic microorganisms in marine and fresh water ecosystems. Finally early land plants established terrestrial ecosystems that eventually had sufficient organic productivity to support early land animals through food chains.

In addition to your interest in the origin of land plants, you also study the ecology of peat bogs. What are peat bogs, and why are they important?

Peat bogs are wetlands in which the dominant plant is Sphagnum, or "peat moss." This is a particularly important moss because it is an ecological engineer. The *Sphagnum* of peat bogs absorbs massive amounts of CO₂ from the atmosphere and stores it in organic materials that are not easily broken down by microorganisms—much like the early bryophytes we just talked about. Peat bogs are very extensive across the Northern Hemisphere—far more than most people realize because the bogs are located in northern regions that are not heavily populated. Very large areas of North America, Europe, and Asia are covered by vast peat lands that store an enormous amount of carbon. By helping to regulate atmospheric CO₂, which is a greenhouse gas, peat bogs function as a global thermostat. The moss helps stabilize the climate. If the temperature rises just a little bit, then that will facilitate moss growth, which will pull more CO₂ out of the atmosphere and help cool the planet. If it gets too cool, the moss won't grow as much, and there is a net release of CO₂ due to microbial degradation, which helps to warm the climate. So, we should be thankful for the vast peat lands that perform this thermostat function for our planet.

And how are we treating this important peat bog ecosystem?

Ecologists who study peat bogs are concerned about the disruption of peat bogs for mining or

for agricultural uses such as cranberry production. By reducing the area of peat bogs, which play such an important role in regulating climate, we may be accelerating global warming.

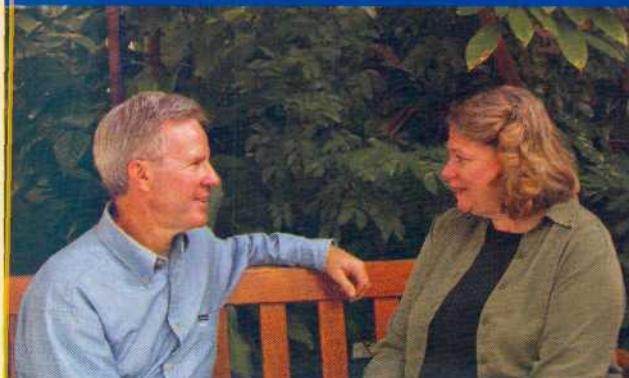

How did you get started in science, Dr. Graham, and how did that interest turn to plants?

I had some wonderful schoolteachers when I was in elementary school, middle school, and high school—teachers who stimulated my interest in science. In particular, I had a female chemistry teacher who was a wonderful role model. She was intelligent and confident, and I got the idea from being in her class that I could be a scientist too. I have always been attracted to microscopes and being able to see the wonders of intricate structures. Plants have very interesting internal organization, and their relatives, the algae, are also very beautiful under a microscope. So, my specific interest in plants mainly came from my fascination with microscopic structure.

And how did that fascination become focused on the origin of land plants?

That was a pivotal event that occurred while studying for a botany final exam when I was an undergraduate at Washington University in St. Louis. One of the topics on the exam was the life cycles of plants, which have an alternation of meiotic haploid and diploid generations. The puzzle of how this complex life cycle originated stimulated my curiosity about the evolution of plants from their algal ancestors.

By helping to regulate atmospheric CO₂, which is a greenhouse gas, peat bogs function as a global thermostat. The moss helps stabilize the climate.

Why do you think it's important for first-year biology students to learn about the diversity of life, including plants, even if they plan to specialize in cellular or molecular biology or plan to go to medical school?

One reason we include biological diversity in our curriculum here at the University of Wisconsin is that we recognize that this may be the only point in the education of biology students that they will be exposed to the variety of organisms. And we recognize that biological diversity is important to all citizens because of its impact on human health. As students learn about prokaryotes, protists, plants, fungi, and animals, including invertebrates, they begin to see how these diverse organisms perform essential roles in ecosystems. And ultimately, our own health depends on the health of these ecosystems, which sustain humans with such services as clean water and clean air.

What other main points do you emphasize in your first-year courses?

I think that one of the most interesting aspects of biology is the linkage that occurs between the different hierarchical approaches. For example, understanding molecular processes and structures tells us a lot about processes at the organismal level and also at the ecological level. I think that what I can contribute to beginning biologists is an appreciation for integrative thinking and thinking across hierarchical levels. So in my classes, I try to point out that biological knowledge is not compartmented, but rather each topic is linked very lightly to other areas of biological inquiry. I also encourage first-year students to think about large issues and big questions—even if those big questions can't be answered by the application of a single experiment or a single set of observations. There are many questions in my personal research area, the origin of plants and extending back into the origin of life, that seem to some people to be unanswerable because they occurred so long ago that we can't perform direct observations. But I would encourage students to expect that we can answer such questions by deduction and integrative thinking. Thinking large and not focusing too much on the details of particular systems will prove useful in understanding all of biology.

The Tree of Life An Introduction to Biological Diversity

A Figure 26.1 An artist's conception of Earth 3 billion years ago.

Key Concepts

- 26.1 Conditions on early Earth made the origin of life possible
- 26.2 The fossil record chronicles life on Earth
- 26.3 As prokaryotes evolved, they exploited and changed young Earth
- 26.4 Eukaryotic cells arose from symbioses and genetic exchanges between prokaryotes
- 26.5 Multicellularity evolved several times in eukaryotes
- 26.6 New information has revised our understanding of the tree of life

Overview

Changing Life on a Changing Earth

Life is a continuum extending from the earliest organisms to the great variety of species that exist today. In this unit, we will survey the diversity of life and trace the evolution of this diversity.

One of this book's themes is the interaction between organisms and their environments (see Chapter 1). Throughout this unit, we will see examples of the connection between biological history and geologic history. Geologic events that alter environments change the course of biological evolution. When a large lake subsides and forms several small lakes, for instance, some populations of organisms in the lakes become isolated and may evolve into different species (see Chapter 24). Conversely, living things change the planet they inhabit. For example, the evolution of photosynthetic organisms that

released oxygen into the air had a dramatic impact on Earth's atmosphere. (The first of these organisms included prokaryotes similar to those in the dense mats that resemble stepping stones in **Figure 26.1**.) Another example of life changing Earth occurred when plants moved onto land, as Linda Graham explained in the interview on pages 510–511. Much more recently, the emergence of *Homo sapiens* has changed the land, water, and air on a scale and at a rate unprecedented for a single species. The histories of Earth and its life are inseparable.

The chapters in this unit also emphasize key junctures in evolution that have punctuated the history of biological diversity. Geologic history and biological history have been episodic, marked by what were in essence revolutions that opened many new ways of life.

Historical study of any sort is an inexact discipline that depends on the preservation, reliability, and interpretation of past records. The fossil record of past life is generally less and less complete the farther into the past we delve. However, each organism alive today carries traces of its evolutionary history in its molecules, metabolism, and anatomy. As we saw in Unit Four, such traces are clues to the past that augment the fossil record. Still, the evolutionary episodes of greatest antiquity are generally the most obscure.

We will begin this chapter by discussing the origin of life. That discussion is the most speculative in the entire unit, for no fossil evidence of that seminal episode exists. We will then turn to the fossil record and the connection between biological events and the physical history of Earth. Next, we will present an overview of major milestones in the 3.8-billion-year story of life on Earth. Finally, we will consider how biologists now understand the tree of life, a prelude to the survey of biological diversity presented in Chapters 27–34.

Concept 26.1

Conditions on early Earth made the origin of life possible

Scientific evidence is accumulating that chemical and physical processes on early Earth, aided by the emerging force of selection, produced very simple cells through a sequence of four main stages: (1) the abiotic (nonliving) synthesis of small organic molecules, such as amino acids and nucleotides; (2) the joining of these small molecules (monomers) into polymers, including proteins and nucleic acids; (3) the packaging of these molecules into "probionts," droplets with membranes that maintained an internal chemistry different from that of their surroundings; and (4) the origin of self-replicating molecules that eventually made inheritance possible. This scenario has many uncertainties, but it does lead to predictions that can be tested in the laboratory. In this section, we will examine some of the evidence for each of these four stages.

Synthesis of Organic Compounds on Early Earth

Earth and the other planets of the solar system formed about 4.6 billion years ago, condensing from a vast cloud of dust and rocks that surrounded the young sun. It is unlikely that life could have originated or survived on Earth for the first few hundred million years because the planet was still being bombarded by huge chunks of rock and ice left over from the formation of the solar system. The collisions generated enough heat to vaporize all the available water and prevent seas from forming, a phase that likely ended about 3.9 billion years ago. The oldest known rocks on Earth's surface, located at a site called Isua in Greenland, are 3.8 billion years old. Although certain chemical data from these rocks suggest that life may have existed then, this evidence is open to different interpretations, and no one has yet found fossils that old.

As the bombardment of early Earth slowed, conditions on the planet were extremely different from those of today. The first atmosphere was probably thick with water vapor, along with various compounds released by volcanic eruptions, including nitrogen and its oxides, carbon dioxide, methane, ammonia, hydrogen, and hydrogen sulfide. As Earth cooled, the water vapor condensed into oceans, and much of the hydrogen quickly escaped into space.

In the 1920s, Russian chemist A. I. Oparin and British scientist J. B. S. Haldane independently postulated that Earth's early atmosphere had been a reducing (electron-adding) environment, in which organic compounds could have formed from simple molecules. The energy for this organic synthesis could have come from lightning and intense UV radiation. Haldane suggested that the early oceans were a solution of organic

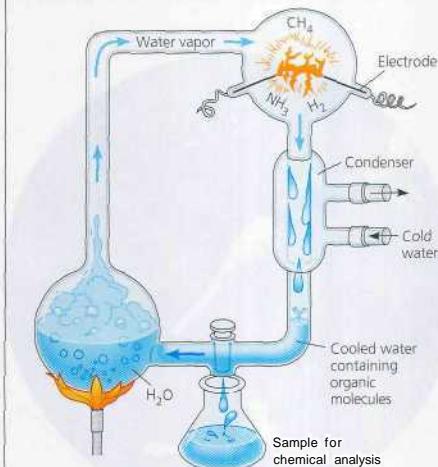

molecules, a "primitive soup" from which life arose. In 1953, Stanley Miller and Harold Urey, of the University of Chicago, tested the Oparin-Haldane hypothesis by creating laboratory conditions comparable to those that scientists at the time thought existed on early Earth. Their apparatus yielded a variety of amino acids found in organisms today, along with other organic compounds (Figure 26.2; also see Figure 4.2). Many laboratories have since repeated the experiment using different

Figure 26.2

Inquiry Can organic molecules form in a reducing atmosphere?

EXPERIMENT

Miller and Urey set up a closed system in their laboratory to simulate conditions thought to have existed on early Earth. A warmed flask of water simulated the primeval sea. The strongly reducing "atmosphere" in the system consisted of H_2 , methane (CH_4), ammonia (NH_3), and water vapor. Sparks were discharged in the synthetic atmosphere to mimic lightning. A condenser cooled the atmosphere, raining water and any dissolved compounds into the miniature sea.

RESULTS

As material circulated through the apparatus, Miller and Urey periodically collected samples for analysis. They identified a variety of organic molecules, including amino acids such as alanine and glutamic acid that are common in the proteins of organisms. They also found many other amino acids and complex, oily hydrocarbons.

CONCLUSION

Organic molecules, a first step in the origin of life, can form in a strongly reducing atmosphere.

recipes for the atmosphere. Organic compounds were also produced in some of these modified models.

However, it is unclear whether young Earth's atmosphere contained enough methane and ammonia to be reducing. Growing evidence suggests that the early atmosphere was made up primarily of nitrogen and carbon dioxide and was neither reducing nor oxidizing (electron-removing). Miller-Urey-type experiments using such atmospheres have not produced organic molecules. Still, it is likely that small "pockets" of the early atmosphere—perhaps near volcanic openings—were reducing.

Instead of forming in the atmosphere, the first organic compounds on Earth may have been synthesized near submerged volcanoes and deep-sea vents—weak points in Earth's crust where hot water and minerals gush into the ocean (**Figure 26.3**). These regions are also rich in inorganic sulfur and iron compounds, which are important in ATP synthesis by present-day organisms.

Extraterrestrial Sources of Organic Compounds

Some of the organic compounds from which the first life on Earth arose may have come from space. Among the meteorites that land on Earth are carbonaceous chondrites, rocks that are 1–2% carbon compounds by mass. Fragments of a

4.5-billion-year-old chondrite collected in southern Australia in 1969 contain more than 80 amino acids, some in large amounts. Remarkably, the proportions of these amino acids are similar to those produced in the Miller-Urey experiment. The chondrite amino acids cannot be contaminants from Earth because they consist of an equal mix of D and L isomers (see Chapter 4); organisms make and use only the L isomers, with a few rare exceptions. Amino acids that reached early Earth aboard chondrites could have added to the primitive soup, but recent calculations suggest that this contribution was likely to have been small.

Looking Outside Earth for Clues About the Origin of Life

The possibility that life is not restricted to Earth is becoming more accessible to scientific testing. Mars is a good place to test hypotheses about the chemistry on Earth before life existed (prebiotic chemistry). The surface of Mars is now a cold, dry, and apparently lifeless desert, but evidence is growing that billions of years ago it was relatively warm for a brief period, with liquid water and a carbon dioxide-rich atmosphere. During that period, prebiotic chemistry similar to that on early Earth may have occurred on Mars. Did life evolve there and then die out, or was prebiotic chemistry terminated by dropping temperatures and a thinning atmosphere before any life-forms developed? Robot explorers are collecting data that may answer these questions in the next decade.

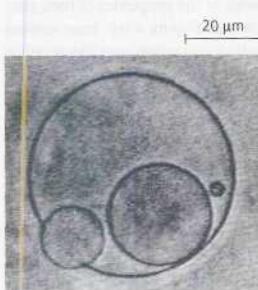

Measurements by the spacecraft Galileo indicate that liquid water lies beneath the ice-covered surface of Europa, one of Jupiter's moons, raising the possibility that Europa's hidden oceans may support prokaryotic life. Outside our solar system, more than a hundred planets orbiting other stars have been found. All these planets are at least as big as Jupiter, but space-based observatories planned for coming decades should have more sensitive telescopes and be able to detect smaller planets and moons of larger planets. If any of them has a strong spectroscopic signal of free oxygen in its atmosphere, that would provide evidence for the presence of oxygen-producing photosynthetic organisms. At present, however, it is unclear what atmospheric properties might indicate the presence of other forms of life.

Abiotic Synthesis of Polymers

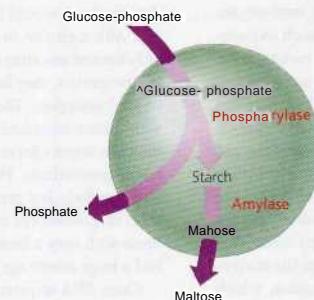

Of course, living cells are more than a collection of amino acids. Every cell has a vast assortment of macromolecules, including proteins and the nucleic acids that are essential for self-replication, and it is difficult to imagine the emergence of life in an environment that did not contain similar macromolecules. Researchers have produced amino acid polymers by dripping solutions of amino acids onto hot sand, clay, or rock. The polymers formed spontaneously, without the help of enzymes or ribosomes. But unlike proteins, these polymers are a complex mix of linked and cross-linked amino acids, and each polymer

A Figure 26.3 A window to early life? An instrument mounted to a robotic arm on the research submarine *Alvin* samples the water around a hydrothermal vent in the Sea of Cortez. More than 1.5 km below the surface, the vent releases hydrogen sulfide and iron sulfide, which react and produce pyrite (fool's gold) and hydrogen gas. Prokaryotes that live near the vent use the hydrogen as an energy source. Such environments are among the most extreme in which life exists today, and some researchers favor the hypothesis that life may have begun in similar regions of early Earth.

(a¹) **Simple reproduction.** This liposome is "giving birth" to smaller liposomes (LM).

(b) **Simple metabolism.** If enzymes—in this case, phosphorylase and amylase—are included in the solution from which the droplets self-assemble, some liposomes can carry out simple metabolic reactions and export the products.

▲ Figure 26.4 Laboratory versions of protobionts.

is different. Nevertheless, such macromolecules may have acted as weak catalysts for a variety of reactions on early Earth.

Fl-otobionts

'Life' is defined partly by two properties: accurate replication and metabolism. Neither property can exist without the other. DNA molecules carry genetic information, including the instructions needed to replicate themselves accurately. But the replication of DNA requires an elaborate enzymatic machinery, along with a copious supply of nucleotide building blocks that must be provided by the cell's metabolism (see Chapter 16). While Miller-Urey-type experiments have yielded some of the nitrogenous bases of DNA and RNA, they have not produced anything like nucleotides. Therefore, the building blocks of nucleic acids probably were not part of the early organic soup. Self-replicating molecules and a metabolism-like source of the building blocks must have appeared together. How did that happen?

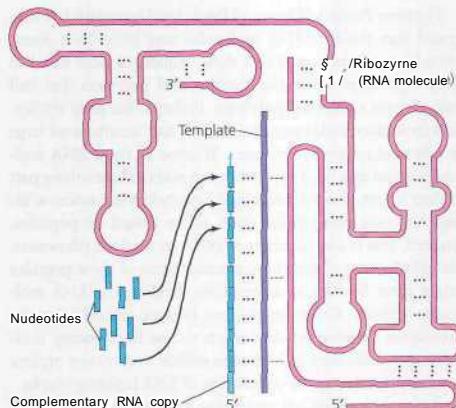

The necessary conditions may have been met by protobionts, aggregates of abiotically produced molecules surrounded by a membrane or membrane-like structure. Protobionts exhibit some of the properties associated with life, including simple reproduction and metabolism, as well as the maintenance of an internal chemical environment different from that of their surroundings.

Laboratory experiments demonstrate that protobionts could have formed spontaneously from abiotically produced organic compounds. For example, small membrane-bounded droplets called liposomes can form when lipids or other organic molecules are added to water (**Figure 26.4**). The hydrophobic molecules in the mixture organize into a bilayer at the surface of the droplet, much like the lipid bilayer of a plasma membrane. Because the liposome bilayer is selectively permeable, liposomes

undergo osmotic swelling or shrinking when placed in solutions of different solute concentrations. Some liposomes store energy in the form of a membrane potential, a voltage across the surface. Such liposomes can discharge the voltage in nerve cell-like fashion; such excitability is characteristic of all life (which is not to say that liposomes are alive, but only that they display some of the properties of life.) If similar droplets forming in ponds on early Earth incorporated random polymers of linked amino acids into their membranes, and if some of those polymers made the membranes permeable to certain organic molecules, then those droplets could have selectively taken up organic molecules from their environment.

The "RNA World" and the Dawn of Natural Selection

The first genetic material was probably RNA, not DNA. Thomas Cech, of the University of Colorado, and Sidney Altman, of Yale University, found that RNA, which plays a central role in protein synthesis, can also carry out a number of enzyme-like catalytic functions. Cech called these RNA catalysts ribozymes. Some ribozymes can make complementary copies of short pieces of RNA, provided that they are supplied with nucleotide building blocks (**Figure 26.5**). Others can

A Figure 26.5 A ribozyme capable of replicating RNA.
This RNA molecule can make a complementary copy of another piece of RNA (a template) containing up to 14 nucleotides.

remove segments of themselves (self-splicing introns; see Chapter 17), or can act on different molecules, such as transfer RNA, excising pieces of these molecules and making them fully functional. Ribozyme-catalyzed reactions are relatively slow, but proteins normally associated with ribozymes can increase the reaction rate more than a thousandfold.

Natural selection on the molecular level has been observed operating on RNA populations in the laboratory. Unlike double-stranded DNA, which takes the form of a uniform helix, single-stranded RNA molecules assume a variety of specific three-dimensional shapes mandated by their nucleotide sequences. The molecule thus has both a genotype (its nucleotide sequence) and a phenotype (its conformation, which interacts with surrounding molecules in specific ways). In a particular environment, RNA molecules with certain base sequences are more stable and replicate faster and with fewer errors than other sequences. Beginning with a diversity of RNA molecules that must compete for monomers to replicate, the sequence best suited to the temperature, salt concentration, and other features of the surrounding solution and having the greatest autocatalytic activity will prevail. Its descendants will not be a single RNA species but will be a family of closely related sequences because of copying errors. Selection screens mutations in the original sequence, and occasionally a copying error results in a molecule that folds into a shape that is even more stable or more adept at self-replication than the ancestral sequence. Similar selection events may have occurred on early Earth. Thus, the molecular biology of today may have been preceded by an "RNA world," in which small RNA molecules that carried genetic information were able to replicate and to store information about the protobionts that carried them.

Physicist Freeman Dyson, of Princeton University, has suggested that the first RNA molecules may have been short, virus-like sequences and that these sequences were aided in their replication by random amino acid polymers that had rudimentary catalytic capabilities. Perhaps this early replication took place inside protobionts that had accumulated large numbers of organic monomers, if some of these RNA molecules could also bind specific amino acids to bases along part of their length, this binding could have held a few amino acids together long enough for them to be linked in peptides. (Indeed, this is one function of rRNA in modern ribosomes, the cellular sites of protein synthesis.) Some of these peptides might have functioned as enzymes, helping the RNA molecules replicate. Others might have become embedded in the protobiont membrane, allowing it to use high-energy inorganic molecules such as hydrogen sulfide to carry out organic reactions, including the production of RNA building blocks.

A protobiont with self-replicating, catalytic RNA would differ from its many neighbors that did not carry RNA or that carried RNA without such capabilities. If that protobiont could grow, split, and pass its RNA molecules to its daughters,

the daughters would have some *of* the properties of their parent. Although the first such protobionts must have carried only limited amounts of genetic information, specifying only a few properties, they had inheritance and could be acted on by natural selection. The most successful of these protobionts would have increased in number, because they could exploit their resources effectively and pass their abilities on to subsequent generations. The emergence of such protobionts may seem unlikely, but remember that there could have been trillions of protobionts in bodies of water on early Earth. Even those with only a limited capacity for inheritance would have had a huge advantage over the rest.

Once RNA sequences that carried genetic information appeared in protobionts, many further changes were possible. For example, RNA could have provided the template on which DNA nucleotides were assembled. Double-stranded DNA is a much more stable repository for genetic information than the more fragile single-stranded RNA, and it can be replicated more accurately. Accurate replication was a necessity as genomes grew larger through gene duplication and other processes, and as more properties of the protobionts became coded in genetic information. After DNA appeared, perhaps RNA molecules began to take on their modern roles as intermediates in the translation of genetic programs, and the "RNA world" gave way to a "DNA world." The stage was now set for an explosion *of* life forms, driven by natural selection, that has continued to the present day.

Concept Check 26.1

1. What hypothesis did Miller and Urey test in their experiment?
2. Why was the appearance of protobionts surrounded by membranes likely a key step in the origin of life?
3. What is a ribozyme?

For suggested answers, see Appendix A.

Concept 26.2

The fossil record chronicles life on Earth

Questions about the earliest stages in the origin of life on Earth may never be fully answered because, as far as we know, there is no record of these ancient events. Many later events, however, are well documented in the fossil record. Careful study of fossils opens a window into the lives of organisms that existed long ago and provides information about the evolution of life over billions of years.

Hovf Rocks and Fossils Are Dated

Recall from Chapter 25 that most fossils are found in sedimentary rocks. The trapping of dead organisms in sediments freezes fossils in time. Thus, the fossils in each stratum of sedimentary rock are a local sample of the organisms that existed when the sediment that formed the stratum was deposited. Because younger sediments are superimposed on older ones, this book of sedimentary pages tells the relative ages of fossils (see Figure 25.3).

The strata at one location can often be correlated with strata at another location by the presence of similar fossils, known as index fossils. The best index fossils for correlating strata that are far apart are the shells of marine organisms that were widespread (Figure 26.6). Index fossils reveal that at any particular location there are likely to be gaps in the sequence. True location may have been above sea level during certain periods, and thus no sedimentation occurred; or some of the sedimentary layers that were deposited when the location was submerged may have been eroded away.

The relative sequence of fossils in rock strata tells us the order in which the fossils were laid down, but it does not tell us their ages. Examining the relative positions of fossils in strata is like peeling layers of wallpaper from a very old house that has had many occupants. You can determine the sequence in which the layers were applied but not the year each layer was added.

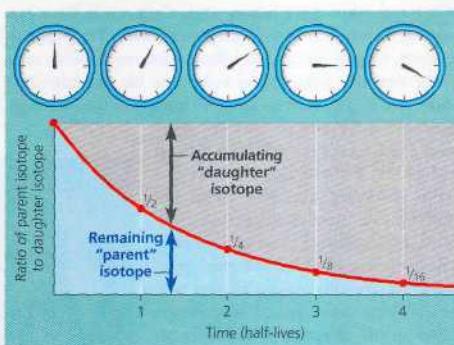

Geologists have developed several methods for obtaining absolute dates for fossils. (Note that "absolute" dating does not mean errorless dating, but only that age is given in years rather than relative terms such as *before* and *after*.) One of the most common techniques is **radiometric dating**, which is based on the decay of radioactive isotopes. Each radioactive isotope has a fixed rate of decay. An isotope's **half-life**, the number of years it takes for 50% of the original sample to decay, is unaffected by temperature, pressure, and other environmental variables (Figure 26.7).

Fossils contain isotopes of elements that accumulated in the organisms when they were alive. For example, the carbon in a living organism includes the most common carbon isotope, carbon-12, as well as a radioactive isotope, carbon-14. When the organism dies, it stops accumulating carbon, and the carbon-14 that it contained at the time of death slowly decays and becomes another element, nitrogen-14. Thus, by measuring the ratio of carbon-14 to total carbon or to nitrogen-14 in a fossil, we can determine the fossil's age. With a half-life of 5,730 years, carbon-14 is useful for dating fossils up to about 75,000 years old. Fossils older than that contain too little carbon-14 to be detected with current techniques. (After 13 half-lives—74,490 years—a fossil contains only $1/2^{13}$, or 0.012%, of the carbon-14 that was present when the fossil formed.) Radioactive isotopes with longer half-lives are used to date older fossils.

Paleontologists can often determine the age of fossils sandwiched between layers of volcanic rocks by measuring the amount of the radioactive isotope potassium-40 in those layers.

▲ **Figure 26.6 Index fossils.** Shelled animals called brachiopods were extremely abundant in the ancient seas. Their fossils are useful indicators of the relative ages of rock strata in different locations.

▲ **Figure 26.7 Radiometric dating.** A radioactive "parent" isotope decays to a "daughter" isotope at a constant rate. The rate of decay is expressed by the half-life, the time required for 50% of the remaining parent isotope to decay (in this diagram, each division of the dock face represents a half-life). Each type of radioactive isotope has a characteristic half-life. For example, carbon-14 decays relatively quickly and has a half-life of 5,730 years; uranium-238 decays slowly and has a half-life of 4.5 billion years.

Potassium-40 decays to the chemically unreactive gas argon-40, which is trapped in the rock. When the rock is heated during a volcanic eruption, the argon is driven off but the potassium remains. This resets the clock for potassium-40 decay to zero. The current ratio of potassium-40 to argon-40 in a layer of volcanic rock gives an estimate of when that layer was formed. Thus, if fossils are found in a sedimentary layer between two volcanic layers that are 530 and 520 million years old, we can infer that the fossils came from organisms that lived about 525 million years ago.

The magnetism of rocks can also provide dating information. During the formation of volcanic or sedimentary rock, iron particles in the rock align themselves with Earth's magnetic field. When the rock hardens, their orientation is frozen in time. By measuring the magnetism of rocks with a device called a magnetometer, geologists have determined that Earth's north and south magnetic poles have reversed repeatedly in the past. Because these magnetic reversals affect the entire planet, they have left their record on rocks throughout the world. Therefore, patterns of magnetic reversals in one location can be matched with corresponding patterns elsewhere, allowing rocks to be dated when other methods are not available.

The Geologic Record

Geologists have established a geologic record of Earth's history, which is divided into three eons (Table 26.1, on the facing page). The first two eons—the Archaean and the Proterozoic—lasted approximately 4 billion years. Collectively, these two eons are often referred to as the Precambrian. The Phanerozoic eon, roughly the last half billion years, encompasses most of the time that multicellular eukaryotic life has existed on Earth, and it is divided in turn into three eras: the Paleozoic, Mesozoic, and Cenozoic. Each era represents a distinct age in the history of Earth and its life. For example, the Mesozoic era is sometimes called the "age of reptiles" because of its abundance of reptilian fossils, including those of dinosaurs. The boundaries between the eras correspond to times of mass extinctions seen clearly in the fossil record, when many forms of life disappeared and were replaced by forms that evolved from the survivors.

Lesser extinctions also mark the boundaries of many of the periods into which each era has been divided. Periods are further subdivided into intervals called epochs. Table 26.1 lists the epochs of the current era, the Cenozoic.

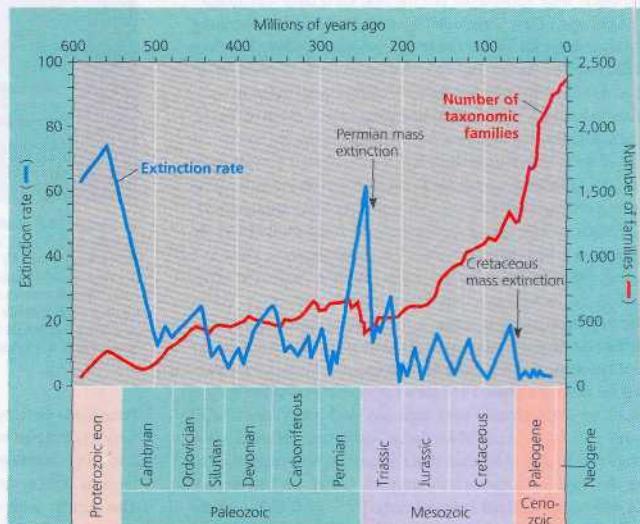

Mass Extinctions

A species may become extinct for many reasons. Its habitat may have been destroyed, or its environment may have changed in a direction unfavorable to the species. If ocean temperatures fall by even a few degrees, many species that are otherwise well adapted will perish. Even if physical factors in the environment remain

stable, biological factors may change; the environment in which a species lives includes the other organisms that live there, and evolutionary change in one species is likely to impact others.

The fossil record chronicles a number of occasions when global environmental changes were so rapid and disruptive that a majority of species were swept away (Figure 26.8). Such mass extinctions are known primarily from the decimation of hard-bodied animals that lived in shallow seas, the organisms for which the fossil record is most complete. Two mass extinctions—the Permian and the Cretaceous—have received the most attention. The Permian mass extinction, which defines the boundary between the Paleozoic and Mesozoic eras, claimed about 96% of marine animal species. Terrestrial life was also affected. For example, 8 out of 27 orders of insects were wiped out. This mass extinction occurred in less than 5 million years, possibly much less—an instant in the context of geologic time. The Cretaceous mass extinction of 65 million years ago, which marks the boundary between the Mesozoic and Cenozoic eras, doomed more than half of all marine species and exterminated many families of terrestrial plants and animals, including most of the dinosaurs.

The Permian mass extinction occurred at the time of enormous volcanic eruptions in what is now Siberia, constituting the most extreme episode of volcanism during the past half billion

A Figure 26.8 Diversity of life and periods of mass extinction. The fossil record of terrestrial and marine organisms reveals a general increase in the diversity of organisms over time (red line and right vertical axis). Mass extinctions, represented by peaks in the extinction rate (blue line and left vertical axis) interrupted the buildup of diversity. The extinction rate is the estimated percentage of extant taxonomic families that died out in each period of geologic time.

Table 26.1 The Geologic Record

| Relative Duration of Eras | Era | Period | Age (Millions of Years Ago) | Some Important Events in the History of Life |
|---------------------------|-----------|------------------------|-----------------------------|--|
| Proterozoic | Cenozoic | Neogene | Holocene 0.01 | Historical time |
| | | | Pleistocene 1.8 | Ice ages; humans appear |
| | | | Pliocene 5.3 | Origin of genus <i>Homo</i> |
| | | | Miocene 23 | Continued radiation of mammals and angiosperms; -ape like ancestors of humans appear |
| | | Paleogene | Oligocene 33.9 | Origins of many primate groups, including apes |
| | | | Eocene 55.8 | Angiosperm dominance increases; continued radiation of most modern mammalian orders |
| | | | Paleocene 65.3 | Major radiation of mammals, birds, and pollinating insects |
| | Mesozoic | Cretaceous 145.5 | | Flowering plants (angiosperms) appear; many groups of organisms, including dinosaurs, become extinct at end of period (Cretaceous extinctions) |
| | | Jurassic 199.6 | | Gymnosperms continue as dominant plants; dinosaurs abundant and diverse |
| | | Triassic 251 | | Cone-bearing plants (gymnosperms) dominate landscape; radiation of dinosaurs; origin of mammal-like reptiles |
| Archaean | Paleozoic | Permian 299 | | Radiation of reptiles; origin of most present-day orders of insects; extinction of many marine and terrestrial organisms at end of period |
| | | Carboniferous 359.2 | | Extensive forests of vascular plants; first seed plants; origin of reptiles; amphibians dominant |
| | | Devonian 416 | | Diversification of fishy fishes; first tetrapods and insects |
| | | Silurian 443.7 | | Diversification of early vascular plants |
| | | Ordovician 488.3 | | Marine algae abundant; colonization of land by plants and invertebrates |
| | | Cambrian 542 | | Sudden increase in diversity of many animal phyla (Cambrian explosion) |
| | | | 600 | Diverse algae and soft-bodied invertebrate animals |
| | | | 2,200 | Oldest fossil of eukaryotic cells |
| | | | 2,500 | Concentration of atmospheric oxygen begins to increase |
| | | | 2,700 | Oldest fossils of cells (prokaryotes) |
| | | | 3,500 | Oldest known rocks on Earth's surface |
| | | | 3,800 | |
| | | | Approx. 4,600 | Origin of Earth |

years. Besides spewing lava and ash into the atmosphere, the eruptions may have produced enough carbon dioxide to warm the global climate. Reduced temperature differences between the equator and the poles would have slowed the mixing of ocean water, which in turn would have reduced the amount of oxygen available to marine organisms. An oxygen deficit in the oceans may have played a large role in the Permian extinction.

One clue to a possible cause of the Cretaceous mass extinction is a thin layer of clay enriched in iridium that separates sediments from the Mesozoic and Cenozoic eras. Iridium is an element very rare on Earth but common in many of the meteorites and other extraterrestrial objects that occasionally fall to Earth. Walter and Luis Alvarez and their colleagues at the University of California proposed that this clay is fallout from a huge cloud of debris that billowed into the atmosphere when an asteroid or a large comet collided with Earth. This cloud would have blocked sunlight and severely disturbed the global climate for several months.

Where did the asteroid or comet hit? Research has focused on the Chicxulub crater, a 65-million-year-old scar beneath sediments off the Yucatan coast of Mexico (Figure 26.9). About 180 km in diameter, the crater is the right size to have been caused by an object with a diameter of 10 km.

Critical evaluation of various hypotheses for these and other mass extinctions continues. At the time of the Cretaceous mass extinction, a spike in volcanic activity took place in what is now India. Was this spike triggered by the Chicxulub impact?

Some scientists hypothesize that the Siberian volcanism that coincided with the Permian mass extinction also may have had an extraterrestrial trigger. Recent evidence suggests that there may have been a huge meteorite impact off the coast of Australia at that time. However, this interpretation is controversial, in part because no iridium-rich layer has been detected in Permian rocks. Alternatively, a near miss or a glancing blow by an asteroid or other body may have been enough to accelerate volcanic activity.

Much remains to be learned about the causes of mass extinctions, but it is clear that they provided life with unparalleled opportunities for adaptive radiations into newly vacated ecological niches. In the rest of this chapter, we will consider some of the major events in the history of life. **Figure 2C.10** uses the analogy of a clock to place these events in the context of the geological record. This clock will reappear at various points in the chapter as a quick reminder of when the events we are discussing took place.

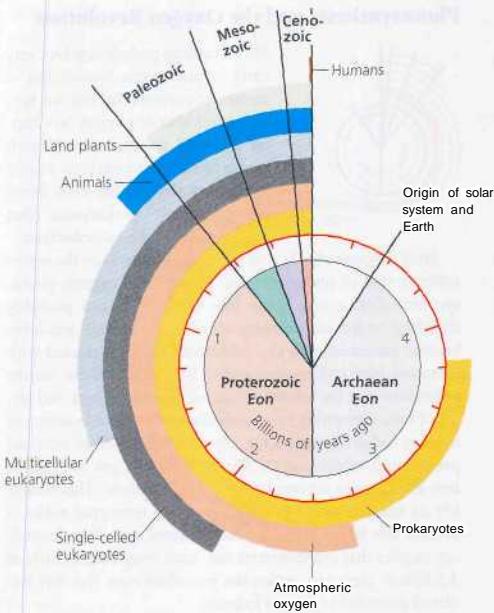

Concept Check 26.2

1. Your measurements indicate that a fossilized skull you unearthed has a carbon-14/carbon-12 ratio about $\frac{1}{10}$ that of the skulls of present-day animals. What is the approximate age of the fossilized skull?
2. Based on Table 26.1, how long did prokaryotes inhabit Earth before eukaryotes evolved?

For suggested answers, see Appendix A.

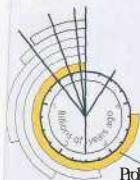

A Figure 26.9 Trauma for Earth and its Cretaceous life. The 65-million-year-old Chicxulub impact crater is located in the Caribbean Sea near the Yucatan Peninsula of Mexico. The horseshoe shape of the crater and the pattern of debris in sedimentary rocks indicate that an asteroid or comet struck at a low angle from the southeast. This artist's interpretation represents the impact and its immediate effect—a cloud of hot vapor and debris that could have killed most of the plants and animals in North America within hours.

A Figure 26.10 Clock analogy for some key events in Earth's history. The clock ticks down from the origin of Earth 4.6 billion years ago to the present.

Concept 26.3

As prokaryotes evolved, they exploited and changed young Earth

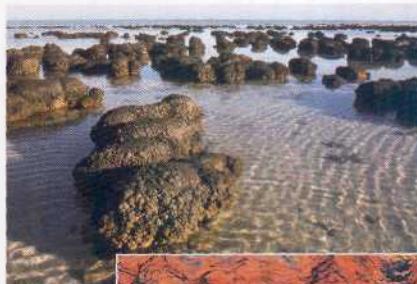

Prokaryotes

The oldest known fossils, dating from 3.5 billion years ago, are fossils of **stromatolites**, which are rocklike structures composed of many layers of bacteria and sediment (Figure 26.11). Present-day stromatolites are found in a few warm, shallow, salty bays. If bacterial communities so complex existed

3.5 billion years ago, it is a reasonable hypothesis that life originated much earlier, perhaps as early as 3.9 billion years ago, when Earth began to cool to a temperature at which liquid water could exist. It is clear that prokaryotic life was already flourishing when Earth was still relatively young. Fairly early

(a) Lynn Margulis (top right), of the University of Massachusetts, and Kenneth Nealson, of the University of Southern California, are shown collecting bacterial mats in a Baja California lagoon. The mats are produced by colonies of bacteria that live in environments inhospitable to most other life. A section through a mat (inset) shows layers of sediment that adhere to the sticky bacteria as the bacteria migrate upward.

(b) Some bacterial mats form rocklike structures called stromatolites, such as these in Shark Bay, Western Australia. The Shark Bay stromatolites began forming about 3,000 years ago. The inset shows a section through a fossilized stromatolite that is about 3.5 billion years old.

A Figure 26.11 Bacterial mats and stromatolites.

in prokaryotic history, two main evolutionary branches, the bacteria and the archaea, diverged. As you will read in Chapter 27, many species in these two lineages continue to thrive in a wide variety of environments today.

The First Prokaryotes

The early probiotics that had both self-replicating and metabolic capabilities must have used molecules for their growth and replication that were already present in the primitive soup. However, even the earliest successful probiotics probably had to make at least some of the molecules they required. Eventually, these probiotics were replaced by organisms that could produce all their needed compounds from molecules in their environment. These probiotics diversified into a rich variety of autotrophs, some of which could use light energy. The diversification of autotrophs likely encouraged the emergence of heterotrophs, which could live on products that the autotrophs excreted or on the autotrophs themselves.

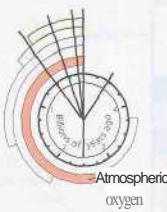

The autotrophs and heterotrophs were the first prokaryotes, and they were Earth's sole inhabitants from at least 3.5 to about 2 billion years ago. As we will see, these organisms transformed the biosphere of our planet.

Electron Transport Systems

The chemiosmotic mechanism of ATP synthesis, in which a complex set of membrane-bound proteins pass electrons to reducible electron acceptors with the generation of ATP from ADP (see Chapter 9), is common to all three domains of life—Bacteria, Archaea, and Eukarya. There is strong evidence that this electron transport mechanism actually originated in organisms that lived before the last common ancestor of all present-day life. The earliest of these electron transport systems likely evolved before there was any free oxygen in the environment and before the appearance of photosynthesis; the organisms that used it would have required a plentiful supply of energy-rich compounds such as molecular hydrogen, methane, and hydrogen sulfide. A great challenge facing scientists studying the origin of life is to determine the steps by which this electron transport mechanism originated, and how important early versions of it might have been in the emergence of the first cells.

We'll explore the metabolically diverse prokaryotes that use different types of electron transport in detail in Chapter 27. For now, the important point is that considerable metabolic diversity among prokaryotes living in various environments had already evolved more than 3 billion years ago. Most subsequent evolution has been more structural than metabolic.

Photosynthesis and the Oxygen Revolution

Photosynthesis probably evolved very early in prokaryotic history, but in metabolic versions that did not split water and liberate oxygen. In Chapter 27, we'll see examples of such nonoxygenic photosynthesis among living prokaryotes. The only living photosynthetic prokaryotes that generate O₂ are the cyanobacteria.

Most atmospheric O₂ is of biological origin, from the water-splitting step of photosynthesis. When this oxygenic photosynthesis first evolved, the free O₂ it produced probably dissolved in the surrounding water until the seas and lakes became saturated with O₂. Additional O₂ then reacted with dissolved iron and precipitated as iron oxide. These marine sediments were the source of banded iron formations, red layers of rock containing iron oxide that are a valuable source of iron ore today (Figure 26.12). Once all the dissolved iron had precipitated, additional O₂ finally began to "gas out" of the seas and lakes to accumulate in the atmosphere. This change left its mark in the rusting of iron-rich terrestrial rocks, a process that began about 2.7 billion years ago. This chronology implies that cyanobacteria may have originated as early as 3.5 billion years ago, when the microbial mats that left fossilized stromatolites began forming.

The amount of atmospheric O₂ increased gradually from about 2.7 to 2.2 billion years ago, but then shot up relatively rapidly to more than 10% of its present level. This "oxygen revolution" had an enormous impact on life. In its free molecular and ionized forms and in compounds such as hydrogen peroxide, oxygen attacks chemical bonds and can inhibit enzymes and damage cells. Its increasing atmospheric

A Figure 26.12 Banded iron formations: evidence of oxygenic photosynthesis. These bands of iron oxide at Jasper Knob in Michigan are about 2 billion years old.

concentration likely doomed many prokaryotic groups. Some species survived in habitats that remained anaerobic, where we find their descendants still living today as obligate anaerobes (see Chapter 27). Among other survivors, a diversity of adaptations to the changing atmosphere evolved, including cellular respiration, which uses oxygen in the process of harvesting the energy stored in organic molecules.

The early, gradual rise in atmospheric O₂ levels was associated with photosynthesis by ancient cyanobacteria. But what caused the accelerated rise in O₂ a few hundred million years later? One hypothesis is that it followed the evolution of eukaryotic cells containing chloroplasts, as we will discuss in the next section.

Concept Check 26.3

1. What do fossilized stromatolites suggest about the evolution of prokaryotes?
2. The first appearance of free oxygen in the atmosphere must have triggered a massive wave of extinctions among the prokaryotes of the time. Why?

For suggested answers, see Appendix A.

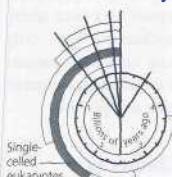

Concept 26.4

Eukaryotic cells arose from symbioses and genetic exchanges between prokaryotes

Eukaryotic cells differ in many respects from the generally smaller cells of bacteria and archaea (see Chapter 6). Even the smallest single-celled eukaryote is far more complex in structure than any prokaryote. Among the most fundamental questions in biology is how these complex eukaryotic cells evolved from much simpler prokaryotic cells.

The First Eukaryotes

The oldest fossils that most researchers agree are eukaryotic are about 2.1 billion years old. Other fossils, of corkscrew-shaped organisms that resembled simple, single-celled algae, are slightly older (2.2 billion years), but their eukaryotic nature is less certain.

However, some researchers postulate a much earlier eukaryotic origin based on traces of molecules similar to cholesterol found in rocks dating back

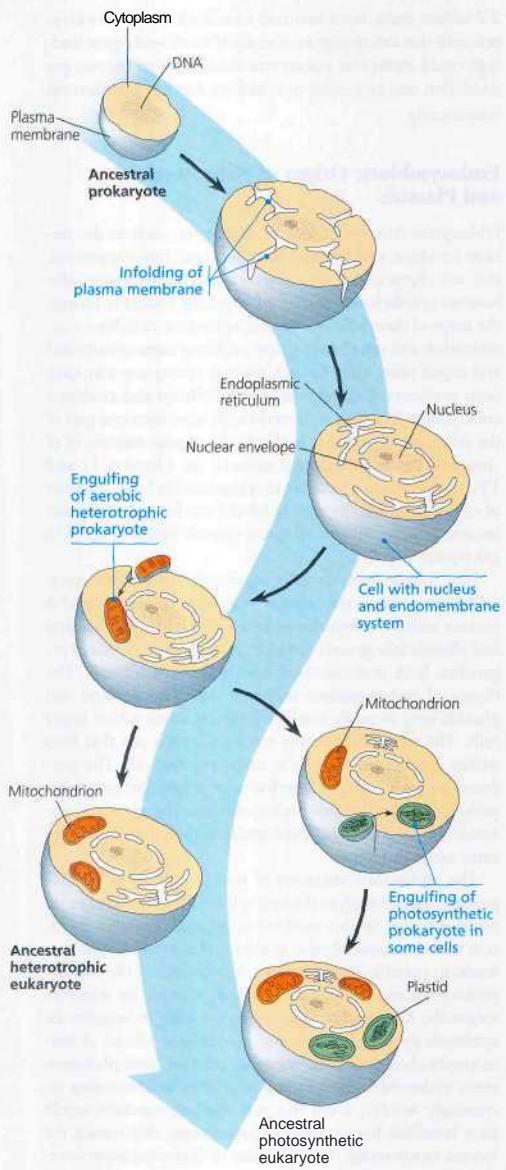

2.7 billion years. Such molecules are made only by eukaryotic cells that can respire aerobically. If confirmed, these findings could mean that eukaryotes evolved when the oxygen revolution was beginning to transform Earth's environments dramatically.

Endosymbiotic Origin of Mitochondria and Plastids

Prokaryotes lack many internal structures, such as the nuclear envelope, endoplasmic reticulum, and Golgi apparatus, that are characteristic of eukaryotic cells. Prokaryotes also have no cytoskeleton, so they are generally unable to change the shape of their cells. In contrast, eukaryotic cells have a cytoskeleton and can change shape, enabling them to surround and engulf other cells. Indeed, the first eukaryotes may have been predators of other cells. A cytoskeleton also enables a eukaryotic cell to shift its internal structures from one part of the cell to another, and it facilitates the regular movement of chromosomes in mitosis and meiosis (see Chapters 12 and 13). Mitosis made it possible to reproduce the large genomes of eukaryotes, and the closely related mechanism of meiosis became an essential part of sexual recombination of genes in eukaryotes.

How did the more complex organization of the eukaryotic cell evolve from the simpler prokaryotic condition? A process called endosymbiosis probably led to mitochondria and plastids (the general term for chloroplasts and related organelles, both photosynthetic and nonphotosynthetic). The theory of endosymbiosis proposes that mitochondria and plastids were formerly small prokaryotes living within larger cells. The term *endosymbiont* refers to such a cell that lives within another cell, which is called the *host cell*. The proposed ancestors of mitochondria were aerobic heterotrophic prokaryotes that became endosymbionts; the proposed ancestors of plastids were photosynthetic prokaryotes that became endosymbionts.

The prokaryotic ancestors of mitochondria and plastids probably gained entry to the host cell as undigested prey or internal parasites. Such a mechanism suggests an earlier evolution of an endomembrane system and a cytoskeleton that made it possible for the larger cell to engulf the smaller prokaryotes and package them within vesicles. By whatever means the relationships began, it is not hard to imagine the symbiosis eventually becoming mutually beneficial. A heterotrophic host could use nutrients released from photosynthetic endosymbionts. And in a world that was becoming increasingly aerobic, a cell that was itself an anaerobe would have benefited from aerobic endosymbionts that turned the oxygen to advantage. In the process of becoming more interdependent, the host and endosymbionts would have become a single organism, its parts inseparable. All eukaryotes, whether heterotrophic or autotrophic, have mitochondria or genetic

A Figure 26.13 A model of the origin of eukaryotes through serial endosymbiosis.

remnants of these organelles. However, not all eukaryotes have plastids. Thus, the hypothesis of serial endosymbiosis (a sequence of endosymbiotic events) supposes that mitochondria evolved before plastids (**Figure 26.13**).

The evidence supporting an endosymbiotic origin of plastids and mitochondria is overwhelming. The inner membranes of both organelles have enzymes and transport systems that are homologous to those found in the plasma membranes of living prokaryotes. Mitochondria and plastids replicate by a splitting process reminiscent of binary fission in certain prokaryotes. Each organelle contains a single, circular DNA molecule that, like the chromosomes of bacteria, is not associated with histones or other proteins. These organelles contain the transfer RNAs, ribosomes, and other molecules needed to transcribe and translate their DNA into proteins. In terms of size, nucleotide sequence, and sensitivity to certain antibiotics, the ribosomes of mitochondria and plastids are more similar to prokaryotic ribosomes than they are to the cytoplasmic ribosomes of eukaryotic cells.

Which prokaryotic lineages gave rise to mitochondria and plastids? To answer this question, **systematists** have focused on the nucleotide sequence of the RNA in one of the ribosomal subunits. The gene for this small-subunit ribosomal RNA (SSU-rRNA) is present in all organisms, making it a good choice for studying the deepest branches of the tree of life (see Chapter 25). Comparisons of SSU-rRNA from mitochondria, plastids, and various living prokaryotes indicate that a group of bacteria called the alpha proteobacteria are the closest relatives of mitochondria, and that cyanobacteria are the closest relatives of plastids.

Over time, some of the genes originally present in mitochondria and plastids were transferred to the nucleus, a process that may have been accomplished by transposable **elements** (see Chapter 18). As a result, some mitochondrial and plastid proteins are encoded by the organelles' own DNA, whereas others are encoded by genes in the nucleus. Still other proteins are combinations of polypeptides encoded by genes in both locations; an example is the mitochondrial ATP synthase, the protein complex that generates ATP during cellular respiration (see Chapter 9). The transfer of genes to the nucleus has advanced further in some eukaryotes than in others: Mitochondria in the freshwater protist *Reclinomonas americana* have 97 genes, including several genes that in other eukaryotes have been transferred to the nucleus; vertebrate mitochondria have only 34 genes. It is fair to say that eukaryotic cells now contain only *one* genome, which is mostly nuclear but complemented by DNA that has remained in mitochondria and plastids.

Eukaryotic Cells as Genetic Chimeras

In Greek mythology, the chimera was a monster that was part goat, part lion, and part serpent. The eukaryotic cell is a chimera of prokaryotic parts, its mitochondria derived from one type

of bacteria, its plastids from another, and its nuclear genome from parts of these endosymbionts' genomes and from at least one other cell, the cell that hosted the endosymbionts. Mitochondria and plastids have provided clues to their origins because they still carry small DNA molecules that have genes orthologous to prokaryotic genes (see Figure 25.17). Clues to other aspects of the origin of eukaryotic cells are far more numerous and confusing. For example, some researchers have proposed that the nucleus evolved from an endosymbiont belonging to domain Archaea. Genes with close relatives in both bacteria and archaea have been found in eukaryotic nuclei, but the picture is cloudy because different nuclei have different combinations of such genes.

The genome of eukaryotic cells may be the product of genetic annealing, in which horizontal gene transfers occurred between many different bacterial and archaeal lineages. Carl Woese, of the University of Illinois, has suggested that most of these transfers took place during the early evolution of life, but new evidence indicates that horizontal gene transfers have happened repeatedly up to the present time. Ford Doolittle, of Dalhousie University, has used this evidence of repeated transfers to suggest a variant of genetic annealing: the "you are what you eat" hypothesis, in which evolving eukaryotes consumed various bacteria and archaea and occasionally incorporated some of the engulfed prokaryotes' genes into their nuclei.

The origin of other eukaryotic structures is the subject of active research. The Golgi apparatus and the endoplasmic reticulum may have originated from infoldings of the plasma membrane. Proteins that appear to be homologous to the cytoskeletal proteins actin and tubulin have been found in bacteria, where they are involved in the "pinching off" of bacterial

A Figure 26.14 A complex symbiosis. The remarkable protist *Mixotricha paradoxa*, which lives in the gut of termites, has three types of bacteria attached to its surface that provide it with motility (SEM). A fourth type of bacterium lives inside *Mixotricha* and digests wood fragments eaten by the termite.

cells during cell division. Further investigation of these bacterial proteins and their activities may provide information about the origin of the eukaryotic cytoskeleton. Some investigators have speculated that eukaryotic flagella and cilia evolved from symbiotic bacteria, an idea supported by the observation that bacteria have entered into more recent symbiotic relationships with some protozoans (Figure 26.14). However, the 9 + 2 microtubule apparatus of eukaryotic flagella and cilia (see Chapter 6) has not been found in any prokaryote.

An orchestra can play a greater variety of musical compositions than a violin soloist can. Put simply, increased complexity makes more variations possible. The origin of the eukaryotic cell catalyzed the evolution of much more structural diversity than was possible for the simpler prokaryotic cells. This built on the first great adaptive radiation, the metabolic diversification of the prokaryotes. A third wave of diversification followed the origin of multicellular bodies in several eukaryotic lineages.

Concept Check 26.4

- What evidence supports the hypothesis that mitochondria preceded plastids in the evolution of eukaryotic cells?
- How is a eukaryotic cell like a chimera?

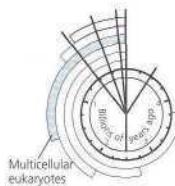

Vor suggested answers, see Appendix A.

Concept 26.5

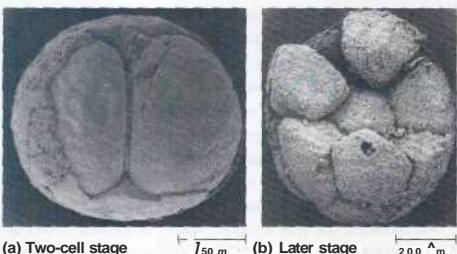

Multicellularity evolved several times in eukaryotes

After the first eukaryotes appeared, a great range of unicellular forms evolved, giving rise to the diversity of single-celled eukaryotes that continue to flourish today. But multicellular forms also evolved. Their descendants include a variety of algae, plants, fungi, and animals.

The Earliest Multicellular Eukaryotes

Molecular clocks date the common ancestor of multicellular eukaryotes to 1.5 billion years ago. However, the oldest known fossils of multicellular eukaryotes are of relatively small algae that lived about 1.2 billion years ago. Larger organisms do not appear in the fossil record until several hundred million years later, in the late Proterozoic. Chinese paleontologists recently described a particularly rich site that contains

A Figure 26.15 Fossils of Proterozoic animal embryos (SEM).

570-million-year-old fossils of a diversity of algae and animals, including beautifully preserved structures that are probably animal embryos (**Figure 26.15**).

Why were multicellular eukaryotes relatively limited in size, diversity, and distribution until the late Proterozoic? Geologic evidence indicates that a severe ice age occurred 750 to 570 million years ago. During this period, glaciers covered the planet's landmasses from pole to pole, and the seas were iced over. According to the snowball Earth hypothesis, most life would have been confined to areas near deep-sea vents and hot springs or to those sparse regions of the ocean where enough ice had melted for sunlight to penetrate the surface waters. The fossil record of the first major diversification of multicellular eukaryotes corresponds to the time when snowball Earth thawed.

The Colonial Connection

The first multicellular organisms were colonies, collections of autonomously replicating cells (**Figure 26.16**). Some cells in the colonies became specialized for different functions. The first such specializations had already appeared in the prokaryotic world. For example, certain cells of the filamentous cyanobacterium *Nostoc* differentiate into nitrogen-fixing cells called heterocysts, which lose their ability to replicate. The undifferentiated cells are photosynthetic and capable of replicating, with the result that the filaments grow longer and eventually break into smaller filaments. *Nostoc* has more than 7,000 genes, twice as many as its close relatives that are single-celled, such as *Synechocystis*, and many of the additional genes are involved in the regulation of developmental pathways that can lead to cellular differentiation.

The evolution of colonies and of cellular specialization was carried much further in eukaryotes. A multicellular eukaryote, such as an animal, generally develops from a single cell—the fertilized egg, or zygote, in the case of sexual reproduction (see Figure 13.5). Cell division and cell differentiation help transform the single cell into a multicellular organism with many types of specialized cells. Increasing cell specialization made it possible for multicellular organisms to divide particular life functions, such as obtaining nutrients and sensing the

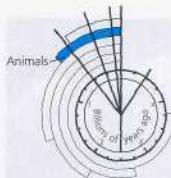

A Figure 26.16 A colonial eukaryote. *Pediastrum* is a photosynthetic eukaryote that forms flat colonies (LM).

environment, among specific groups of cells. This division of function eventually led to the evolution of tissues, organs, and organ systems in many eukaryotes.

Just as the evolution of unicellular eukaryotes increased the structural complexity of cells, the evolution of multicellular eukaryotes broke through another threshold in structural organization and provided the stock for new waves of diversification. Multicellularity evolved several times among early eukaryotes, giving rise to several lineages of algae as well as to plants, fungi, and animals.

The "Cambrian Explosion"

Most of the major phyla of animals appear suddenly in the fossil record that was laid down during the first 20 million years of the Cambrian period, a phenomenon referred to as the "Cambrian explosion." Fossils of two animal phyla—Cnidaria (sea anemones and their relatives) and Porifera (sponges)—are somewhat

older, dating from the late Proterozoic (**Figure 26.17**). However, molecular clocks suggest that many animal phyla originated and began to diverge much earlier, between 1 billion and 700 million years ago, in the memorable phrase of Cambridge University paleontologist Simon Conway Morris, "the Cambrian explosion had a long fuse." At the beginning of the Cambrian, for reasons not yet understood, these already divergent phyla expanded in diversity relatively suddenly and simultaneously. The "explosion" in diversity included many large animals with hard shells and exoskeletons that fossilized easily. We will evaluate possible explanations for this diversification in Chapter 32.

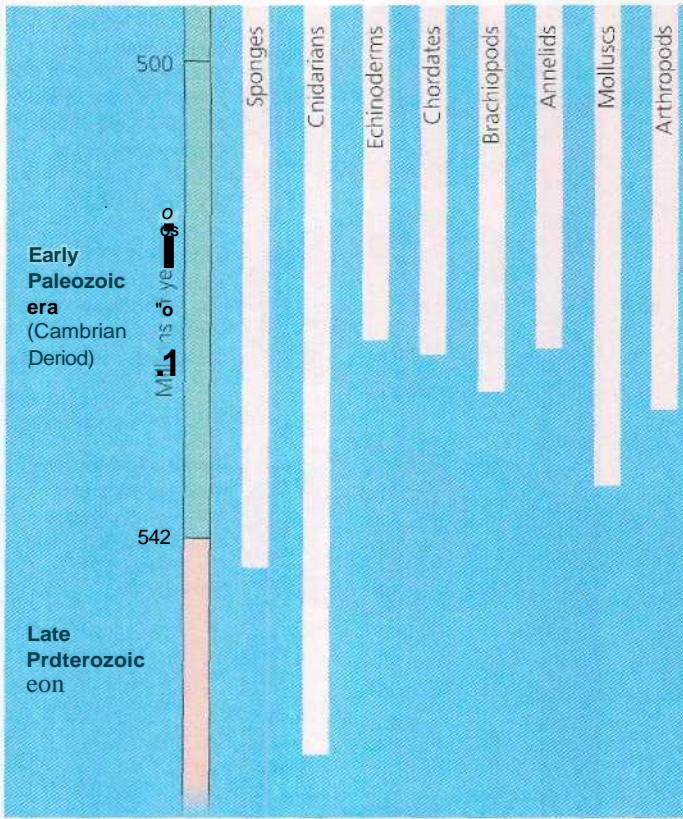

Figure 26.17 The Cambrian radiation of animals. The bars in this diagram show the earliest appearance in the fossil record of several animal phyla. However, molecular evidence suggests that these phyla may have originated much earlier.

Colonization of Land by Plants, Fungi, and Animals

The colonization of land was one of the pivotal milestones in the history of life. There is fossil evidence that cyanobacteria and other photosynthetic prokaryotes coated damp terrestrial surfaces well over a billion years ago. However, macroscopic life in the form of plants, fungi, and animals did not colonize land until about 500 million years ago, during the early Paleozoic era. This gradual evolutionary venture out of ancestral aquatic environments was associated with adaptations that helped prevent dehydration and that made it possible to reproduce on land. For example, plants, which evolved from green algae, have a waterproof coating of wax on their leaves that slows the loss of water to the air.

Plants colonized land in the company of fungi. Even today, the roots of most plants are associated with fungi that aid in the absorption of water and minerals from the soil (see Chapter 31). These root fungi, in turn, obtain their organic nutrients

from the plants. Such symbiotic associations of plants and fungi are evident in some of the oldest fossilized roots, dating this relationship back to the early spread of life onto land.

Although many animal groups are represented in terrestrial environments, the most widespread and diverse land animals are arthropods (particularly insects and spiders) and vertebrates (chiefly amphibians; reptiles, including birds; and mammals). Terrestrial vertebrates are called tetrapods, a reference to the four limbs that distinguish them from the various aquatic vertebrates. Tetrapods include humans, but we are late arrivals on the scene—the human lineage diverged from other hominoids (apes) only within the last 6 to 7 million years. If the clock of Earth's history were rescaled to represent an hour, humans appeared only one second ago.

Continental Drift

As we close this overview of the evolution of life on Earth, note that evolution has dimension in space as well as in time. Indeed, it was biogeography that first nudged Darwin and Wallace toward an evolutionary view of life. On a global scale, the major geographic factor that correlates with the spatial distribution of life is continental drift. This term refers to the fact that Earth's continents are not fixed; they drift across our planet's surface on great plates of crust that float on the hot, underlying mantle. In many cases, these plates pull away from or push against other plates where they meet each other (**Figure 26.18**). For example, North America and Europe are presently drifting apart at a rate of about 2 cm per year, and California's infamous San Andreas Fault is part of a border where two plates slide past each other. Plate movements rearrange geography slowly, but their cumulative effects are dramatic. Many important geologic processes, including the

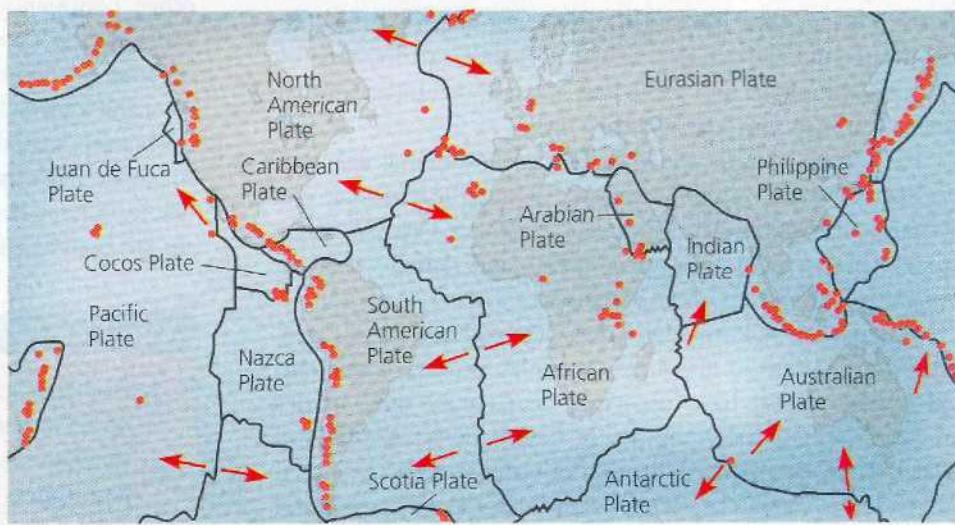

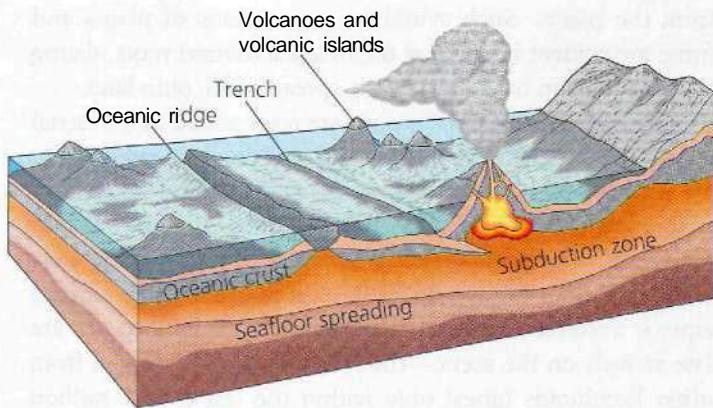

Figure 26.18 Earth's major crustal plates. The plates change constantly; for example, a new plate boundary (not shown here) is forming between East Africa and the rest of the continent. The red dots indicate zones of violent tectonic events; many of these are subduction zones (see Figure 26.19).

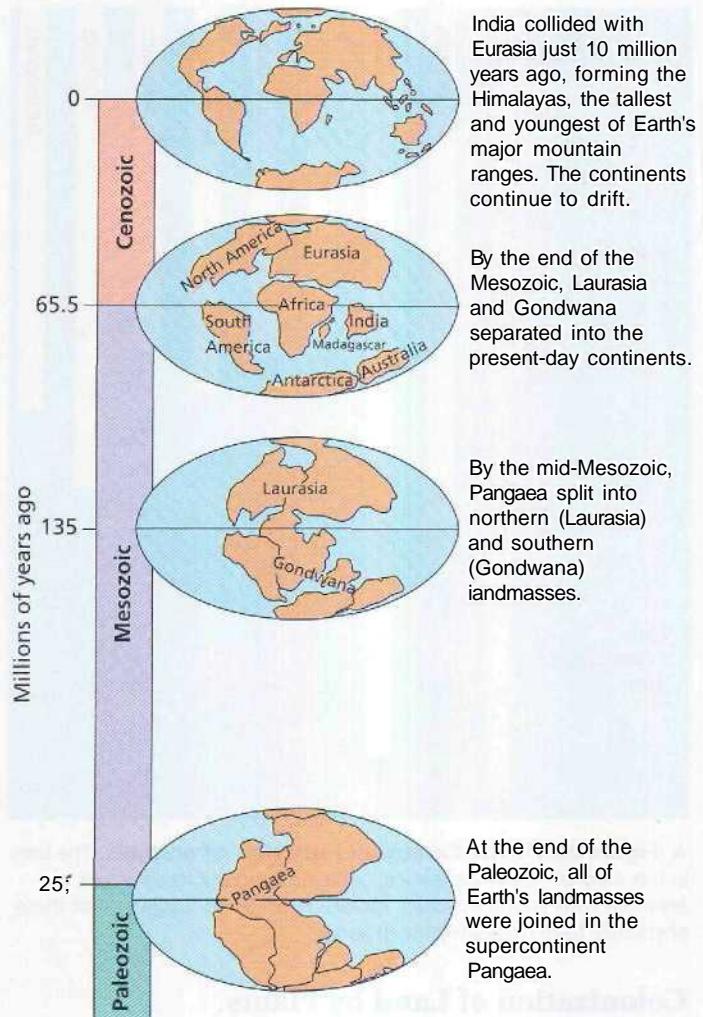

A Figure 26.19 Events at plate boundaries. At some plate boundaries, such as oceanic ridges (indicated by paired, opposing arrows in Figure 26.18), the plates separate, and molten rock wells up in the gap. The rock solidifies and adds crust symmetrically to both plates, causing seafloor spreading. At subduction zones, where plates move toward each other, the more dense plate dives below the less dense one, forming a trench. Sudden release of accumulating tension at subduction zones causes earthquakes. When continents carried by different plates collide, continental and ocean floor material piles up, forming mountain ranges.

building of mountains and islands, occur at plate boundaries or at weak points in the plates themselves (**Figure 26.19**).

Two chapters in the continuing saga of continental drift had especially strong influences on life. About 250 million years ago, near the end of the Paleozoic era, plate movements brought all the previously separated landmasses together into a supercontinent that has been named Pangaea, meaning "all land" (**Figure 26.20**). Ocean basins became deeper, which lowered sea level and drained shallow coastal seas. At that time, as now, most marine species inhabited shallow waters, and the formation of Pangaea destroyed a considerable amount of that habitat. The interior of the vast continent was cold and dry, probably an even more severe environment than that of central Asia today. The formation of Pangaea had a tremendous environmental impact that reshaped biological diversity by causing extinctions and providing new opportunities for taxonomic groups that survived the crisis.

The second chapter in the history of continental drift was written about 180 million years ago, during the Mesozoic era. As the continents drifted apart, each became a separate evolutionary arena, with lineages of plants and animals that diverged from those on other continents.

This pattern of continental mergings and separations provides the solution to many biogeographic puzzles. For example, paleontologists have discovered fossils of the same species of Permian freshwater reptiles in Ghana (West Africa) and Brazil. These two parts of the world, now separated by 3,000 km of ocean, were joined together during the late Paleozoic and early Mesozoic eras. Continental drift also explains much about the current distribution of organisms, such as why Australian fauna and flora contrast so sharply with those of the rest of the world. Marsupial mammals fill ecological roles in Australia

A Figure 26.20 The history of continental drift during the Phanerozoic.

analogous to those filled by eutherians (placental mammals) on other continents (see Figure 25.5). Marsupials probably evolved first in what is now North America and reached Australia via South America and Antarctica while the continents were still joined. The subsequent breakup of the southern continents set Australia "afloat" like a great ark of marsupials. In Australia, marsupials diversified, and the few early eutherians that lived there became extinct; on other continents, most marsupials became extinct, and the eutherians diversified.

Concept Check 26.5

- How does the division of function differ for single-celled and multicellular organisms?
- In what way is "Cambrian explosion" a good description of the early part of the fossil record of animal history? What is meant by the metaphor of a "long fuse" for the Cambrian explosion?

For suggested answers, see Appendix A.

Concept 26.6

New information has revised our understanding of the tree of life

As we discussed in Chapter 25, systematics is an analytical approach to reconstructing the evolutionary relationships of life's diverse forms. In recent decades, molecular data have provided new insights regarding the deepest branches of the tree of life, and ongoing research spurs biologists to continually revise the finer divisions of these branches.

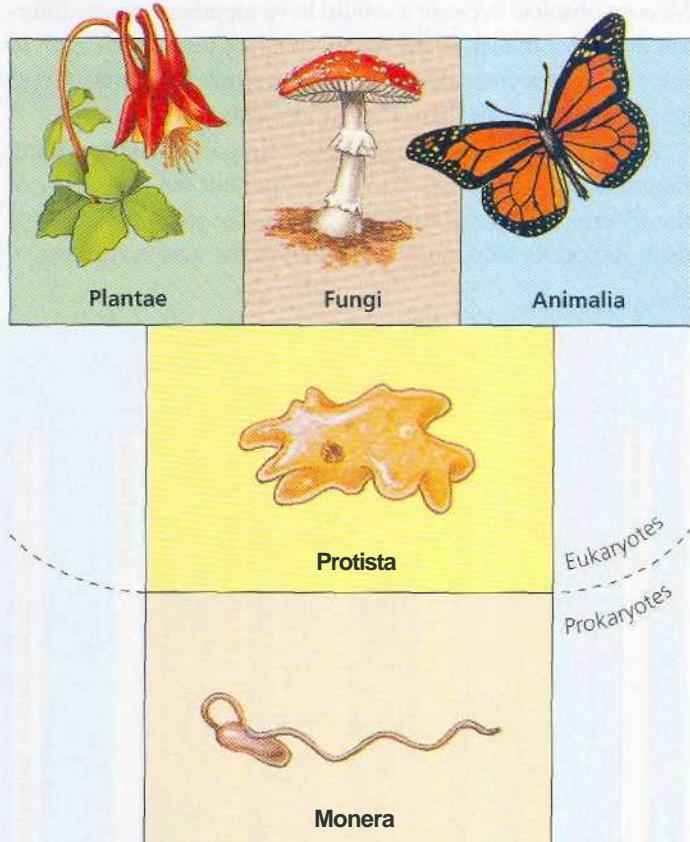

Previous Taxonomic Systems

Many of us grew up with the notion that there are only two kingdoms of life—plants and animals—because we see a macroscopic, terrestrial realm and rarely notice those organisms that do not fit neatly into a plant-animal dichotomy. The two-kingdom scheme also had a long tradition in formal taxonomy; Linnaeus divided all known forms of life between the plant and animal kingdoms.

Even with the discovery of the diverse microbial world, the two-kingdom system persisted. Taxonomists placed bacteria in the plant kingdom, citing the rigid cell walls of bacteria as justification. Eukaryotic unicellular organisms with chloroplasts were also considered plants. Fungi, too, were classified as plants, partly because most fungi, like most plants, are unable to move about, even though fungi are not photosynthetic and have little in common structurally with plants. In the two-kingdom system, unicellular organisms that move and ingest food—protozoans—were called animals. Microbes such as *Euglena* that move and are photosynthetic were claimed by both botanists and zoologists and showed up in both kingdoms.

Taxonomic schemes with more than two kingdoms did not become popular with the majority of biologists until 1969, when Cornell University's Robert H. Whittaker argued effectively for a system consisting of five kingdoms: Monera, Protista, Plantae, Fungi, and Animalia (Figure 26.21). Whittaker's system recognized the two fundamentally different types of cells, prokaryotic and eukaryotic, and set the prokaryotes apart from all eukaryotes by placing them in their own kingdom, Monera.

Whittaker distinguished three kingdoms of multicellular eukaryotes—Plantae, Fungi, and Animalia—partly on the criterion of nutrition. Plants are autotrophs, making their food by photosynthesis. Fungi and animals are heterotrophs. Most fungi are decomposers that invade their food source, secreting digestive enzymes and absorbing the small organic molecules produced by digestion. Most animals ingest (eat) food and digest it within a specialized body cavity.

A Figure 26.21 Whittaker's five-kingdom system.

The kingdom Protista was not as clearly defined in Whittaker's five-kingdom system. Protista consisted of all eukaryotes that did not fit the definitions of plants, fungi, or animals. Most protists are unicellular, but the boundaries of Protista were expanded to include some multicellular organisms, such as seaweeds, because of their relationships to certain unicellular protists. With such refinements, the five-kingdom system prevailed in biology for more than 20 years.

Reconstructing the Tree of Life: A Work in Progress

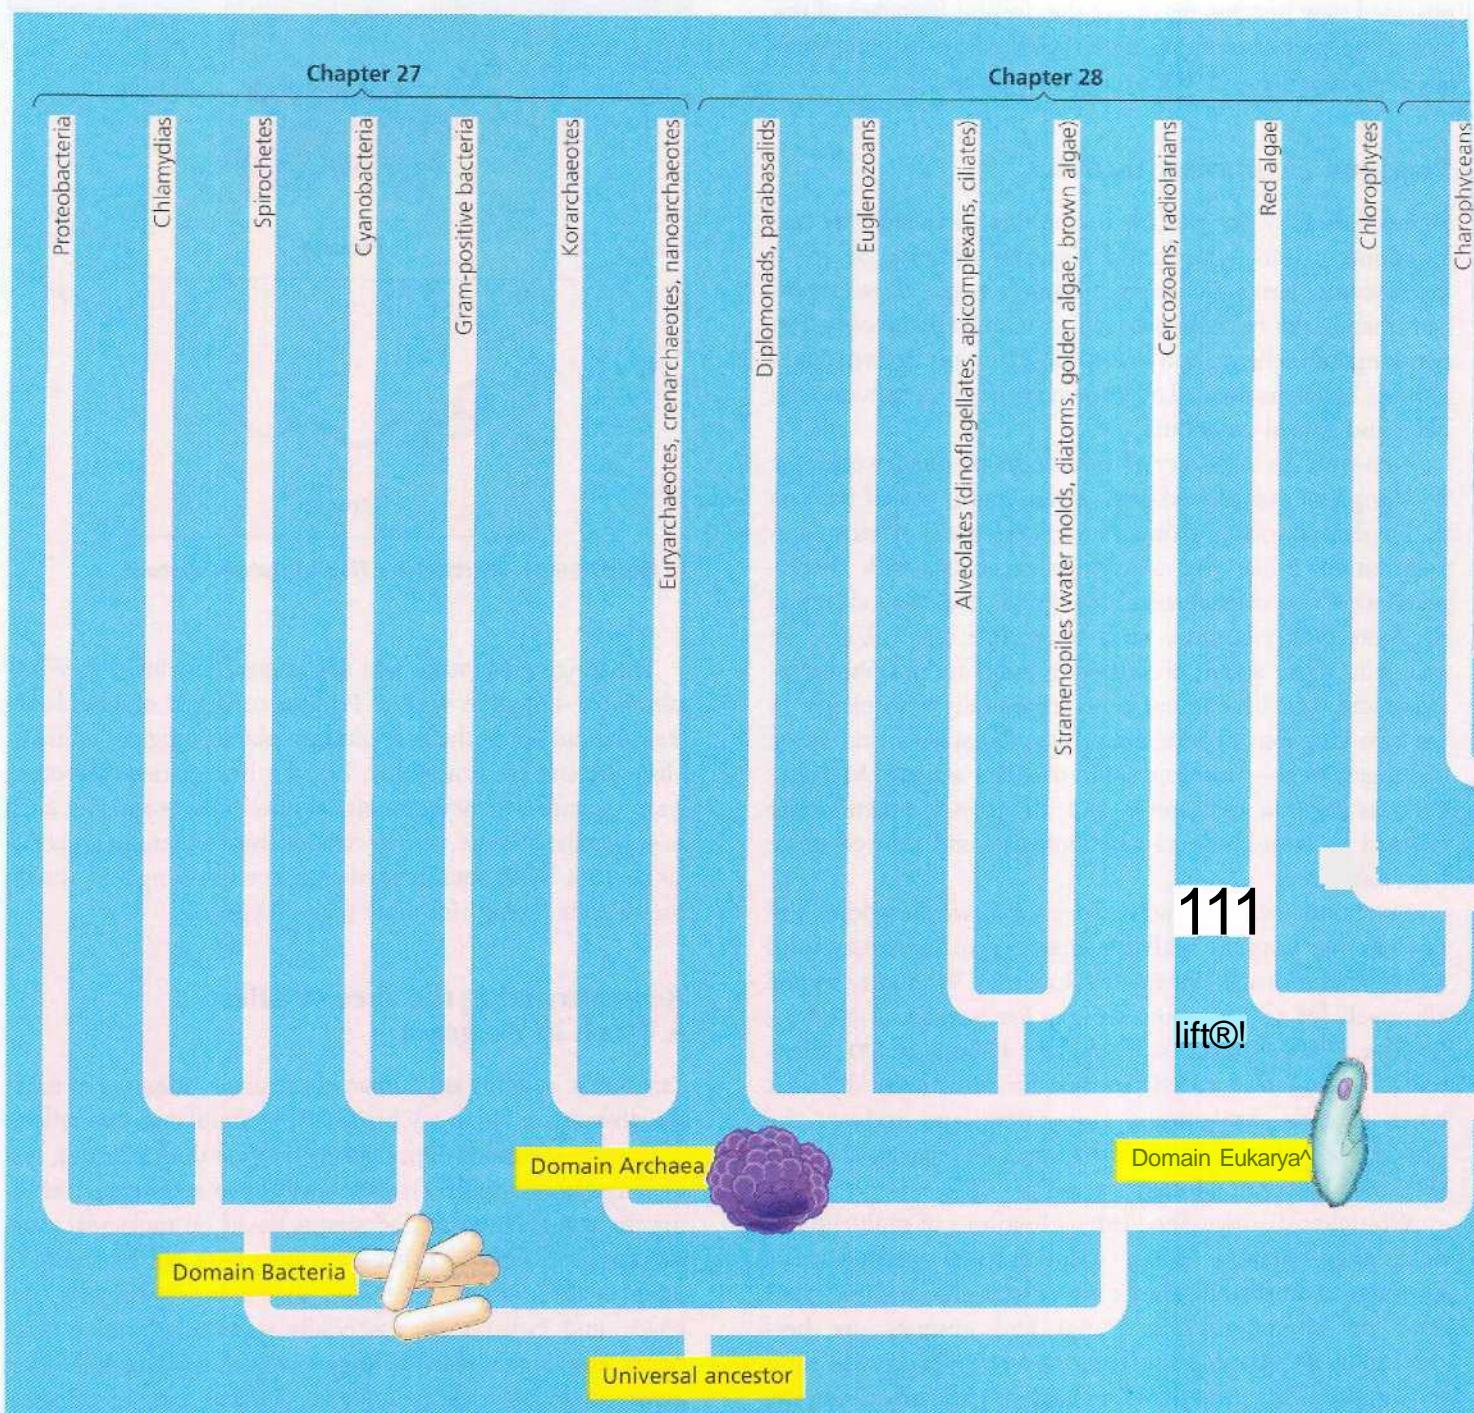

Taxonomic systems are human constructs—attempts to order the diversity of life in a scheme that is useful and that reflects phylogenetic relationships. During the past three decades, systematists have applied cladistic analysis to taxonomy, including the construction of cladograms based on molecular data. We saw in Chapter 25 that these data have led biologists to adopt a **three-domain system**. The domains Bacteria, Archaea, and Eukarya are essentially superkingdoms, a taxonomic level higher than the kingdom level. Bacteria differ from archaea in many key structural, biochemical, and physiological characteristics, which will be highlighted in Chapter 27. These differences justify placing bacteria and archaea in separate domains. Note that the three-domain system makes the kingdom

Monera obsolete because it would have members in two different domains. In fact, many microbiologists now divide each of the two prokaryotic domains into multiple kingdoms based on phylogenetic analysis of molecular data (**Figure 26.22**).

Another major challenge to the five-kingdom system is being mounted by systematists who are sorting out the phylogeny of the diverse eukaryotes formerly grouped in the kingdom Protista. Biologists who study these organisms now split most of

them into five or more newly designated kingdoms, which have a common ancestor near the base of the eukaryotic branch of the tree. Debate continues over whether some single-celled protists should be transferred to Plantae, Fungi, or Animalia.

Much more research is needed before we can arrive at a consensus about how the three domains of life are related and about how many kingdoms each domain should include. As we explore newly discovered microbial communities, such as

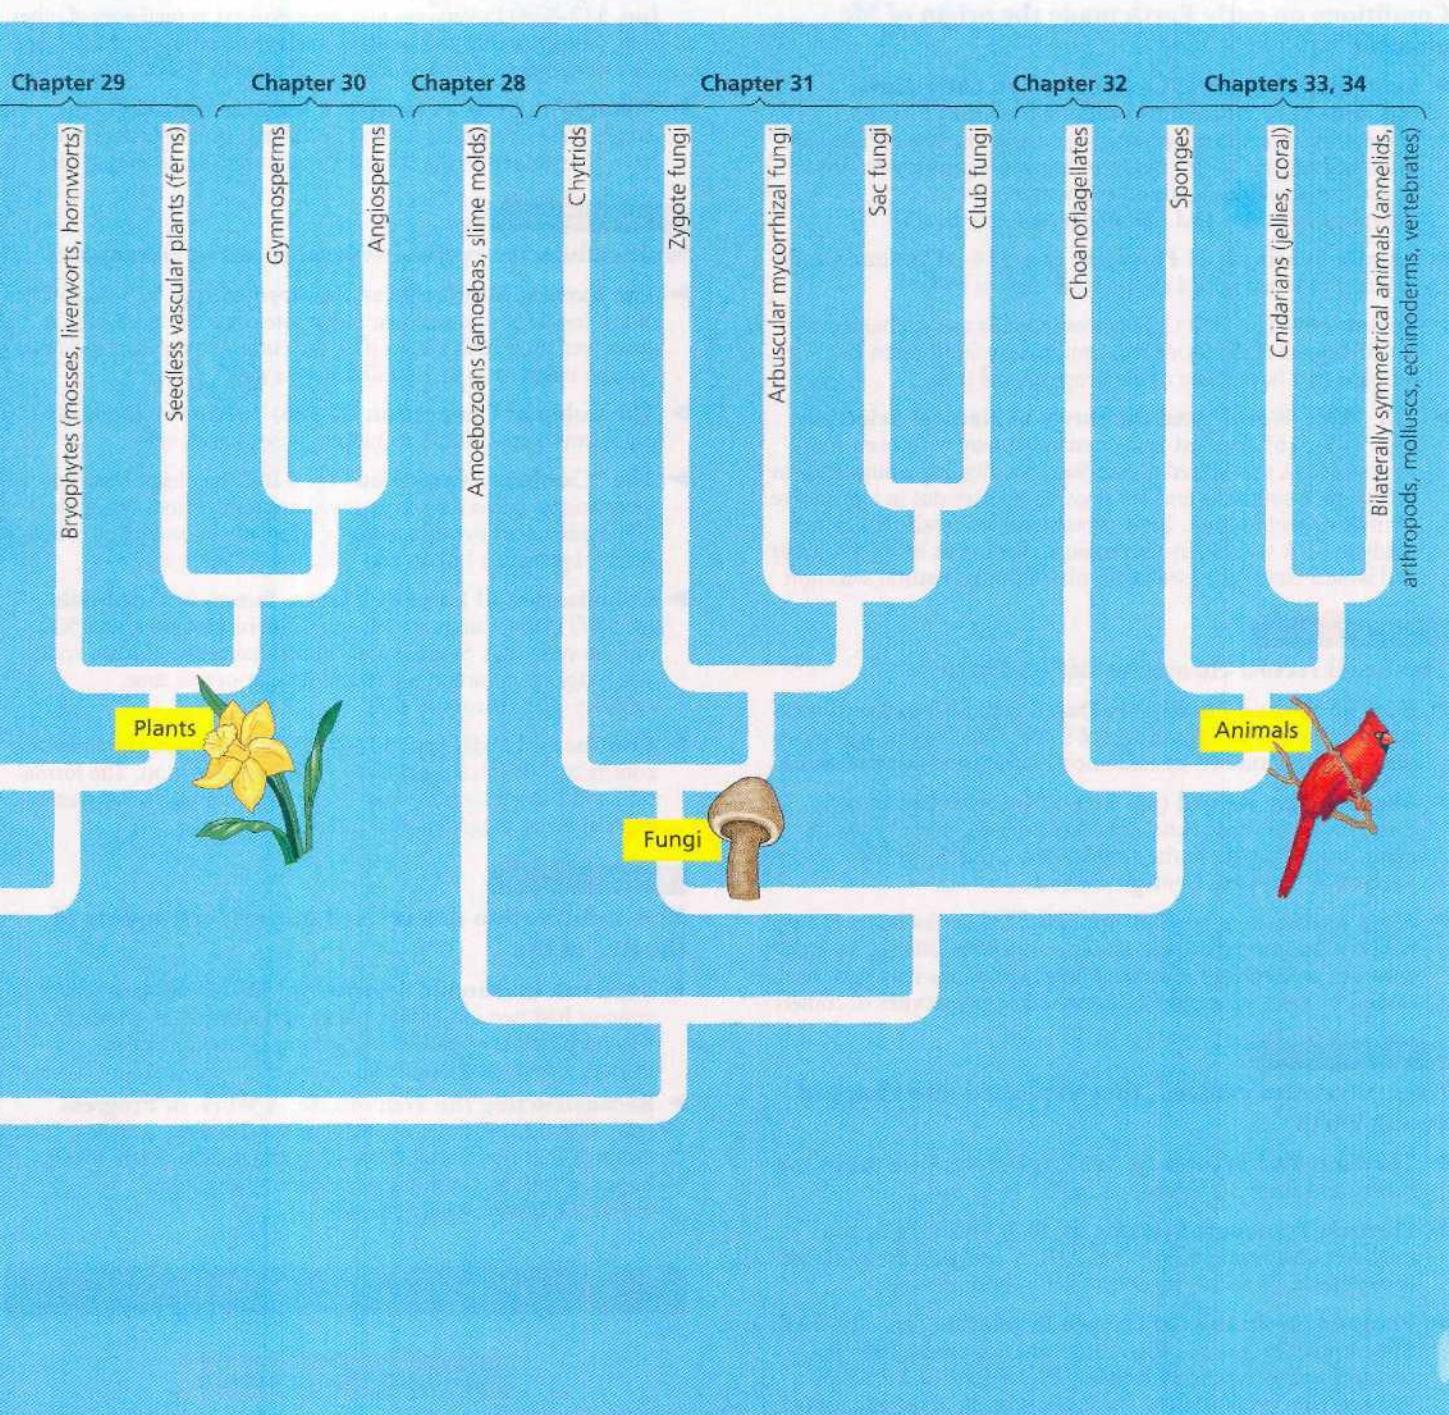

k Figure 26.22 One current view of biological diversity. This tree summarizes the diversification of life over evolutionary time. There is lively debate about some of the relationships shown here, as you will read in the chapters listed across the top of the branches.

those that live deep underground, and as we learn how to culture more of the organisms in those communities, we will no doubt discover new groups that will lead to further taxonomic remodeling. As you survey the diversity of life in Chapters 27–34, keep in mind that phylogenetic trees and taxonomic groupings are hypotheses that fit the best available data. It is the continuing scrutiny of testable hypotheses that validates evolutionary biology as a natural science.

Concept Check ^6.6

1. Which kingdoms in Whittaker's five-kingdom system include organisms now in the domain Eukarya?
2. Based on Figure 26.22, explain why the kingdom Monera is no longer considered a valid taxon.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 26.1

Conditions on early Earth made the origin of life possible

• Synthesis of Organic Compounds on Early Earth

(pp. 513-514) Earth formed about 4.6 billion years ago.

Laboratory experiments simulating a reducing atmosphere have produced organic molecules from inorganic precursors. Amino acids have also been found in meteorites.

Investigation How Did Life Begin on Early Earth?

• Abiotic Synthesis of Polymers (pp. 514-515)

Amino acids polymerize when added to hot sand, clay, or rock.

• Protobionts (p. 515)

Organic compounds can spontaneously assemble in the laboratory into protobionts, lipid-bound droplets that have some of the properties of cells.

• The "RNA World" and the Dawn of Natural Selection

(pp. 515-516) The first genetic material may have been short pieces of RNA that served as templates for aligning amino acids in polypeptide synthesis and for aligning nucleotides in a primitive form of self-replication. Early protobionts with self-replicating, catalytic RNA would have been more effective at using resources and would have increased in number through natural selection.

Concept 26.2

The fossil record chronicles life on Earth

• How Rocks and Fossils Are Dated (pp. 517-518)

Sedimentary strata reveal the relative ages of fossils. The absolute ages of fossils can be determined by radiometric dating and other methods.

• The Geologic Record (pp. 518-519)

Earth's history is divided into geologic eons, eras, and periods, many of which mark major changes in the composition of fossil species.

Activity A Scrolling Geologic Record

• Mass Extinctions (p. 518, pp. 520-521)

Evolutionary history has been punctuated by several mass extinctions followed by grand episodes of adaptive radiation. These extinctions may have been caused by volcanic activity or impacts from meteorites or comets.

Concept 26.3

As prokaryotes evolved, they exploited and changed young Earth

• The First Prokaryotes (p. 522)

Prokaryotes were Earth's sole inhabitants from 3.5 to about 2 billion years ago.

• Electron Transport Systems (p. 522)

The first electron transport chains may have saved ATP by coupling the oxidation of organic acids to the transport of H⁺ out of the cell.

• Photosynthesis and the Oxygen Revolution (pp. 522-523)

The earliest types of photosynthesis did not produce oxygen. Oxygenic photosynthesis probably evolved about 3.5 billion years ago in cyanobacteria. The accumulation of oxygen in the atmosphere about 2.7 billion years ago posed a challenge for life, but it also selected for certain adaptations such as cellular respiration using oxygen.

Concept 26.4

Eukaryotic cells arose from symbioses and genetic exchanges between prokaryotes

• The First Eukaryotes (p. 523)

The oldest fossils of eukaryotic cells date back 2.1 billion years.

• Endosymbiotic Origin of Mitochondria and Plastids

(pp. 523-524) Eukaryotes may have evolved as predators of other cells. Mitochondria and plastids likely evolved from prokaryotes that were ingested by and lived symbiotically inside larger cells.

• Eukaryotic Cells as Genetic Chimeras (pp. 524-525)

Additional endosymbioses and horizontal gene transfers may have contributed to the complex structures of eukaryotic cells.

Concept 26.5

Multicellularity evolved several times in eukaryotes

• The Earliest Multicellular Eukaryotes (pp. 525-526)

The oldest fossils of multicellular eukaryotes date back 1.2 billion years, but molecular clocks date the common ancestor of multicellular eukaryotes to 1.5 billion years ago.

• The Colonial Connection (p. 526)

The first multicellular organisms were colonies containing specialized cells.

• The "Cambrian Explosion" (p. 526)

The oldest fossils of most animal phyla date from the Cambrian period, but molecular evidence shows that many of these phyla originated much earlier, between 1 billion and 700 million years ago.

• Colonization of Land by Plants, Fungi, and Animals

(p. 527) Plants, fungi, and animals colonized land about 500 million years ago. Symbiotic relationships between plant roots and fungi are common today and date from this time.

Activity The History of Life

• Continental Drift (pp. 527-528)

By rearranging landmasses, continental drift has significantly affected evolution. The formation and subsequent breakup of the supercontinent Pangaea explain many biogeographic puzzles.

Concept 26.6

New information has revised our understanding of the tree of life

• Previous Taxonomic Systems (p. 529)

Early classification systems had two kingdoms: plants and animals. A system that was proposed later had five kingdoms: Monera, Protista, Plantae, Fungi, and Animalia.

• Reconstructing the Tree of Life: A Work in Progress

(pp. 529-532) A three-domain system (Bacteria, Archaea, and Eukarya) has replaced the five-kingdom system. Each domain has been split by taxonomists into many kingdoms.

Activity Classification Schemes

TESTING YOUR KNOWLEDGE

Evolution Connection

Describe the minimum structural, metabolic, and genetic equipment for a protobiont to be considered a true cell,

Scientific Inquiry

If life were discovered elsewhere in the solar system, an obvious question would be whether terrestrial and extraterrestrial life had independent origins. If the physical and chemical attributes of such new life could be studied, what kinds of evidence would support a single origin? What scientific questions would be raised by evidence of a single origin? Of multiple origins?

Investigation How Did Life Begin on Early Earth?

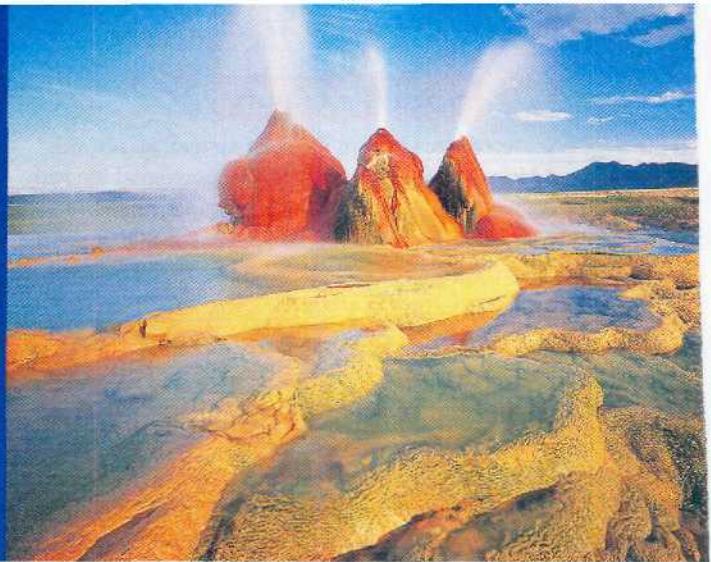

Science, Technology, and Society

Experts estimate that human activities cause the extinction of hundreds of species every year. In contrast, the natural rate of extinction is thought to average only a few species per year. As we continue to alter the global environment, especially by destroying tropical rain forests and altering Earth's climate, the resulting wave of extinctions will probably rival those at the end of the Cretaceous period. Considering that life has endured numerous mass extinctions, should we be concerned about the present mass extinction? How does it differ from previous extinctions? What might be some of the consequences for the surviving species, including ourselves?

Biology Inquiry: A Workbook of investigative Cases *Life on Earth has gone through many cycles of mass extinction and diversification. Explore the latter with the case "Unveiling the Carboniferous."*

Prokaryotes

A Figure 27.1 Orange and yellow colonies of "heat-loving" prokaryotes in the hot water of a Nevada geyser.

Key Concepts

- 27.1 Structural, functional, and genetic adaptations contribute to prokaryotic success
- 27.2 A great diversity of nutritional and metabolic adaptations have evolved in prokaryotes
- 27.3 Molecular systematics is illuminating prokaryotic phylogeny
- 27.4 Prokaryotes play crucial roles in the biosphere
- 27.5 Prokaryotes have both harmful and beneficial impacts on humans

Overview

They're (Almost) Everywhere!

Most prokaryotes are microscopic, but what they lack in size they more than make up for in numbers. Their collective biological mass (biomass) is at least ten times that of all eukaryotes. The number of prokaryotes in a single handful of fertile soil is greater than the number of people who have ever lived. What has enabled these tiny organisms to dominate the biosphere throughout their history? One reason for their success is a wealth of adaptations that enable various prokaryotes to inhabit diverse environments. Prokaryotes thrive almost everywhere, including places too acidic, too salty, too cold, or too hot for most other organisms (**Figure 27.1**). They have even been discovered in rocks 2 miles below Earth's surface. In reconstructing the evolutionary history underlying the varied lifestyles of prokaryotes, biologists are discovering that these organisms have an astonishing genetic diversity. For example, comparing ribosomal RNA reveals that two strains of the bacterial species *Escherichia coli* are genetically more different than a human and a platypus.

As you read in Chapter 26, prokaryotes are classified into two domains, Bacteria and Archaea, which differ in many structural, physiological, and biochemical characteristics. In this chapter, you will read about the remarkable adaptations of prokaryotes, as well as some of the essential ecological services they perform, such as the recycling of chemicals. You will also read about the minority of prokaryotic species that cause serious illness in humans. Finally, you will learn how humans depend on benign prokaryotes for our very survival, and how biotechnology is beginning to harness the metabolic powers of these pervasive organisms.

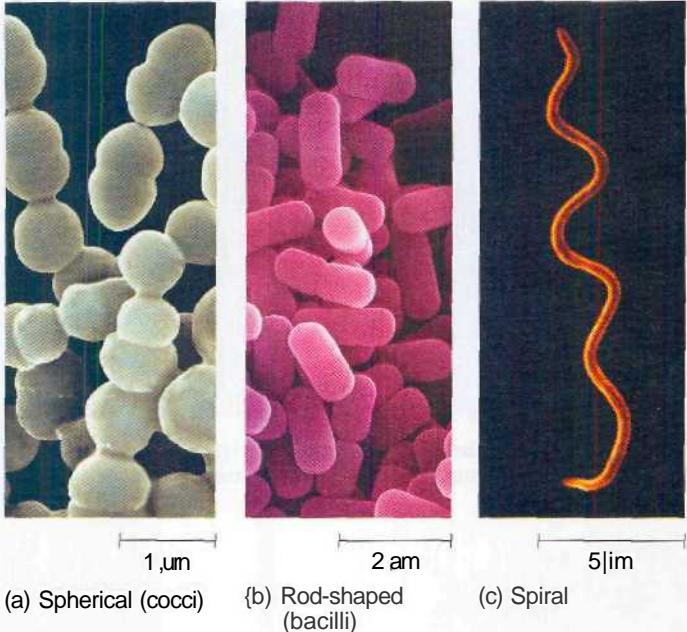

Concept 27.1

Structural, functional, and genetic adaptations contribute to prokaryotic success

Most prokaryotes are unicellular, although some species aggregate transiently or permanently in colonies. Prokaryotic cells typically have diameters in the range of 1–5 μm , much smaller than the 10–100 μm diameter of many eukaryotic cells. (One notable exception is the giant prokaryote *Thiomargarita namibiensis*, which is about 750 μm in diameter—just visible to the unaided eye.) Prokaryotic cells have a variety of shapes, the three most common of which are spheres (cocci), rods (bacilli), and spirals (**Figure 27.2**).

Cell-Surface Structures

One of the most important features of nearly all prokaryotic cells is their cell wall, which maintains cell shape, provides physical protection, and prevents the cell from bursting in a hypotonic environment (see Chapter 7). In a hypertonic environment,

A Figure 27.2 The most common shapes of prokaryotes.

(a) Coccis (singular, *coccus*) are spherical prokaryotes. They occur singly, in pairs (diplococci), in chains of many cells (streptococci, shown here), and in clusters resembling bunches of grapes (staphylococci). (b) Bacilli (singular, *bacillus*) are rod-shaped prokaryotes. They are usually solitary, but in some forms the rods are arranged in chains (streptobacilli). (c) Spiral prokaryotes include spirilla, which range from comma-like shapes to long coils, and spirochetes (shown here), which are corkscrew-shaped (colorized SEMs).

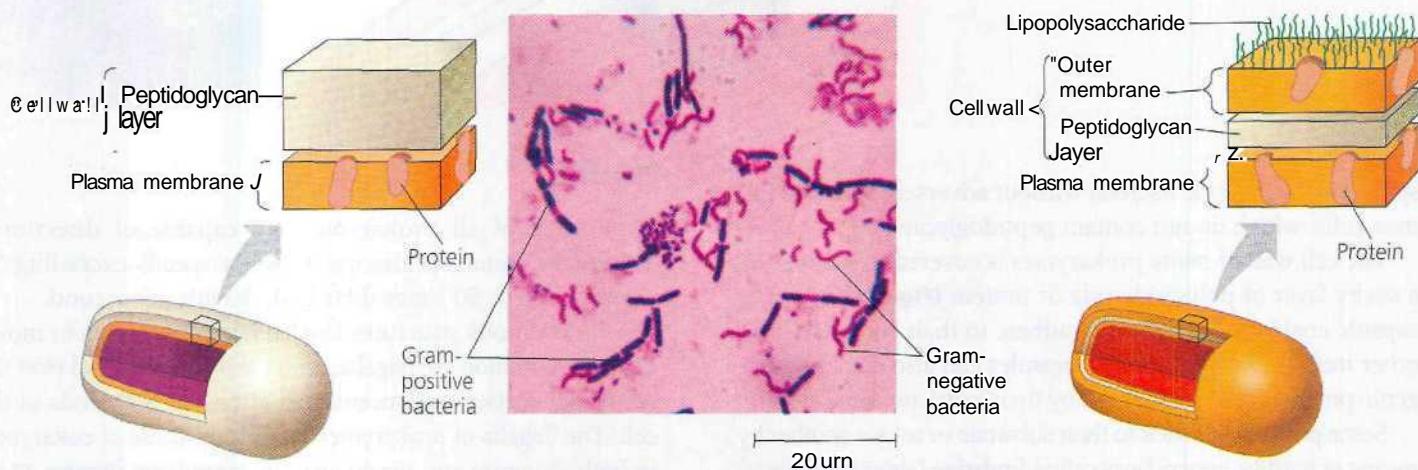

most prokaryotes lose water and shrink away from their wall (plasmolyze), like other walled cells. Severe water loss inhibits the reproduction of prokaryotes, which explains why salt can be used to preserve certain foods, such as pork and fish.

The cell walls of prokaryotes differ in molecular composition and construction from those of eukaryotes. As you read in Chapter 5, eukaryotic cell walls are usually made of cellulose or chitin. In contrast, most bacterial cell walls contain peptidoglycan, a network of modified-sugar polymers cross-linked by short polypeptides. This molecular fabric encloses the entire bacterium and anchors other molecules that extend from its surface. Archaeal cell walls contain a variety of polysaccharides and proteins but lack peptidoglycan.

Using a technique called the Gram stain, developed by the nineteenth-century Danish physician Hans Christian Gram, scientists can classify many bacterial species into two groups based on differences in cell wall composition. Gram-positive bacteria have simpler walls with a relatively large amount of peptidoglycan (**Figure 27.3a**). Gram-negative bacteria have less peptidoglycan and are structurally more complex, with an outer membrane that contains lipopolysaccharides (carbohydrates bonded to lipids) (**Figure 27.3b**).

Gram staining is a particularly valuable identification tool in medicine. Among pathogenic, or disease-causing, bacteria, gram-negative species are generally more threatening than gram-positive species. The lipopolysaccharides on the walls of gram-negative bacteria are often toxic, and the outer membrane helps protect these bacteria against the body's defenses. Furthermore, gram-negative bacteria are commonly more resistant than gram-positive species to antibiotics because the outer membrane impedes entry of the drugs.

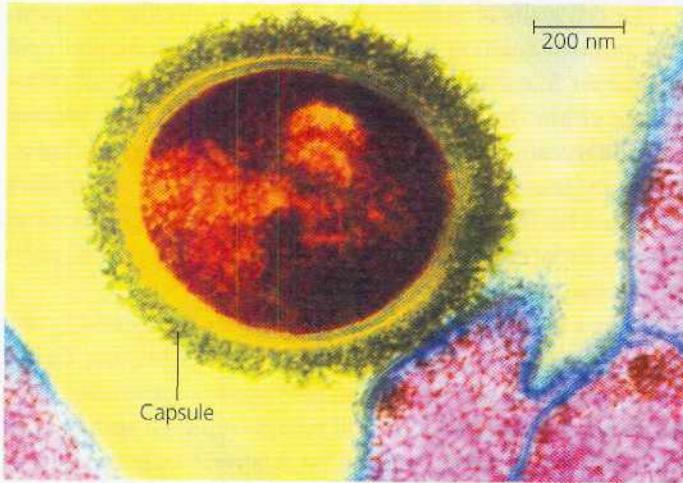

The effectiveness of certain antibiotics, including penicillin, derives from their inhibition of the peptidoglycan cross-linking, thus preventing the formation of a functional cell wall, particularly in gram-positive bacteria. Such drugs destroy many

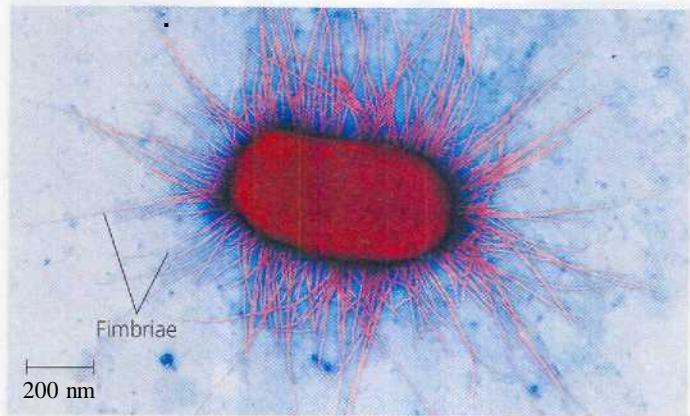

(a) Gram-positive. Gram-positive bacteria have a cell wall with a large amount of peptidoglycan that traps the violet dye in the cytoplasm. The alcohol rinse does not remove the violet dye, which masks the added red dye.

(b) Gram-negative. Gram-negative bacteria have less peptidoglycan, and it is located in a layer between the plasma membrane and an outer membrane. The violet dye is easily rinsed from the cytoplasm, and the cell appears pink or red.

A. Figure 27.3 Gram staining. Bacteria are stained with a violet dye and iodine, rinsed in alcohol, and then stained with a red dye. The structure of the cell wall determines the staining response (LM).

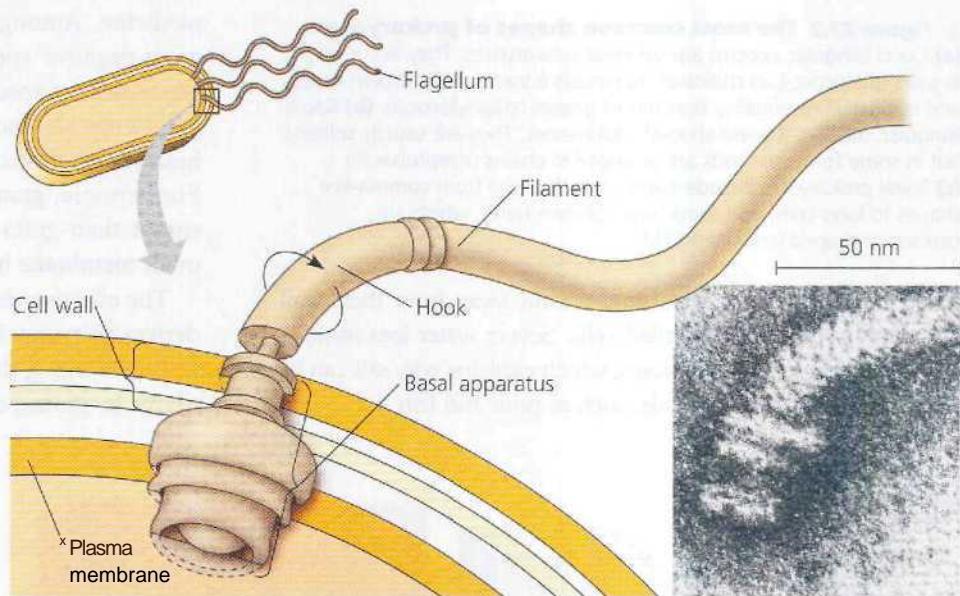

A Figure 27.4 Capsule. The polysaccharide capsule surrounding this *Streptococcus* bacterium enables the pathogenic prokaryote to attach to cells that line the human respiratory tract—in this image, a tonsil cell (colorized TEM).

4 Figure 27.5 Fimbriae. These numerous appendages enable some prokaryotes to attach to surfaces or to other prokaryotes (colorized TEM).

*• Figure 27.6 Prokaryotic flagellum.

The motor of the prokaryotic flagellum is the basal apparatus, a system of rings embedded in the cell wall and plasma membrane (TEM). ATP-driven pumps transport protons out of the cell, and the diffusion of protons back into the cell powers the basal apparatus, which turns a curved hook. The hook is attached to a filament composed of chains of flagellin, a globular protein. (This diagram shows flagellar structures characteristic of gram-negative bacteria.)

species of pathogenic bacteria without adversely affecting human cells, which do not contain peptidoglycan.

The cell wall of many prokaryotes is covered by a capsule, a sticky layer of polysaccharide or protein (Figure 27.4). The capsule enables prokaryotes to adhere to their substrate or to other individuals in a colony. Capsules can also shield pathogenic prokaryotes from attacks by their host's immune system.

Some prokaryotes stick to their substrate or to one another by means of hairlike appendages called fimbriae (singular, *fimbria*) and pili (singular, *pilus*). Fimbriae are usually more numerous and shorter than pili (Figure 27.5). *Neisseria gonorrhoeae*, the bacterium that causes gonorrhea, uses fimbriae to fasten itself to the mucous membranes of its host. Specialized pili, called sex pili, link prokaryotes during conjugation, a process in which one cell transfers DNA to another cell (see Figure 18.17).

Motility

About half of all prokaryotes are capable of directional movement. Some species can move at speeds exceeding 50 $\mu\text{m/sec}$ —up to 50 times their body length per second.

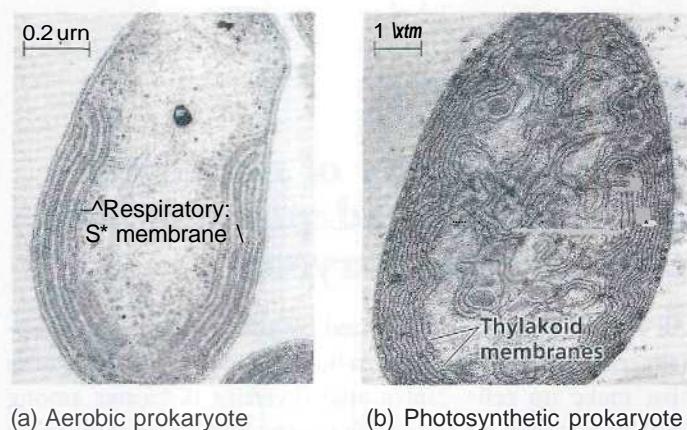

Of the various structures that enable prokaryotes to move, the most common are flagella, which may be scattered over the entire cell surface or concentrated at one or both ends of the cell. The flagella of prokaryotes differ from those of eukaryotes in both structure and mechanism of propulsion (Figure 27.6). Prokaryotic flagella are one-tenth the width of eukaryotic flagella and are not covered by an extension of the plasma membrane (see Figures 6.24 and 6.25 to review eukaryotic flagella).

In a relatively uniform environment, flagellated prokaryotes may move randomly. In a heterogeneous environment, many prokaryotes exhibit taxis, movement toward or away

from a stimulus (from the Greek *taxis*, to arrange). For example, prokaryotes that exhibit chemotaxis respond to chemicals by changing their movement pattern. They may move *toward* nutrients or oxygen (positive chemotaxis) or *away from* a toxic substance (negative chemotaxis). In 2003, scientists at Princeton University and the Institut Curie in Paris demonstrated that solitary *E. coli* cells exhibit positive chemotaxis toward other members of their species, enabling the formation of colonies.

Internal and Genomic Organization

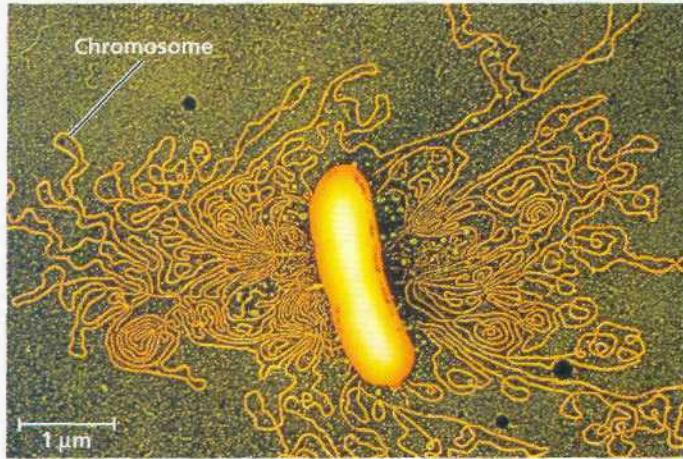

The cells of prokaryotes are simpler than those of eukaryotes, in both their internal structure and their genomic organization. Prokaryotic cells lack the complex compartmentalization found in eukaryotic cells (see Figure 6.6). However, some prokaryotic cells do have specialized membranes that perform **metabolic functions** (Figure 27.7). These membranes are usually infoldings of the plasma membrane.

(a) Aerobic prokaryote (b) Photosynthetic prokaryote

A Figure 27.7 Specialized membranes of prokaryotes.

(a) Infoldings of the plasma membrane, reminiscent of the cristae of mitochondria, function in cellular respiration in some aerobic prokaryotes (TEM). (b) Photosynthetic prokaryotes called cyanobacteria have thylakoid membranes, much like those in chloroplasts (TEM).

A Figure 27.8 A prokaryotic chromosome. The thin, tangled loops surrounding this ruptured *E. coli* cell are parts of a single ring of DNA (colorized TEM).

The genome of a prokaryote is structurally very different from a eukaryotic genome and has on average only about one-thousandth as much DNA. In the majority of prokaryotes, most of the genome consists of a ring of DNA that has relatively few proteins associated with it. This ring of genetic material is usually called the prokaryotic chromosome (Figure 27.8). Unlike eukaryotic chromosomes, which are contained within the nucleus, the prokaryotic chromosome is located in a nucleoid region, a part of the cytoplasm that appears lighter than the surrounding cytoplasm in electron micrographs.

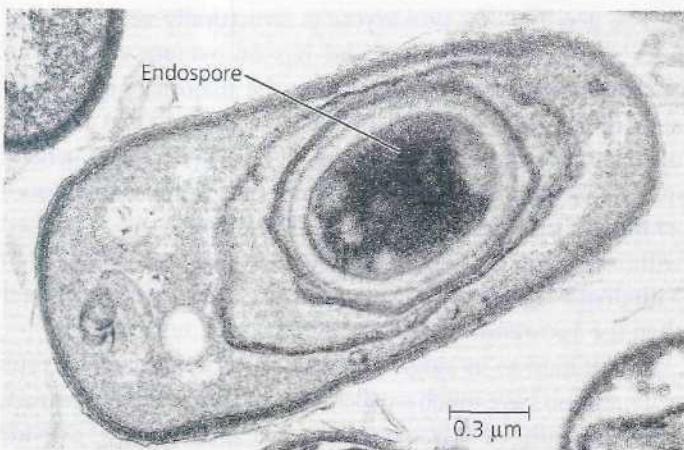

In addition to its single chromosome, a typical prokaryotic cell may also have much smaller rings of DNA called plasmids, most consisting of only a few genes. The plasmid genes provide resistance to antibiotics, direct the metabolism of rarely encountered nutrients, or have other such "contingency" functions. In most environments, the prokaryotic cell can survive without its plasmids, since all essential functions are encoded by the chromosome. But in certain circumstances, such as when antibiotics are used to treat an infection, the presence of a plasmid can significantly increase a prokaryote's chance of survival. Plasmids replicate independently of the main chromosome, and many can be readily transferred between partners when prokaryotes conjugate (see Figure 18.18).

As explained in Chapters 16 and 17, DNA replication, transcription, and translation are fundamentally similar in prokaryotes and eukaryotes, although there are some differences. For example, prokaryotic ribosomes are slightly smaller than eukaryotic ribosomes and differ in their protein and RNA content. These differences are great enough that certain antibiotics, such as erythromycin and tetracycline, bind to ribosomes and block protein synthesis in prokaryotes but not in eukaryotes. As a result, we can use these antibiotics to kill bacteria without harming ourselves.

Reproduction and Adaptation

Prokaryotes are highly successful in part because of their potential to reproduce quickly in a favorable environment. Dividing by binary fission (see Figure 12.11), a single prokaryotic cell becomes 2 cells, which then become 4, 8, 16, and so on. While most prokaryotes can divide every 1–3 hours, some species can produce a new generation in only 20 minutes under optimal conditions. If reproduction continued unchecked at this rate, a single prokaryote could give rise to a colony outweighing Earth in only three days! In reality, of course, prokaryotic reproduction is limited, as the cells eventually exhaust their nutrient supply, poison themselves with metabolic wastes, or are consumed by other organisms. Prokaryotes in nature also face competition from other microorganisms, many of which produce antibiotic chemicals that slow prokaryotic reproduction.

The ability of some prokaryotes to withstand harsh conditions also contributes to their success. Certain bacteria, for example, can form resistant cells called endospores when an

• **Figure 27.9 An endospore.** *Bacillus anthracis*, the bacterium that causes the deadly disease anthrax, produces endospores (TEM). An endospore's thick, protective coat helps it survive in the soil for years.

essential nutrient is lacking in the environment (Figure 27.9). The original cell produces a copy of its chromosome and surrounds it with a tough wall, forming the endospore. Water is removed from the endospore, and metabolism inside it comes to a halt. The rest of the original cell then disintegrates, leaving the endospore behind. Most endospores are so durable that they can survive in boiling water. To kill endospores, microbiologists must heat their lab equipment with steam at 121°C under high pressure. In less hostile environments, endospores can remain dormant but viable for centuries, able to rehydrate and resume metabolism when they receive cues that their environment has become more benign.

Prokaryotes can adapt quickly to changes in their environment through evolution by natural selection. Because of prokaryotes' rapid reproduction, mutations that confer greater fitness can swiftly become more common in a population. For this reason, prokaryotes are important model organisms for scientists who study evolution in the laboratory. At Michigan State University, for example, Richard Lenski and his team have maintained colonies of *E. coli* through more than 20,000 generations since 1988. The researchers regularly freeze samples of the colonies and later thaw them to compare their characteristics with those of later generations. Such comparisons have revealed that the colonies today can grow 60% faster than the 1988 colonies under the same environmental conditions. Lenski's team is exploring the genetic changes underlying the colonies' evolutionary adaptation to their environment. In 2003, they reported that two colonies showed parallel changes in expression for the same 59 genes compared to the original colonies. The rapid reproduction of *E. coli* enabled the scientists to document this example of adaptive evolution.

Horizontal gene transfer (see Chapter 25) also facilitates rapid evolution in prokaryotes. For example, conjugation can permit the exchange of a plasmid containing a few genes or even large groups of genes. Once the transferred genes are

incorporated into a prokaryote's genome, they are subject to natural selection during subsequent rounds of binary fission. Horizontal gene transfer is a major force in the long-term evolution of pathogenic bacteria, a topic explored later in this chapter.

Concept Check 27.1

- Identify and explain at least two examples of adaptations that enable prokaryotes to survive in environments too harsh for other organisms.
- Contrast the cellular and genomic organization of prokaryotes and eukaryotes.
- Explain how rapid reproduction allows prokaryotes to adapt to changing environments.

For suggested answers, see Appendix A.

Concept 27.2

A great diversity of nutritional and metabolic adaptations have evolved in prokaryotes

All organisms can be categorized by nutrition—how they obtain energy and carbon used in building the organic molecules that make up cells. Nutritional diversity is greater among prokaryotes than among all eukaryotes: Every type of nutrition observed in eukaryotes is represented among prokaryotes, along with some nutritional modes unique to prokaryotes.

Organisms that obtain energy from light are called *phototrophs*, and those that obtain energy from chemicals are called *chemotrophs*. Organisms that need only the inorganic compound CO₂ as a carbon source are called *autotrophs*. In contrast, *heterotrophs* require at least one organic nutrient—such as glucose—to make other organic compounds. Combining these possibilities for energy sources and carbon sources results in four major modes of nutrition, described here and summarized in Table 27.1.

- Photoautotrophs are photosynthetic organisms that capture light energy and use it to drive the synthesis of organic compounds from CO₂. Cyanobacteria and many other groups of prokaryotes are photoautotrophs, as are plants and algae.
- Chemoautotrophs also need only CO₂ as a carbon source. However, instead of using light for energy, they oxidize inorganic substances, such as hydrogen sulfide (H₂S), ammonia (NH₃), or ferrous ions (Fe²⁺). This mode of nutrition is unique to certain prokaryotes.

Table 27.1 Major Nutritional Modes

| Mode of Nutrition | Energy Source | Carbon Source | Types of Organisms |
|-------------------|---------------------|-------------------|---|
| Autotroph | | | |
| Photoautotroph | Light | CO ₂ | Photosynthetic prokaryotes (for example, cyanobacteria); plants; certain protists (algae) |
| Chemoautotroph | Inorganic chemicals | CO ₂ | Certain prokaryotes (for example, <i>Sulfolobus</i>) |
| Heterotroph | | | |
| Photoheterotroph | Light | Organic compounds | Certain prokaryotes (for example, <i>Rhodobacter</i> , <i>Chloroflexus</i>) |
| Chemoheterotroph | Organic compounds | Organic compounds | Many prokaryotes (for example, <i>Clostridium</i>) and protists; fungi; animals; some plants |

- Photoheterotrophs use light for energy but must obtain their carbon in organic form. A number of marine prokaryotes use this mode of nutrition.
- Chemoheterotrophs must consume organic molecules for both energy and carbon. This nutritional mode is found widely among prokaryotes as well as protists, fungi, animals, and even some parasitic plants.

Metabolic Relationships to Oxygen

Prokaryotic metabolism also varies with respect to oxygen (see Chapter 9). Obligate aerobes use O₂ for cellular respiration and cannot grow without it. Facultative anaerobes use O₂ if it is present but can also grow by fermentation in an anaerobic environment. Obligate anaerobes are poisoned by O₂. Some obligate anaerobes live exclusively by fermentation; others extract chemical energy by anaerobic respiration, in which substances other than O₂, such as nitrate ions (NO₃⁻) or sulfate ions (SO₄²⁻), accept electrons at the "downhill" end of electron transport chains.

Nitrogen Metabolism

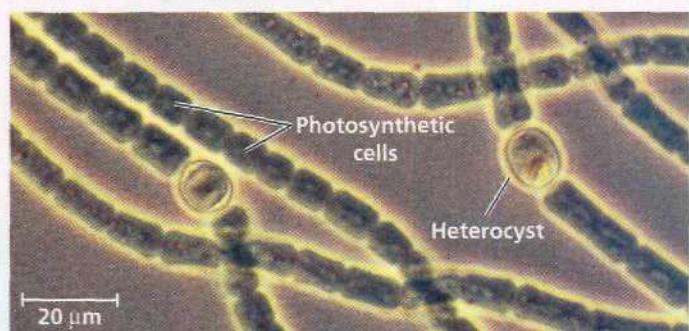

Nitrogen is essential for the production of amino acids and nucleic acids in all organisms. While eukaryotes are limited in the nitrogenous compounds they can use, prokaryotes can metabolize nitrogen in a wide variety of forms. For example, certain prokaryotes, including some cyanobacteria, convert atmospheric nitrogen (N₂) to ammonia (NH₃), a process called nitrogen fixation. The cells can then incorporate this "fixed" nitrogen into amino acids and other organic molecules. In terms of their nutrition, nitrogen-fixing cyanobacteria are the most self-sufficient of all organisms. They require only light, CO₂, N₂, water, and some minerals to grow. Chapter 54 discusses the essential roles that prokaryotes play in the nitrogen cycles of ecosystems.

Metabolic Cooperation

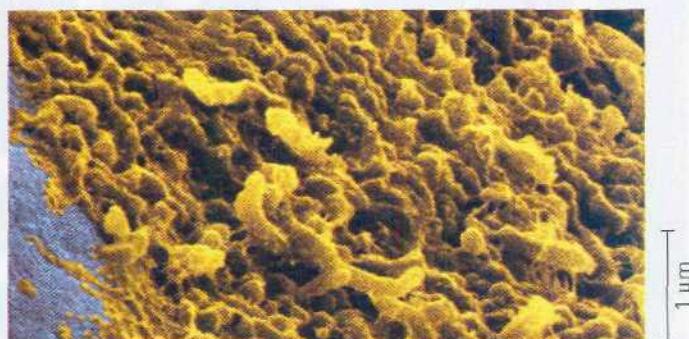

Cooperation between prokaryotes allows them to use environmental resources they could not use as individual cells. In some cases, this cooperation takes place between specialized cells of a colony. For instance, the cyanobacterium *Anabaena* has genes encoding proteins for photosynthesis and for nitrogen fixation, but a single cell cannot carry out both processes at the same time. The reason is that photosynthesis produces O₂, which inactivates the enzymes involved in nitrogen fixation. Instead of living as isolated cells, *Anabaena* forms filamentous colonies (Figure 27.10). Most cells in a filament carry out only photosynthesis, while a few specialized cells called *heterocysts* carry out only ni-

rogen fixation. Heterocysts are surrounded by a thickened cell wall that restricts entry of O₂ produced by neighboring photosynthetic cells. Intercellular connections allow heterocysts to transport fixed nitrogen to neighboring cells in exchange for carbohydrates.

In some prokaryotic species, metabolic cooperation occurs in surface-coating colonies known as biofilms (Figure 27.11).

A Figure 27.10 Metabolic cooperation in a colonial prokaryote. In the filamentous cyanobacterium *Anabaena*, cells known as heterocysts fix nitrogen, while the other cells carry out photosynthesis (LM). *Anabaena* is found in many freshwater lakes.

A Figure 27.11 A biofilm. The yellow mass in this colorized SEM is dental plaque, a biofilm that forms on tooth surfaces.

Cells in a colony secrete signaling molecules that recruit nearby cells, causing the colony to grow. The cells also produce proteins that adhere the cells to the substrate and to one another. Channels in the biofilm allow nutrients to reach cells in the interior and wastes to be expelled.

Prokaryotes belonging to different species also cooperate. For example, sulfate-consuming bacteria and methane-consuming archaea coexist in ball-shaped aggregates on the ocean floor. The bacteria appear to use the archaea's waste products, such as organic compounds and hydrogen. In turn, the bacteria produce compounds that facilitate methane consumption by the archaea. This partnership has global ramifications: Each year, these archaea consume an estimated 300 billion kg of methane, a major contributor to the greenhouse effect (see Chapter 54).

Concept Check 27.2

1. A bacterium requires only the amino acid methionine as an organic nutrient and lives in lightless caves. What mode of nutrition does it employ? Explain.
2. What are the sources of carbon and nitrogen for the cyanobacterium *Anabaena*?

For suggested answers, see Appendix A.

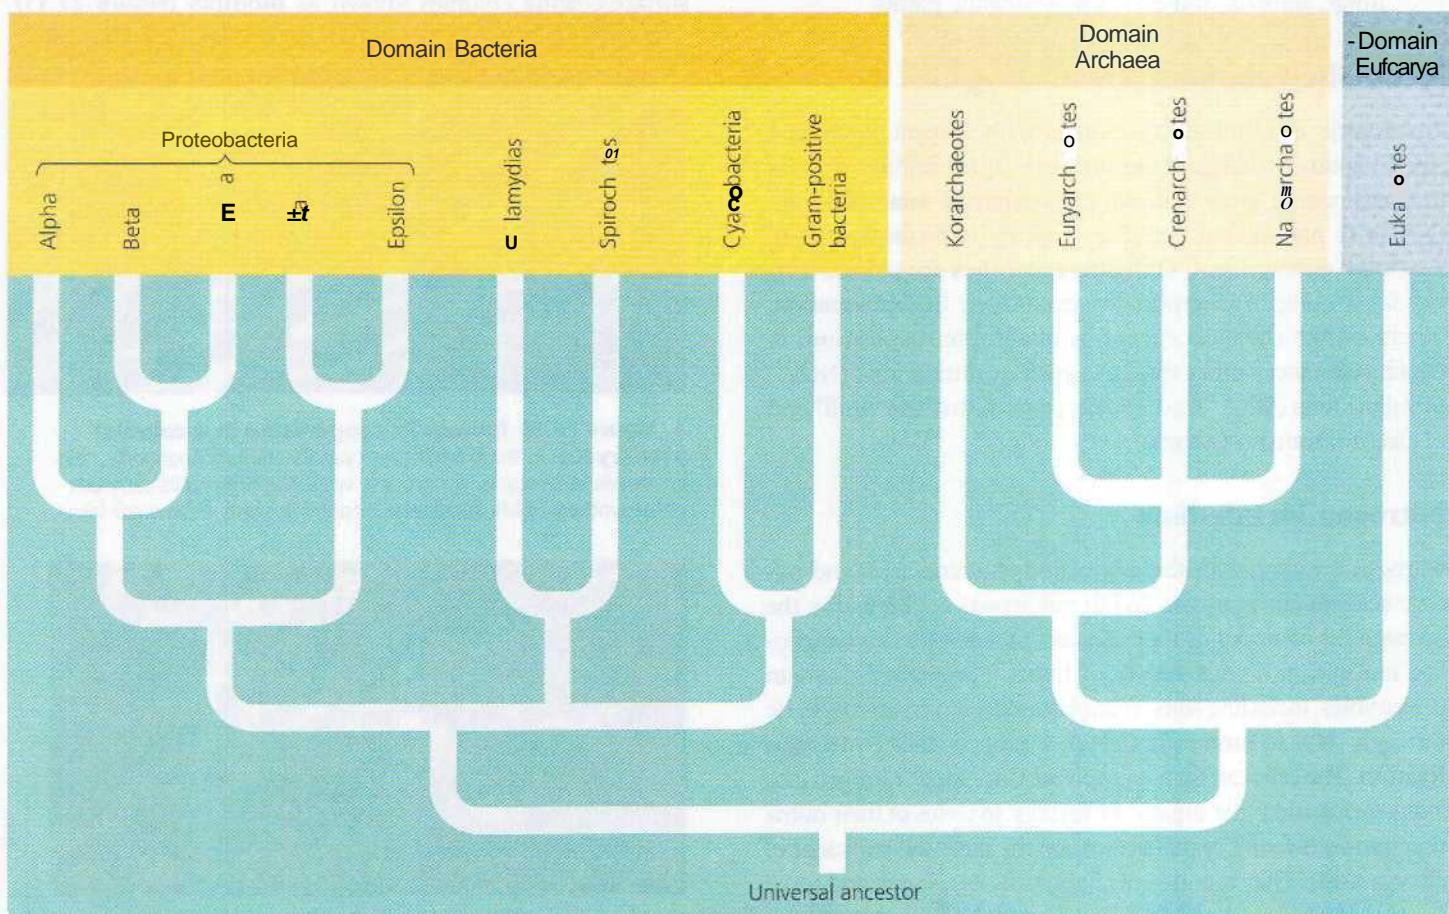

Concept 27.3

Molecular systematics is illuminating prokaryotic phylogeny

Until the late 20th century, systematists based prokaryotic taxonomy on phenotypic criteria such as shape, motility, nutritional mode, and response to Gram staining. These criteria are still valuable in certain contexts, such as the rapid identification of pathogenic bacteria cultured from a patient's blood. But when it comes to prokaryotic phylogeny, comparing these characteristics does not reveal a clear history. Applying molecular systematics to the investigation of prokaryotic phylogeny, however, has produced dramatic results.

Lessons from Molecular Systematics

As discussed in Chapter 25, microbiologists began comparing the sequences of prokaryotic genes in the 1970s. Using small-subunit ribosomal RNA (16S rRNA) as a marker for evolutionary relationships, Carl Woese and his colleagues concluded that many prokaryotes once classified as bacteria are actually

A Figure 27.12 A simplified phylogeny of prokaryotes. This phylogenetic tree based on molecular data highlights the relationships between the major prokaryotic groups discussed in this chapter.

more closely related to eukaryotes and belong in a domain of their own—Archaea. Microbiologists have since analyzed larger amounts of genetic data—in some cases, entire genomes—and have concluded that a few traditional taxonomic groups, such as cyanobacteria, are in fact monophyletic. However, other groups, such as gram-negative bacteria, are scattered throughout several lineages. **Figure 27.12** shows a tentative phylogeny of some of the major taxa of prokaryotes based on molecular systematics.

Prokaryotic phylogeny is still a work in progress, but two important lessons have already emerged. One is that the genetic diversity of prokaryotes is immense. When researchers began to sequence the genes of prokaryotes, they could investigate only those species that could be cultured in the laboratory—a small minority of all prokaryotic species. Methods pioneered by Norman Pace of the University of Colorado in the 1980s now allow researchers to sample genetic material directly from the environment. Every year this "genetic prospecting" adds major new branches to the tree of life. (Some researchers suggest that certain branches represent entire new kingdoms.) While only 4,500 prokaryotic species have been fully characterized, a single handful of soil could contain 10,000 prokaryotic species, according to some estimates. You can see why taking full stock of this diversity will require many years of research.

Another important lesson is the apparent significance of horizontal gene transfer in the evolution of prokaryotes. Over hundreds of millions of years, prokaryotes have acquired genes from distantly related species, and they continue to do so today. As a result, significant portions of the genomes of many prokaryotes are actually mosaics of genes imported from other species.

Note again in Figure 27.12 a key inference based on molecular systematics: the very early divergence of prokaryotes into two main lineages, bacteria and archaea.

Bacteria

Bacteria include the vast majority of prokaryotes that most people are aware of, from the pathogenic species that cause strep throat and other diseases to the beneficial species used to make Swiss cheese. Every major mode of nutrition and metabolism is represented among bacteria, and even a small taxonomic group of bacteria may contain species exhibiting many different nutritional modes. Examine **Figure 27.13** on the following pages for a closer look at several major groups of bacteria.

Archaea

Archaea share certain traits with bacteria and other traits with eukaryotes (**Table 27.2**). However, archaea also have many unique characteristics, as we would expect for a taxon that has followed a separate evolutionary path for so long.

Table 27.2 A Comparison of the Three Domains of Life

| CHARACTERISTIC | DOMAIN | | |
|--|-------------------------|----------------------------|-------------------------|
| | Bacteria | Archaea | Eukarya |
| Nuclear envelope | Absent | Absent | Present |
| Membrane-enclosed organelles | Absent | Absent | Present |
| Peptidoglycan in cell wall | Present | Absent | Absent |
| Membrane lipids | Unbranched hydrocarbons | Some branched hydrocarbons | Unbranched hydrocarbons |
| RNA polymerase | One kind | Several kinds | Several kinds |
| Initiator amino acid for protein synthesis | Formyl-methionine | Methionine | Methionine |
| Introns (noncoding parts of genes) | Rare | Present in some genes | Present |
| Response to the antibiotics Streptomycin and chloramphenicol | Growth inhibited | Growth not inhibited | Growth not inhibited |
| Histones associated with DNA | Absent | Present | Present |
| Circular chromosome | Present | Present | Absent |
| Ability to grow at temperatures > 100°C | No | Some species | No |

The first prokaryotes that were classified in domain Archaea are species that live in environments so extreme that few other organisms can survive there. Such organisms are known as extremophiles, meaning "lovers" of extreme conditions (from the Greek *pkifos*, lover). Extremophiles include extreme thermophiles, extreme halophiles, and methanogens.

Extreme thermophiles (from the Greek *thermos*, hot) thrive in very hot environments (see Figure 27.1). For example, archaea in the genus *Sulfolobus* live in sulfur-rich volcanic springs at temperatures up to 90°C. *Pyrolobus fumani*, an extreme thermophile found around deep-sea hydrothermal vents on the Mid-Atlantic Ridge, can survive at temperatures as high as 113°C. Another extreme thermophile, *Pyrococcus furiosus*, is used in biotechnology as a source of DNA polymerase for the polymerase chain reaction (PCR) technique (see Chapter 20).

Extreme halophiles (from the Greek *halo*, salt) live in highly saline environments, such as the Great Salt Lake and the Dead Sea. Some species merely tolerate salinity while others require an environment that is several times saltier than seawater. Colonies of certain extreme halophiles form a purple-red scum that owes its color to bacteriorhodopsin, a

Figure 27.13

Exploring Major Groups of Bacteria

GROUP/DESCRIPTION

EXAMPLE

PROTEOBACTERIA

This large and diverse clade of gram-negative bacteria includes photoautotrophs, chemoautotrophs, and heterotrophs. Some proteobacteria are anaerobic; others are aerobic. Molecular systemstists currently recognize five subgroups of proteobacteria.

SUBGROUP: ALPHA PROTEOBACTERIA

Many of the species in this subgroup are closely associated with eukaryotic hosts. For example, *Rhizobium* species live in nodules within the roots of legumes (plants of the pea/bean family), where the bacteria convert atmospheric N₂ to compounds the host plant can use to make proteins. Species in the genus *Agrobacterium* produce tumors In plants; genetic engineers use these bacteria to carry foreign DNA into the genomes of crop plants (see Figure 20.19). As explained in Chapter 26, scientists hypothesize that mitochondria evolved from aerobic alpha proteobacteria through endosymbiosis.

Rhizobium (arrows) inside a root cell of a legume (TEM)

SUBGROUP: BETA PROTEOBACTERIA

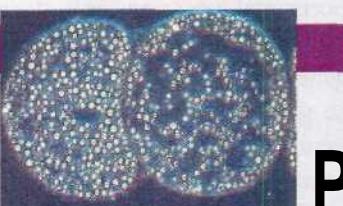

This nutritionally diverse subgroup includes *Nitrosomonas*, a genus of soil bacteria that play an important role in nitrogen recycling by oxidizing ammonium (NH₄⁺), producing nitrite (NO₂⁻) as a waste product.

Nitrosomonas (colorized TEM)

SUBGROUP: GAMMA PROTEOBACTERIA

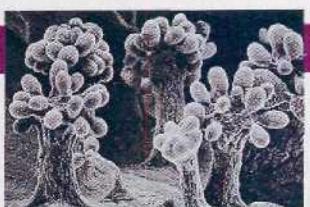

This subgroup's photosynthetic members include sulfur bacteria such as *Chromatium*, which obtain energy by oxidizing H₂S, producing sulfur as a waste. Some heterotrophic gamma proteobacteria are pathogens; for example, *Legionella* causes Legionnaires' disease, *Salmonella* is responsible for some cases of food poisoning, and *Vibrio cholerae* causes cholera. *Escherichia coli*, a common resident of the intestines of humans and other mammals, normally is not pathogenic.

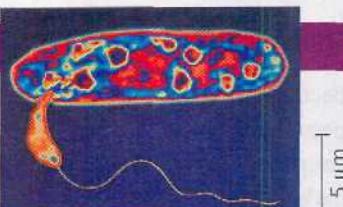

Chromatium; the small globules are sulfur wastes (LM)

SUBGROUP: DELTA PROTEOBACTERIA

This subgroup includes the slime-secreting myxobacteria, which form elaborate colonies. When the soil dries out or food is scarce, the cells congregate into a fruiting body that releases resistant spores. The spores become active and found new colonies in favorable environments. Bdellovibrions are delta proteobacteria that attack other bacteria. They charge their prey at up to 100 μm/sec (comparable to a human running 600 km/hr) and bore into the prey by spinning at 100 revolutions per second.

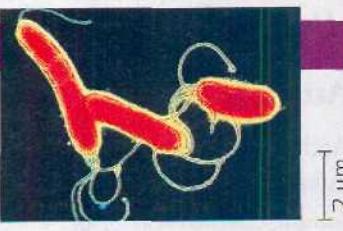

Fruiting bodies of *Chondromyces crocatus*, a myxobacterium (SEM)

Bdellovibrio bacteriophorus attacking a larger bacterium (colorized TEM)

SUBGROUP: EPSILON PROTEOBACTERIA

Most species in this subgroup are pathogenic to humans or other animals- Epsilonion proteobacteria include *Campylobacter*; which causes blood poisoning and intestinal inflammation, and *Helicobacter pylori*, which causes stomach ulcers.

Helicobacter pylori (colorized TEM)

GROUP/DESCRIPTION

EXAMPLE

CHLAMYDIAS

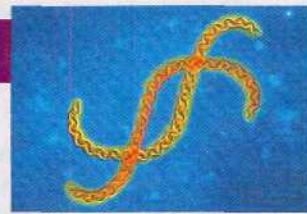

These parasites can survive only within animal cells, depending on their hosts for resources as basic as ATE. The gram-negative walls of chlamydias are unusual in that they lack peptidoglycan. One species, *Chlamydia trachomatis*, is the most common cause of blindness in the world and also causes nongonococcal urethritis, the most common sexually transmitted disease in the United States.

Chlamydia (arrows) inside an animal cell (colorized TEM)

SPIROCHETES

These helical heterotrophs spiral through their environment by means of rotating, internal, flagellum-like filaments. Many spirochetes are free-living, but others are notorious pathogenic parasites: *Treponema pallidum* causes syphilis, and *Borrelia burgdorferi* causes Lyme disease.

Leptospira, a spirochete (colorized TEM)

GRAM-POSITIVE BACTERIA

Gram-positive bacteria rival the proteobacteria in diversity. Species in one subgroup, the actinomycetes (from the Greek *mykes*, fungus, for which these bacteria were once mistaken), form colonies containing branched chains of cells. Two species of actinomycetes cause tuberculosis and leprosy. However, most actinomycetes are free-living species that help decompose the organic matter in soil; their secretions are partly responsible for the "earthy" odor of rich soil. Soil-dwelling species in the genus *Streptomyces* are cultured by pharmaceutical companies as a source of many antibiotics, including streptomycin.

In addition to the colonial actinomycetes, gram-positive bacteria include many solitary species, such as *Bacillus anthracis* (see Figure 27.9), which causes anthrax, and *Clostridium botulinum*, which causes botulism. Various species of *Staphylococcus* and *Streptococcus* are also gram-positive bacteria.

Mycoplasmas are the only bacteria known to lack cell walls. They are also the tiniest of all "known" cells, with diameters as small as 0.1 μm, only about five times as large as a ribosome. Mycoplasmas have remarkably small genomes—*Mycoplasma genitalium* has only 517 genes, for example. Many mycoplasmas are free-living soil bacteria, but others are pathogens, including a species that causes "walking pneumonia" in humans.

Streptomyces, the source of many antibiotics (colorized SEM)

Hundreds of mycoplasmas covering a human fibroblast cell (colorized SEM)

CYANOBACTERIA

These photoautotrophs are the only prokaryotes with plantlike, oxygen-generating photosynthesis. (In fact, chloroplasts likely evolved from an endosymbiotic cyanobacterium; see Chapter 26). Both solitary and colonial cyanobacteria are abundant wherever there is water, providing an enormous amount of food for freshwater and marine ecosystems. Some filamentous colonies have cells specialized for nitrogen fixation, the process that converts atmospheric N₂ to compounds that can be incorporated into proteins and other organic molecules (see Figure 27.10).

Two species of *Oscillatoria*, filamentous cyanobacteria (LM)

A Figure 27.14 Extreme halophiles. Colorful "salt-loving" archaea thrive in these ponds near San Francisco. Used for commercial salt production, the ponds contain water that is five to six times as salty as seawater.

photosynthetic pigment very similar to the visual pigments in the vertebrate retina (**Figure 27.14**).

Methanogens are named for the unique way they obtain energy: They use CO₂ to oxidize H₂, releasing methane as a waste product. Among the strictest of anaerobes, methanogens are poisoned by O₂. Some species live in swamps and marshes where other microorganisms have consumed all the O₂. The "marsh gas" found in such environments is the methane produced by these archaea. Other species of methanogens inhabit the anaerobic environment within the guts of cattle, termites, and other herbivores, playing an essential role in the nutrition of these animals. Methanogens are also important decomposers in sewage treatment facilities,

All known extreme halophiles and methanogens are members of a clade called Euryarchaeota (from the Greek *eurys*, broad, a reference to the habitat range of these prokaryotes). Euryarchaeota also includes some extreme thermophiles, though most thermophilic species belong to a second clade, Crenarchaeota (*cren* means "spring," as in hydrothermal springs). Genetic prospecting has revealed that both Euryarchaeota and Crenarchaeota also include many species of archaea that are not extremophiles. These species exist in habitats ranging from farm soils to lake sediments to the surface waters of the open ocean.

New findings continue to update the picture of archaean phylogeny. In 1996, researchers sampling a hot spring in Yellowstone National Park discovered archaea that do not appear to belong to either Euryarchaeota or Crenarchaeota. They placed these archaea in a new clade, Korarchaeota (from the Greek *koron*, young man). The oldest lineage in the domain Archaea, Korarchaeota may offer clues to the early evolution of life on Earth. In 2002, researchers exploring hydrothermal vents off the coast of Iceland discovered archaean cells only 0.4 μm in diameter attached to a much larger crenarchaeote.

The genome of the tiny archaean is one of the smallest known of any organism, containing only 500,000 base pairs. Analysis of the genome indicates that this prokaryote belongs to a fourth archaean clade, now called Nanoarchaeota (from the Greek *nanos*, dwarf). Within a year after this clade was named, three other DNA sequences from nanoarchaeote species were isolated: one from Yellowstone's hot springs, one from hot springs in Siberia, and one from a hydrothermal vent in the Pacific. As prospecting continues, it seems likely that the tree in Figure 27.12 will undergo further change in years to come.

Concept Check 27.3

1. Explain how molecular systematics has greatly increased our understanding of prokaryotic phylogeny.
2. What do syphilis and Lyme disease have in common?
3. What characteristics enable some species of archaea to live in extreme environments?

For suggested answers, see Appendix A.

Concept 27.4

Prokaryotes play crucial roles in the biosphere

If humans were to disappear from the planet tomorrow, life on Earth would go on for most other species. But prokaryotes are so important to the biosphere that if they were to disappear, the prospects for any other life surviving would be dim.

Chemical Recycling

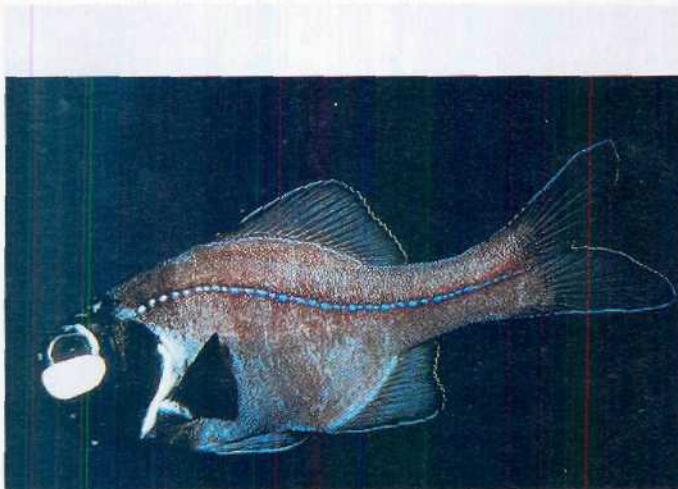

The atoms that make up the organic molecules in all living things were at one time part of inorganic compounds in the soil, air, and water. Sooner or later, that is where those atoms will return. Ecosystems depend on the continual recycling of chemical elements between the living and nonliving components of the environment, and prokaryotes play a major role in this process. For example, chemoheterotrophic prokaryotes function as decomposers, breaking down corpses, dead vegetation, and waste products, thereby unlocking supplies of carbon, nitrogen, and other elements. (See Chapter 54 for a detailed discussion of chemical cycles.)

Prokaryotes also convert inorganic compounds into forms that can be taken up by other organisms. Autotrophic prokaryotes, for example, use CO₂ to make organic compounds, which are then passed up through food chains. Cyanobacteria produce atmospheric O₂, and some species also fix nitrogen into a form that other organisms can use to make proteins.

Symbiotic Relationships

Just as certain species of prokaryotes have beneficial associations with other prokaryotes (metabolic cooperation), some prokaryotes form similarly intimate relationships with eukaryotes. An ecological relationship between organisms of different species that are in direct contact is called symbiosis (from a Greek word meaning "living together"). If one of the symbiotic organisms is much larger than the other, the larger is known as the host and the smaller is known as the symbiont. Symbiotic relationships are categorized as either mutualism, commensalism, or parasitism. In mutualism, both symbiotic organisms benefit (Figure 27.15). In commensalism, one organism benefits while neither harming nor helping the other in any significant way. (Commensalism is rare in nature, as further discussed in Chapter 53.) In parasitism, one organism, called a parasite, benefits at the expense of the host.

The well-being of many eukaryotes—yourself included—depends on mutualistic prokaryotes. For example, human intestines are home to an estimated 500 to 1,000 species of bacteria; their cells outnumber all human cells in the body by as much as ten times. Many of these species are mutualists, digesting food that our own intestines cannot break down. In 2003, scientists at Washington University in St. Louis published the first complete genome of one of these gut mutualists, *Bacillus thtaiotaomicron*. The genome includes a large array of genes involved in synthesizing carbohydrates, vitamins, and other nutrients needed by humans. Signals from the bacterium activate human genes that build the network of intestinal blood vessels necessary to absorb food. Other signals induce human cells to produce antimicrobial compounds to which *B. thtaiotaomicron* is not susceptible. Keeping other competing bacteria out of the intestines benefits *B. thtaiotaomicron* as well as its human host.

A Figure 27.15 Mutualism: bacterial "headlights." The glowing oval below the eye of the flashlight fish (*Photoblepharon palpebratus*) is an organ harboring bioluminescent bacteria. The fish uses the light to attract prey and to signal potential mates. The bacteria receive nutrients from the fish.

Concept Check 27.4

1. Although individual prokaryotes may be tiny, they are giants in their collective impact on Earth and its life. Explain.
2. Explain how the relationship between humans and *B. thtaiotaomicron* is an example of mutualism.

For suggested answers, see Appendix A.

Concept 27.5

Prokaryotes have both harmful and beneficial impacts on humans

While the best-known prokaryotes tend to be those that cause illness in humans, these pathogens represent only a small fraction of prokaryotic species. Many other prokaryotes have positive interactions with humans, even serving as essential tools in agriculture and industry.

Pathogenic Prokaryotes

The prokaryotic species that are human parasites deserve their negative reputation. All told, prokaryotes cause about half of all human diseases. Between 2 and 3 million people a year die of the lung disease tuberculosis, which is caused by the bacillus *Mycobacterium tuberculosis*, while another 2 million die from various diarrheal diseases caused by other prokaryotes. In the United States, the most widespread pest-carried disease is Lyme disease (Figure 27.16). Caused by a bacterium carried

A Figure 27.16 Lyme disease. Ticks in the genus *Ixodes* spread the disease by transmitting the spirochete *Borrelia burgdorferi* (colorized SEM). A large, ring-shaped rash may develop at the site of the tick's bite, as shown in the photograph of a person's lower leg.

by ticks that live on deer and field mice, Lyme disease can produce debilitating arthritis, heart disease, and nervous disorders if untreated.

Pathogenic prokaryotes usually cause illness by producing poisons, which are classified as exotoxins or endotoxins. Exotoxins are proteins secreted by prokaryotes. Cholera, a dangerous diarrheal disease, is caused by an exotoxin released by the proteobacterium *Vibrio cholerae*. The exotoxin stimulates intestinal cells to release chloride ions into the gut, and water follows by osmosis. Exotoxins can produce disease even if the prokaryotes that manufacture them are not present. For example, the fatal disease botulism is caused by botulinum toxin, an exotoxin secreted by the gram-positive bacterium *Clostridium botulinum* as it ferments improperly canned foods.

Endotoxins are lipopolysaccharide components of the outer membrane of gram-negative bacteria. In contrast to exotoxins, endotoxins are released only when the bacteria die and their cell walls break down. Examples of endotoxin-producing bacteria include nearly all species in the genus *Salmonella*, which are not normally present in healthy animals. *Salmonella typhi* causes typhoid fever, and several other *Salmonella* species, some of which are frequently found in poultry, cause food poisoning.

Since the 19th century, improvements in sanitation in the developed world have greatly reduced the threat of pathogenic prokaryotes. Antibiotics have saved a great many lives and reduced the incidence of disease. However, resistance to antibiotics is currently evolving in many strains of prokaryotes. As you read earlier, the rapid reproduction of prokaryotes enables genes conferring resistance to multiply quickly throughout prokaryotic populations as a result of natural selection, and these genes can spread to other species by horizontal gene transfer.

Horizontal gene transfer can also spread genes associated with virulence, turning normally harmless prokaryotes into fatal pathogens. *E. coli*, for instance, is ordinarily a harmless symbiont in the human intestines, but pathogenic strains that cause bloody diarrhea have emerged. One of the most dangerous strains, called O157:H7, first came to the attention of microbiologists in 1982. Today it is a global threat; in the United States alone there are 75,000 cases of O157:H7 infection per year, often from contaminated beef. In 2001, an international team of scientists sequenced the genome of O157:H7 and compared it with the genome of a harmless strain of *E. coli* called K-12. They discovered that 1,387 out of the 5,416 genes in O157:H7 have no counterpart in K-12. These 1,387 genes must have been incorporated into the genome of O157:H7 through horizontal gene transfer, most likely through the action of bacteriophages (see Figure 18.16). Many of the imported genes are associated with the pathogenic bacterium's invasion of its host. For example, some genes code for exotoxins that enable O157:H7 to attach itself to the intestinal wall and extract nutrients.

Pathogenic prokaryotes pose a potential threat as weapons of bioterrorism. In October 2001, endospores of *Bacillus anthracis*, the bacterium that causes anthrax, were found in envelopes mailed to members of news media and the U.S. Senate. Eighteen people developed cases of anthrax, and five died. Other prokaryotes that could be candidates as weapons include *C. botulinum* and *Yersinia pestis*, which causes plague. The threat has stimulated intense research on pathogenic prokaryotic species. In May 2003, scientists at the Institute for Genomic Research in Maryland published the complete genome of the strain of *B. anthracis* that had been used in the October 2001 attack, in the hope of developing new vaccines and antibiotics.

Prokaryotes in Research and Technology

On a positive note, we reap many benefits from the metabolic capabilities of prokaryotes. For example, humans have long used bacteria to convert milk to cheese and yogurt. In recent years, our greater understanding of prokaryotes has led to an explosion of new applications in biotechnology; the use of *E. coli* in gene cloning and of *Agrobacterium tumefaciens* in producing transgenic plants are two examples (see Chapter 20).

Prokaryotes are the principal agents in bioremediation, the use of organisms to remove pollutants from soil, air, or water. For example, anaerobic bacteria and archaea decompose the organic matter in sewage, converting it to material that can be used as landfill or fertilizer after chemical sterilization. Other bioremediation applications include breaking down radioactive waste and cleaning up oil spills (**Figure 27.17**).

In the mining industry prokaryotes help recover metals from ores. Bacteria assist in extracting over 30 billion kg of copper from copper sulfides each year. Harnessing other prokaryotes that can extract gold from ore, one factory in the

A Figure 27.17 Bioremediation of an oil spill. A worker sprays fertilizers on an oil-soaked beach in Alaska. The fertilizers stimulate growth of native bacteria that initiate the breakdown of the oil—in some cases, speeding the natural breakdown process fivefold.

African nation of Ghana processes 1 million kg of gold concentrate a day—about half of Ghana's foreign exchange.

Through genetic engineering, humans can now modify prokaryotes to produce vitamins, antibiotics, hormones, and other products (see Chapter 20). One of the most radical ideas for modifying prokaryotes has come from Craig Venter (one of the leaders of the Human Genome Project), who has announced that he and his colleagues are attempting to build "synthetic chromosomes" for prokaryotes—in effect, producing entirely new species from scratch. Venter hopes to "design" prokaryotes that can perform specific tasks, such as producing large amounts of hydrogen to reduce dependence on fossil fuels.

The usefulness of prokaryotes largely derives from their diverse forms of nutrition and metabolism. All this metabolic

versatility evolved prior to the appearance of the structural novelties that heralded the evolution of eukaryotic organisms, the topic of the remainder of this unit.

Concept Check 27.5

1. Contrast exotoxins and endotoxins.
2. What features of prokaryotes make them a potential bioterrorism threat?
3. Identify at least two ways that prokaryotes have affected you positively today.

For suggested answers, see Appendix A.

Chapter 27 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 27.1

Structural, functional, and genetic adaptations contribute to prokaryotic success

- **Cell-Surface Structures** (pp. 534-536) Nearly all prokaryotes have a cell wall. Gram-positive and gram-negative bacteria differ in the structure of their walls. Many species have a capsule, fimbriae, and pili outside the cell wall, which help the cells adhere to one another or to a substrate.
Activity *Prokaryotic Cell Structure and Function*
- **Motility** (pp. 536-537) Most motile bacteria propel themselves by flagella, which are structurally and functionally different from eukaryotic flagella. In heterogeneous environments, many prokaryotes can move toward or away from certain stimuli.
- **Internal and Genomic Organization** (p. 537) Prokaryotic cells usually lack complex compartmentalization. The typical prokaryotic genome is a ring of DNA that is not surrounded by a membrane. Some species also have smaller rings of DNA called plasmids.
- **Reproduction and Adaptation** (pp. 537-538) Prokaryotes reproduce quickly by binary fission. Many form endospores, which can remain viable in harsh conditions for centuries. Rapid reproduction and horizontal gene transfer facilitate the evolution of prokaryotes in changing environments.

Concept 27.2

A great diversity of nutritional and metabolic adaptations have evolved in prokaryotes

- Examples of all four modes of nutrition—photoautotrophy, chemoautotrophy, photoheterotrophy, and chemoheterotrophy—are found among prokaryotes (pp. 538-539).
- **Metabolic Relationships to Oxygen** (p. 539) Obligate aerobes require O₂, obligate anaerobes are poisoned by O₂, and facultative anaerobes can survive with or without O₂.

- **Nitrogen Metabolism** (p. 539) Prokaryotes can metabolize a wide variety of nitrogenous compounds. Some can convert atmospheric nitrogen to ammonia in a process called nitrogen fixation.

- **Metabolic Cooperation** (pp. 539-540) Many prokaryotes depend on the metabolic activities of other prokaryotes. In the cyanobacterium *Anabaena*, photosynthetic cells and nitrogen-fixing cells exchange metabolic products. Some prokaryotes can form surface-coating colonies called biofilms, which may include different species.

Investigation *What Are the Modes of Nutrition in Prokaryotes?*

Concept 27.3

Molecular systematics is illuminating prokaryotic phylogeny

- **Lessons from Molecular Systematics** (pp. 540-541) Molecular systematics is leading to a phylogenetic classification of prokaryotes, allowing systematists to identify major new clades.
Activity *Classification of Prokaryotes*
- **Bacteria** (pp. 541-543) Diverse nutritional types are scattered among the major groups of bacteria. The two largest groups are the proteobacteria and the gram-positive bacteria.
- **Archaea** (pp. 541-544) Archaea share certain traits with bacteria and other traits with eukaryotes. Some archaea live in extreme environments; they include extreme thermophiles, extreme halophiles, and methanogens.

Concept 27.4

Prokaryotes play crucial roles in the biosphere

- **Chemical Recycling** (p. 544) Decomposition by heterotrophic prokaryotes and the synthetic activities of autotrophic and nitrogen-fixing prokaryotes contribute to the recycling of elements in ecosystems.
- **Symbiotic Relationships** (p. 545) Many prokaryotes live with other organisms in symbiotic relationships: mutualism, commensalism, or parasitism.

Concept 27.5

Prokaryotes have both harmful and beneficial impacts on humans

- **Pathogenic Prokaryotes** (pp. 545–546) Pathogenic prokaryotes typically cause disease by releasing exotoxins or endotoxins and are potential weapons of bioterrorism. Horizontal gene transfer can spread genes associated with virulence to harmless strains,
- **Prokaryotes in Research and Technology** (pp. 546–547) Experiments involving prokaryotes such as *E. coli* and *A. tumefaciens* have led to important advances in DNA technology. Prokaryotes are major tools in bioremediation, mining, and the synthesis of vitamins, antibiotics, and other products.

TESTING YOUR KNOWLEDGE

Evolution Connection

Health officials worldwide are concerned about a resurgence of diseases caused by bacteria that are resistant to standard antibiotics. For instance, antibiotic-resistant bacteria are causing an epidemic of tuberculosis (TB), a lung disease spread by airborne droplets. Drugs can relieve TB symptoms in a few weeks, but it takes much longer to halt the infection, and patients are likely to discontinue treatment while bacteria are still present. Why can prokaryotes quickly reinfect a patient if they are not wiped out? How might this result in the evolution of drug-resistant pathogens?

Scientific Inquiry

You read that some scientists are investigating the possibility of engineering entirely new prokaryotic species. What are the risks and potential benefits of such a project? What insights into this research can be found in the natural history and evolutionary biology of prokaryotes?

Investigation *What Are the Modes of Nutrition in Prokaryotes?*

Science, Technology, and Society

Many local newspapers regularly publish a list of restaurants that have been cited by inspectors for poor sanitation. Locate such a report and highlight the cases that are likely associated with potential food contamination by pathogenic prokaryotes.

28

Protists

A Figure 28.1 Unicellular and colonial eukaryotes in a drop of pond water (LM).

Key Concepts

- 28.1 Protists are an extremely diverse assortment of eukaryotes
- 28.2 Diplomonads and parabasalids have modified mitochondria
- 28.3 Euglenozoans have flagella with a unique internal structure
- 28.4 Alveolates have sacs beneath the plasma membrane
- 28.5 Stramenopiles have "hairy" and smooth flagella
- 28.6 Ciliates and radiolarians have threadlike pseudopodia
- 28.7 Amoebozoans have lobe-shaped pseudopodia
- 28.8 Red algae and green algae are the closest relatives of land plants

In the past, taxonomists classified all protists in a single kingdom, Protista. However, advances in eukaryotic systematics have caused the kingdom to crumble. It has become clear that Protista is in fact paraphyletic (see Figure 25.10): Some protists are more closely related to plants, fungi, or animals than they are to other protists. As a result, the kingdom Protista has been abandoned, and various lineages of protists are now recognized as kingdoms in their own right by some biologists. Most biologists still use the term protist, but only as a convenient way to refer to eukaryotes that are neither plants, animals, nor fungi.

In this chapter, you will become acquainted with some of the most significant groups of protists. You will learn about their structural and biochemical adaptations as well as their enormous impact on ecosystems, industry, and human health.

Concept #28.1

Protists are an extremely diverse assortment of eukaryotes

Given the paraphyletic nature of the group once called Protista, it isn't surprising that few general characteristics of protists can be cited without exceptions. In fact, protists exhibit more structural and functional diversity than any other group of organisms.

Most protists are unicellular, although there are some colonial and multicellular species. Unicellular protists are justifiably considered the simplest eukaryotes, but at the cellular level, many protists are exceedingly complex—the most elaborate of all cells. We should expect this of organisms that must carry out within the boundaries of a single cell the basic functions performed by all of the specialized cells in a multicellular organism.

Overview

A World in a Drop of Water

Even a low-power light microscope can reveal an astonishing menagerie of organisms in a drop of pond water (**Figure 28.1**). Some of these tiny organisms propel themselves with whipping flagella, while others creep along by means of blob-like appendages. Some resemble miniature jewelry; others look like tumbling green globes. These beautiful creatures belong to the many diverse kingdoms of mostly unicellular eukaryotes informally known as **protists**. They have been intriguing scientists for more than 300 years, ever since the Dutch microscopist Antoni van Leeuwenhoek first laid eyes on them. Recalling his discovery of these organisms, he wrote, "No more pleasant sight has met my eye than this."

Protists are the most nutritionally diverse of all eukaryotes. Some protists are photoautotrophs, containing chloroplasts. Some are heterotrophs, absorbing organic molecules or ingesting larger food particles. Still others, called **mixotrophs**, combine photosynthesis *and* heterotrophic nutrition. Photoautotrophy, heterotrophy, and mixotrophy have all arisen independently in many protist lineages. Distinguishing these nutritional modes helps us to understand the roles of protists in biological communities. In such an ecological context, we can divide protists into three categories: photosynthetic (plant-like) protists, or algae (singular, *alga*); ingestive (animal-like) protists, or protozoans; and absorptive (fungus-like) protists, which have no other general name. Bear in mind, however, that although the terms *alga* and *protozoan* are useful in discussing protist ecology, they do not refer to monophyletic groups.

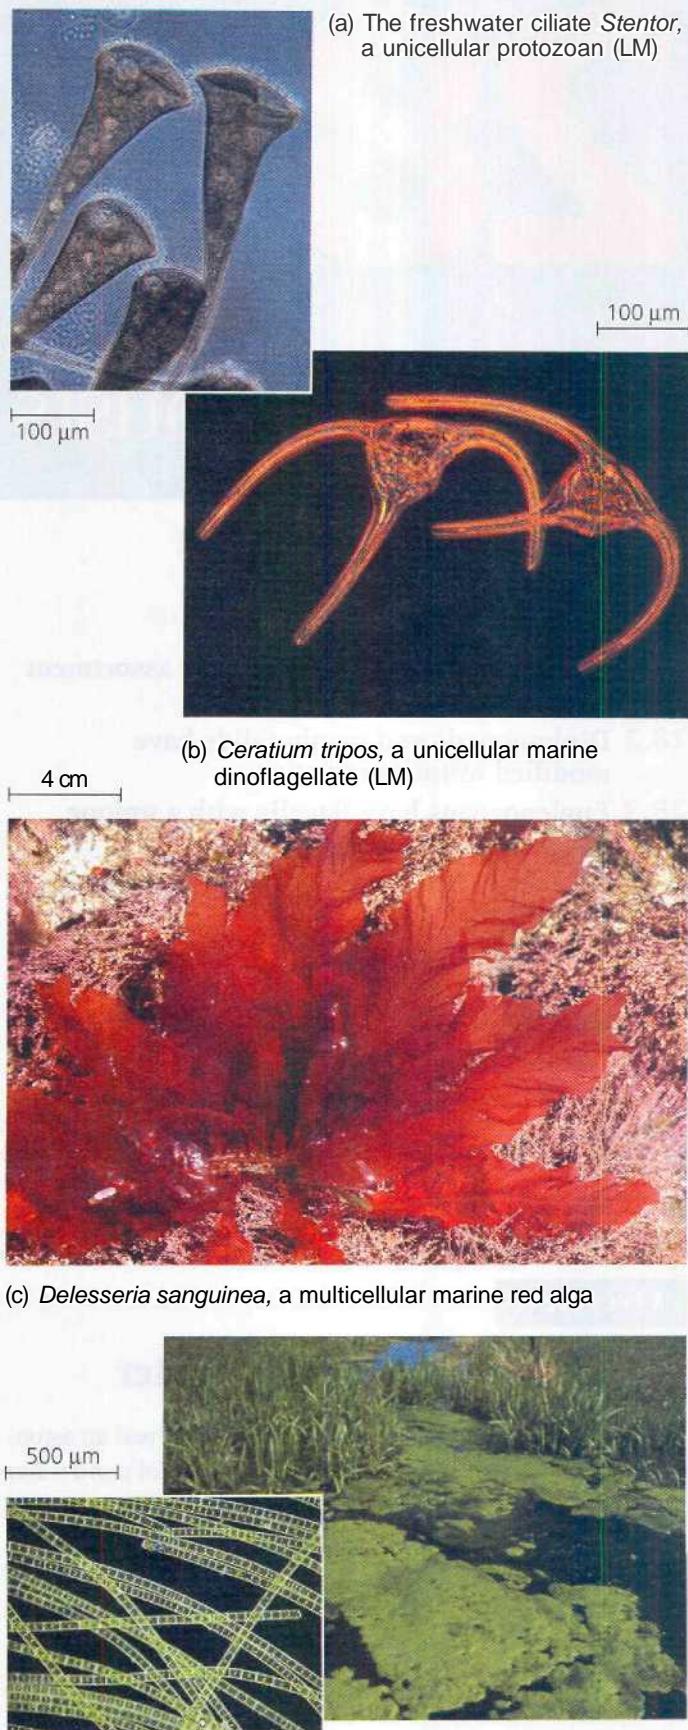

Protist habitats, too, are diverse (Figure 28.2). Most protists are aquatic, and they are found almost anywhere there is water, including moist terrestrial habitats such as damp soil and leaf litter. In oceans, ponds, and lakes, many protists are bottom-dwellers that attach themselves to rocks and other substrates or creep through the sand and silt. Protists are also important constituents of plankton (from the Greek *planktos*, wandering), the communities of organisms that drift passively near the water's surface. Phytoplankton (planktonic algae and cyanobacteria) form the foundation of most marine and freshwater food webs. In addition to these free-living species, many protists live as symbionts in other organisms.

Reproduction and life cycles are highly varied among protists. Some protists are exclusively asexual; others can also reproduce sexually or at least employ the sexual processes of meiosis and syngamy. All three basic types of sexual life cycles (see Figure 13.6) are represented among protists, along with some variations that do not quite fit any of these types. We will investigate the life cycles of several protist groups in this chapter.

Endosymbiosis in Eukaryotic Evolution

What gave rise to the enormous diversity of protists that exist today? There is now considerable evidence that much of protist diversity has its origins in endosymbiosis, a process in which certain unicellular organisms engulfed other cells, which became endosymbionts and ultimately organelles in the host cell. For example, as we discussed in Chapter 26, the earliest eukaryotes probably acquired mitochondria by engulfing alpha proteobacteria. The early origin of mitochondria is supported by the fact that all eukaryotes studied so far either have mitochondria or show signs that they had them in the past.

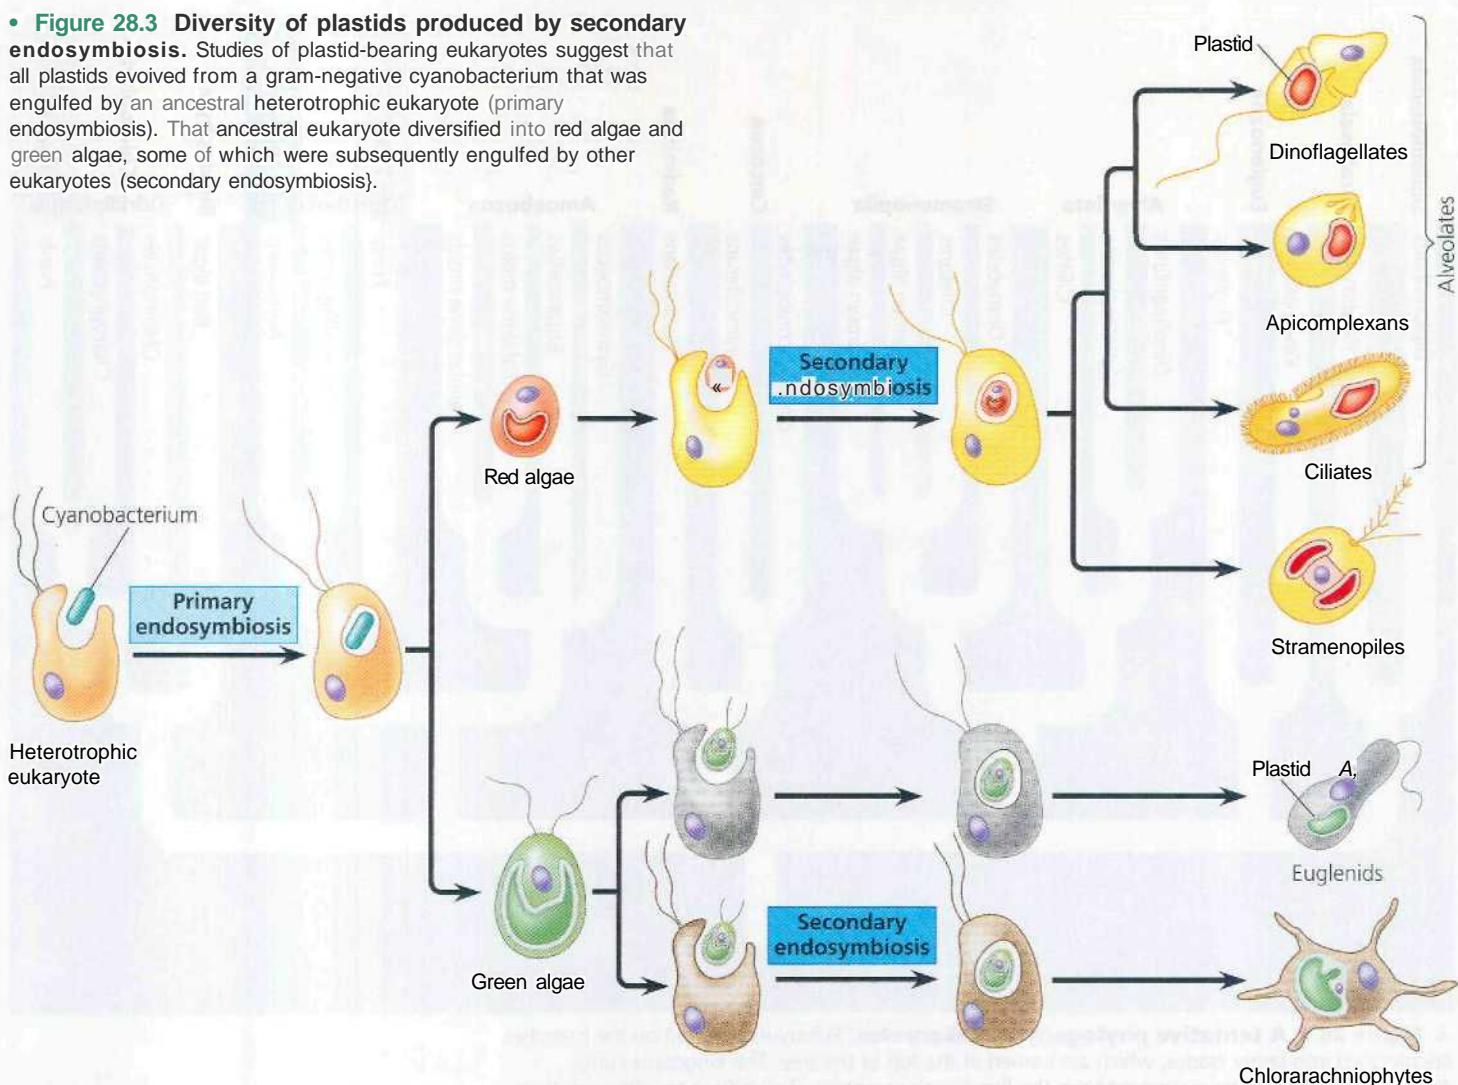

Biologists postulate that later in eukaryotic history, one lineage of heterotrophic eukaryotes acquired an additional endosymbiont—a photosynthetic cyanobacterium—that then evolved into plastids. In the model illustrated in Figure 28.3, this plastid-bearing lineage eventually gave rise to red algae

(d) *Spirogyra*, a filamentous freshwater green alga (inset LM)

A Figure 28.2 A small sample of protist diversity.

- Figure 28.3 Diversity of plastids produced by secondary endosymbiosis.** Studies of plastid-bearing eukaryotes suggest that all plastids evolved from a gram-negative cyanobacterium that was engulfed by an ancestral heterotrophic eukaryote (primary endosymbiosis). That ancestral eukaryote diversified into red algae and green algae, some of which were subsequently engulfed by other eukaryotes (secondary endosymbiosis).

and green algae. These hypotheses are supported by the observation that the DNA of plastid genes in red algae and green algae closely resembles the DNA of cyanobacteria. In addition, plastids in red algae and green algae are surrounded by two membranes, which correspond to the inner and outer membranes of the gram-negative cyanobacterial endosymbionts.

On several occasions during eukaryotic evolution, red algae and green algae underwent **secondary endosymbiosis**: They were ingested in the food vacuole of a heterotrophic eukaryote and became endosymbionts themselves. For example, algae known as chlorarachniophytes evolved when a heterotrophic eukaryote engulfed a green alga. This process likely occurred relatively recently in evolutionary time because the engulfed alga still carries out photosynthesis with its plastids and contains a tiny, vestigial nucleus of its own, called a *nudeomorph*. Consistent with the hypothesis that chlorarachniophytes evolved from a eukaryote that engulfed another eukaryote, their plastids are surrounded by *four* membranes. The two inner membranes originated as the inner and outer membranes of the ancient cyanobacterium. The third mem-

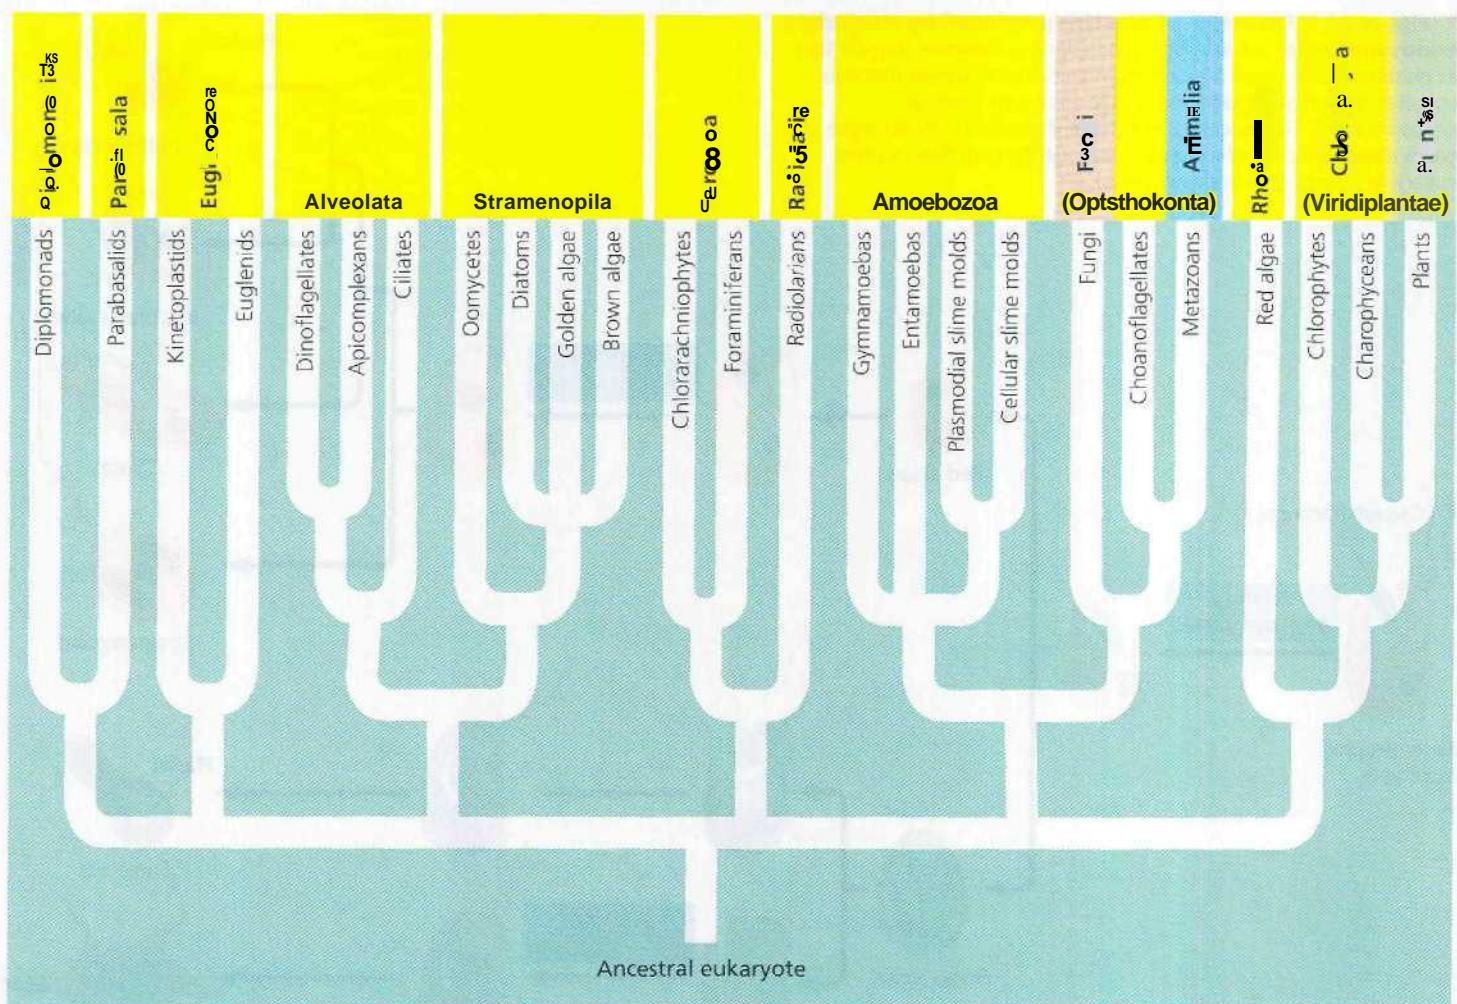

brane is derived from the engulfed alga's plasma membrane, and the outermost membrane is derived from the heterotrophic eukaryote's food vacuole.

Among lineages in which secondary endosymbiosis occurred in the more distant past, many parts of the engulfed alga have become reduced or have been lost completely. In most of these lineages, for example, the nucleomorph has disappeared.

Concept Check 28.1

1. List at least four examples of structural and functional diversity among protists.
2. Immediately after a eukaryotic cell ingests a gram-negative cyanobacterium during primary endosymbiosis, how many membranes separate the cytoplasm of the bacterium from the fluid outside the eukaryotic cell? Identify each membrane.

For suggested answers, see Appendix A.

A Figure 28.4 A tentative phylogeny of eukaryotes. Eukaryotes labeled on the branches are grouped into larger clades, which are named at the top of the tree. The kingdoms Fungi, Animalia, and Plantae have survived from the five-kingdom system of classification, although their boundaries have changed somewhat. Clades that used to be included in the kingdom Protista are color-coded yellow.

Concept 28.2

Diplomonads and parabasalids have modified mitochondria

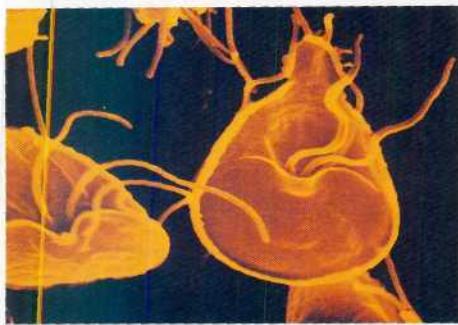

Now that we have examined some of the broad patterns in eukaryotic evolution, we will look more closely at several of the main clades of protists (Figure 28.4).

We begin this tour with Diplomonadida (the diplomonads) and Parabasalida (the parabasalids). Protists in these two clades lack plastids, and their mitochondria do not have DNA, electron transport chains, or enzymes that are normally needed for the citric acid cycle. In some species, the mitochondria are very small and produce cofactors for enzymes involved in ATP production in the cytosol. Most diplomonads and parabasalids are found in anaerobic environments.

Diplomonads

Diplomonads have two equal-sized nuclei and multiple flagella. Recall that eukaryotic flagella are extensions of the cytoplasm, consisting of bundles of microtubules covered by the cell's plasma membrane (see Figure 6.24). They are quite different from prokaryotic flagella, which are filaments composed of the globular protein flagellin attached to the cell surface (see Figure 27.6).

An infamous example of a diplomonad is *Giardia intestinalis* (Figure 28.5a), a parasite that inhabits the intestine of mammals. People most often pick up *Giardia* by drinking water contaminated with feces containing the parasite in a dormant cyst stage. Drinking such contaminated water from a seemingly pristine stream or river can cause severe diarrhea and ruin a camping trip. Boiling the water before drinking it kills the cysts.

(a) *Giardia intestinalis*, a diplomonad (colorized SEM)

(b) *Trichomonas vaginalis*, a parabasalid (colorized SEM)

- Figure 28.5 Diplomonads and parabasalids.

Farabasalids

Farabasalids include the protists called trichomonads. The most well-known species is *Trichomonas vaginalis*, a common inhabitant of the vagina of human females (Figure 28.5b). *T. vaginalis* travels along the mucus-coated lining of the reproductive and urinary tracts of its host by moving its flagella and by undulating part of its plasma membrane. If the normal acidity of the vagina is disturbed, *X. vaginalis* can outcompete beneficial microbes and infect the vaginal lining. Such infections, which can be sexually transmitted, can also occur in the urethra of males, though often without symptoms. Genetic studies of *X. vaginalis* suggest that the species became pathogenic when some of these parabasalids acquired a particular gene through horizontal gene transfer from bacteria that also dwell in the vagina. The gene allows *T. vaginalis* to feed on epithelial cells, resulting in infection.

Concept Check 28.2

1. Why do some biologists describe the mitochondria of diplomonads and parabasalids as "highly reduced"?
2. How is the structure of *Trichomonas vaginalis* well suited to its parasitic lifestyle inside its host's reproductive and urinary tracts?

For suggested answers, see Appendix A.

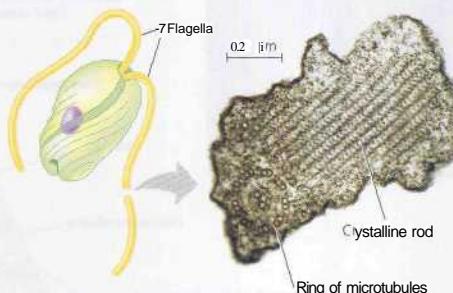

Concept 28.3

Euglenozoans have flagella with a unique internal structure

Euglenozoans (the euglenozoans) is a diverse clade that includes predatory heterotrophs, photosynthetic autotrophs, and pathogenic parasites. The main feature that distinguishes protists in this clade is the presence of a spiral or crystalline rod of unknown function inside their flagella (Figure 28.6). Most euglenozoans also have disk-shaped mitochondrial cristae. The two best-studied groups of euglenozoans are the kinetoplastids and the euglenids.

Kinetoplastids

Kinetoplastids have a single, large mitochondrion that contains an organized mass of DNA called a kinetoplast. These protists include free-living consumers of prokaryotes in freshwater, marine, and moist terrestrial ecosystems, as well as species that parasitize animals, plants, and other protists. For example,

A Figure 28.6 Euglenozoan flagellum. Most euglenozoans have a crystalline rod inside one of their flagella (TEM). The rod lies alongside the $9 + 2$ ring of microtubules found in all eukaryotic flagella (compare with Figure 6.24).

kinetoplastids in the genus *Trypanosoma* cause sleeping sickness in humans, a disease spread by the African tsetse fly that is invariably fatal if left untreated (Figure 28.7). Trypanosomes also cause Chagas' disease, which is transmitted by bloodsucking insects and can lead to congestive heart failure.

Trypanosomes evade immune detection with an effective "bait-and-switch" defense. The surface of a trypanosome is

A Figure 28.7 *Trypanosoma*, the kinetoplastid that causes sleeping sickness. The squiggles among these red blood cells are the trypanosomes (colorized SEM).

coated with millions of copies of a single protein. However, before the host's immune system can recognize the protein and mount an attack, new generations of the parasite switch to another surface protein with a slightly different molecular structure. Frequent changes in the structure of the surface protein prevent the host from developing immunity. As much as a third of *Trypanosoma*'s genome is dedicated to the production of these surface proteins.

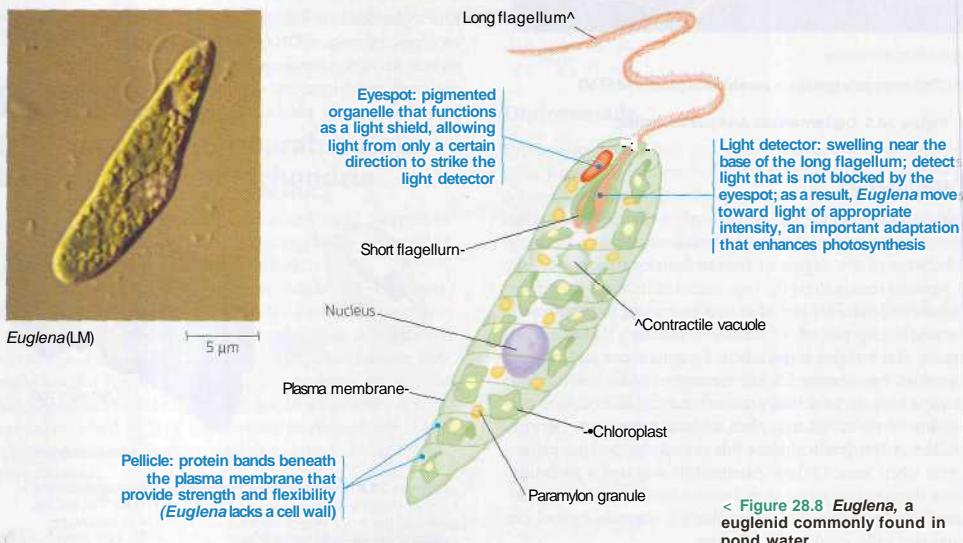

Euglenids

Euglenids have a pocket at one end of the cell from which one or two flagella emerge (Figure 28.8). Paramylon, a glucose polymer that functions as a storage molecule, is also characteristic of euglenids. Many species of the euglenid *Euglena* are autotrophic, but when sunlight is unavailable, they can become heterotrophic, absorbing organic nutrients from their environment. Many other euglenids can engulf prey by phagocytosis.

Concept Check 28.3

- How is *Trypanosoma*'s ability to produce an array of cell-surface proteins advantageous to its survival?
- Is *Euglena* an alga? Explain your answer.

For suggested answers, see Appendix A.

< Figure 28.8 *Euglena*, a euglenid commonly found in pond water.

Concept 28.4

Alveolates have sacs beneath the plasma membrane

Another clade of protists whose identity is emerging from molecular systematics, Alveolata (the alveolates), is characterized by membrane-bounded sacs (alveoli) just under the plasma membrane (**Figure 28.9**). The function of the alveoli is unknown; researchers hypothesize that they may help stabilize the cell surface or regulate the cell's water and ion content.

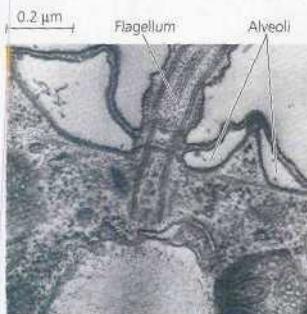

Alveolata includes three groups: a group of flagellates (dinoflagellates), a group of parasites (apicomplexans), and a group of protists that move by means of cilia (ciliates).

Dinoflagellates

Dinoflagellates are abundant components of both marine and freshwater phytoplankton. There are also heterotrophic dinoflagellates. Of the several thousand known dinoflagellate species, most are unicellular, but some are colonial. Each has a characteristic shape that in many species is reinforced by internal plates of cellulose. Two flagella located in perpendicular grooves in this "armor" make dinoflagellates (from the Greek *dinos*, whirling) spin as they move through the water (**Figure 28.10**).

Dinoflagellate blooms—episodes of explosive population growth—can cause a phenomenon called "red tide" in coastal waters. The blooms appear brownish red or pinkish orange because of the presence of carotenoids, the most common pigments in dinoflagellate plastids. Toxins produced by certain dinoflagellates can cause massive kills of invertebrates and fishes. Humans who consume molluscs that have accumulated the toxins are affected as well, sometimes fatally.

Some dinoflagellates are spectacularly bioluminescent: An ATP-driven chemical reaction creates an eerie glow at night when waves, boats, or swimmers agitate seawater with dense populations of the dinoflagellates. One possible function of

•4 Figure 28.9
Alveoli. These sacs under the plasma membrane are a defining characteristic of alveolates (TEM).

4 Figure 28.10 *Pfiesteria shumwayae*, a dinoflagellate. Beating of the spiral flagellum, which lies in a groove that encircles the cell, makes this alveolate spin (colorized SEM).

this bioluminescence is that when the water is disturbed by organisms that feed on dinoflagellates, the light attracts fishes that eat those predators.

Some dinoflagellates are mutualistic symbionts of coral polyps, animals that build coral reefs. The dinoflagellates' photosynthetic output is the main food for reef communities.

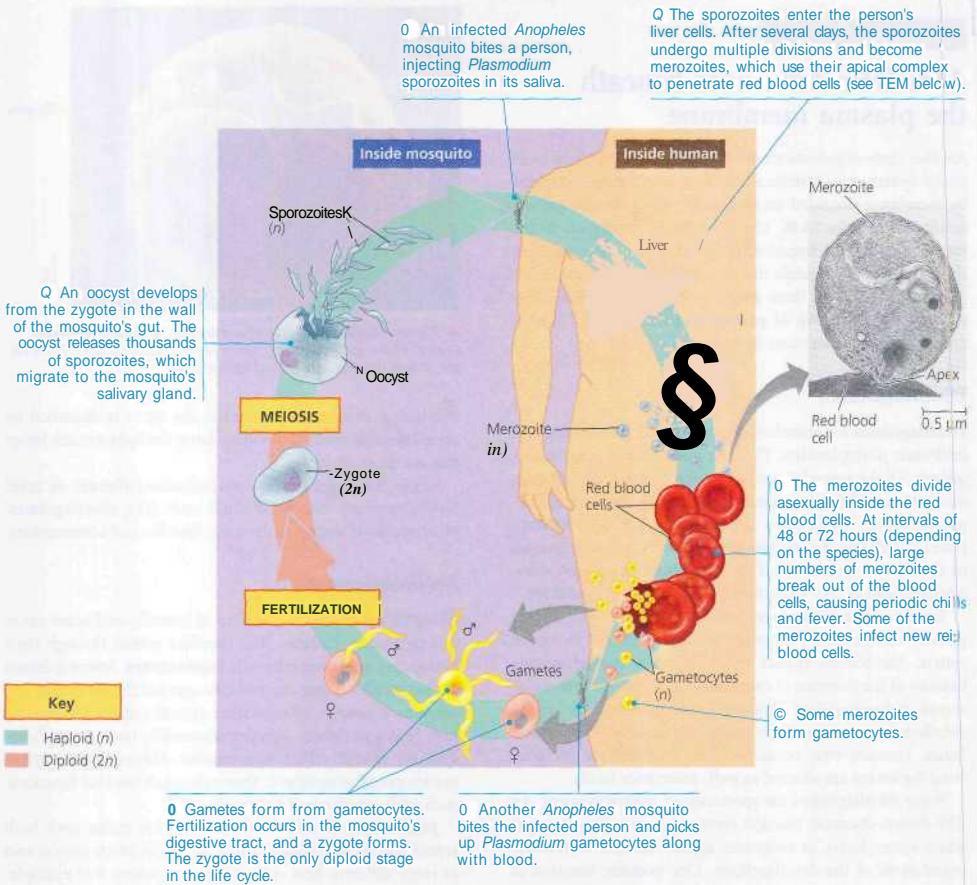

Apicomplexans

All apicomplexans are parasites of animals, and some cause serious human diseases. The parasites spread through their host as tiny infectious cells called sporozoites. Apicomplexans are so named because one end (the apex) of the sporozoite cell contains a complex of organelles specialized for penetrating host cells and tissues. Apicomplexans also have a nonphotosynthetic plastid, called the apicoplast. Although apicomplexans are not photosynthetic, their apicoplast has vital functions, such as the synthesis of fatty acids.

Most apicomplexans have intricate life cycles with both sexual and asexual stages. Those life cycles often require two or more different host species for completion. For example, *Plasmodium*, the parasite that causes malaria, lives in both mosquitoes and humans (**Figure 28.11**, on the next page).

The incidence of malaria was greatly diminished in the 1960s by the use of insecticides that reduced populations of *Anopheles* mosquitoes, which spread the disease, and by drugs that killed *Plasmodium* in humans. But the emergence of resistant varieties of both *Anopheles* and *Plasmodium* has led to a resurgence of malaria. About 300 million people in the tropics are now infected, and up to 2 million die each year from the disease.

The search for malarial vaccines has been hampered by the fact that *Plasmodium* spends most of its time inside human cells, hidden from the host's immune system. And, like trypanosomes, *Plasmodium* continually changes its surface proteins. The urgent need for new treatments for malaria inspired an ambitious effort to sequence *Plasmodium*'s genome. By 2003, researchers

A Figure 28.11 The two-host life cycle of *Plasmodium*, the apicomplexan that causes malaria. (Colors are not true to life.)

had tracked the expression of most of the parasite's genes at numerous points in its life cycle. This research could help scientists identify potential new targets for vaccines.

Ciliates

Ciliates are a large, varied group of protists named for their use of cilia to move and feed. The cilia may completely cover the cell surface or may be clustered in a few rows or tufts. In certain species, such as *Stentor* (see Figure 28.2a), rows of tightly packed cilia function collectively in locomotion. Other ciliates scurry about on leglike structures constructed from

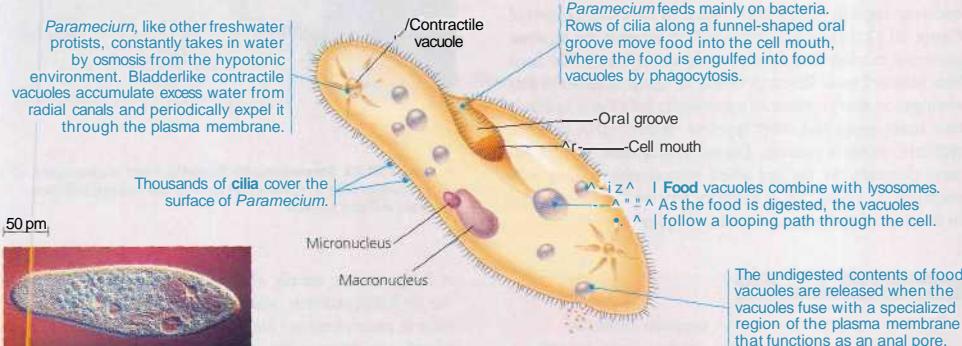

many cilia bonded together. A submembrane system of microtubules coordinates ciliary movements.

A distinctive feature of ciliates is the presence of two types of nuclei: large macronuclei and tiny micronuclei. A cell may have one or more nucleus of each type. Each macronucleus typically contains dozens of copies of the ciliates genome. These genes are not organized in chromosomes but instead are packaged in smaller units, each bearing many duplicates of just a few genes. Macronuclear genes control the everyday functions of the cell, such as feeding, waste removal, and maintaining water balance. The upper portion of Figure 28.12 explores these functions in the ciliate *Paramecium*.

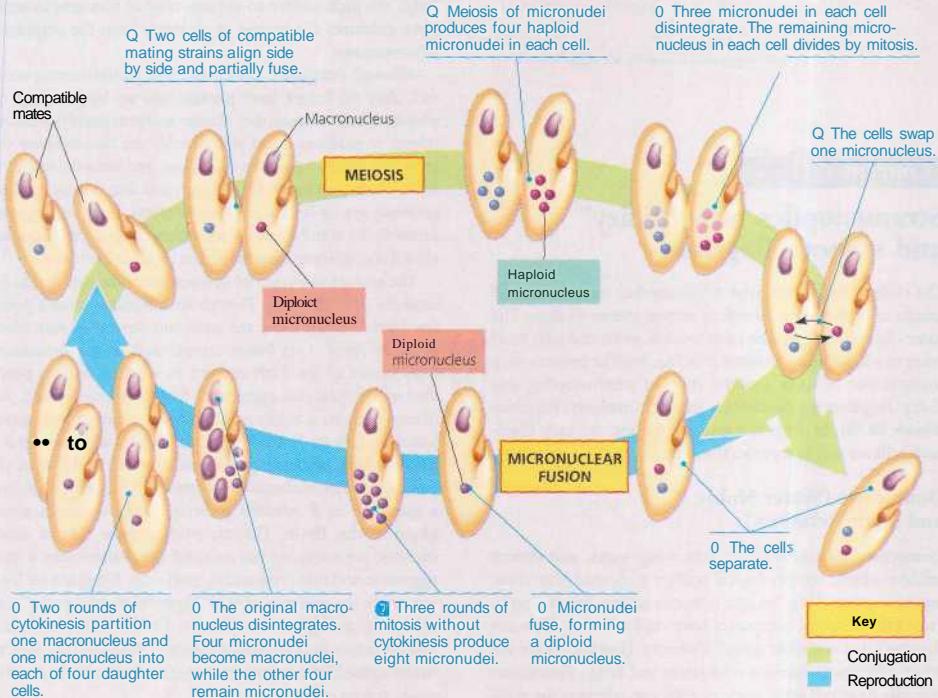

Exploring Structure and Function in the Ciliate *Paramecium caudatum*

FEEDING, WASTE REMOVAL, AND WATER BALANCE

Paramecium, like other freshwater protists, constantly takes in water by osmosis from the hypotonic environment. Bladderlike contractile vacuoles accumulate excess water from radial canals and periodically expel it through the plasma membrane.

CONJUGATION AND REPRODUCTION

Ciliates generally reproduce asexually by binary fission, during which the macronucleus elongates and splits, rather than undergoing mitotic division. Genetic variation results from conjugation, a sexual process in which two individuals exchange haploid micronuclei. Notice in the lower portion of Figure 28.12 that reproduction and conjugation are separate processes in ciliates. In 2003, a team of scientists at the Fred Hutchinson Cancer Research Center in Seattle discovered that conjugation also provides an opportunity for ciliates to eliminate transposons and other types of "selfish" DNA that can replicate within a genome. During conjugation, foreign genetic elements are excised when micronuclei develop into macronuclei. Up to 15% of a ciliate's genome may be removed in this way every time it undergoes conjugation.

Concept Check 28.4

- What morphological feature supports molecular data that suggest combining dinoflagellates, apicomplexans, and ciliates in a single clade?
- Why is a "red tide" a cause for concern to people who eat locally caught seafood?
- Why is it incorrect to refer to conjugation in ciliates as a form of reproduction?

For suggested answers, see Appendix A.

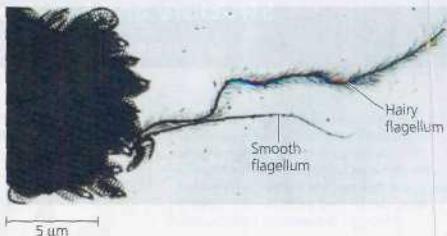

Concept 28.5

Stramenopiles have "hairy" and smooth flagella

The clade Stramenopila (the stramenopiles) includes several groups of heterotrophs as well as certain groups of algae. The name of the clade (from the Latin *stramen*, straw, and *pilos*, hair) refers to a flagellum with numerous fine, hairlike projections, a characteristic of these protists. In most stramenopiles, this "hairy" flagellum is paired with a "smooth" (nonhairy) flagellum (Figure 28.13). In some stramenopile groups, the only flagellated cells are motile reproductive cells.

Oomycetes (Water Molds and Their Relatives)

Oomycetes include water molds, white rusts, and downy mildews. Early morphological studies suggested that these organisms were fungi (in fact, *oomycete* means "egg fungus"). For example, many oomycetes have multinucleate filaments (hyphae) that resemble fungal filaments. However, there are many differences between oomycetes and fungi. Oomycetes typically have cell walls made of cellulose, whereas the walls

A Figure 28.13 Stramenopile flagella. Most stramenopiles, such as *Synura petersenii*, have two flagella: one covered with fine, stiff hairs and one smooth.

of fungi consist mainly of another polysaccharide, chitin. The diploid condition, which is reduced in fungi, predominates in most oomycete life cycles. Oomycetes also have flagellated cells, whereas almost all fungi lack flagella. Molecular systematics has confirmed that oomycetes are not closely related to fungi. Their superficial similarity is a case of convergent evolution (see Chapter 25). In both oomycetes and fungi, the high surface-to-volume ratio of filamentous structures enhances the uptake of nutrients from the organisms' environments.

Although oomycetes descended from plastid-bearing ancestors, they no longer have plastids and no longer carry out photosynthesis. Instead, they acquire nutrients mainly as decomposers or parasites. Most water molds are decomposers that grow as cottony masses on dead algae and animals, mainly in fresh water (Figure 28.14). White rusts and downy mildews generally live on land as parasites of plants. They are dispersed primarily by windblown spores, although they also form flagellated zoospores at some point during their life cycles.

The ecological impact of oomycetes can be significant. For example, the oomycete *Phytophthora infestans* causes potato late blight, which turns the stalk and stem of potato plants to black slime. Late blight contributed to the devastating Irish famine of the 19th century, in which a million people died and at least that many were forced to leave Ireland. The disease remains a major problem today, causing typical crop losses of 15% in North America and 70% in some parts of Russia where pesticides are unavailable. To understand this pathogen better, molecular biologists have isolated DNA from a specimen of *P. infestans* preserved from the Irish potato blight of the 1840s. Genetic studies show that in recent decades, the oomycete has acquired genes that make it more aggressive and more resistant to pesticides. Scientists are looking within the genomes of both *Phytophthora* and potatoes for new weapons against the disease. In 2003, for example, a team of researchers produced domestic potatoes that were resistant to late blight by transferring genes from a blight-resistant strain of wild potato.

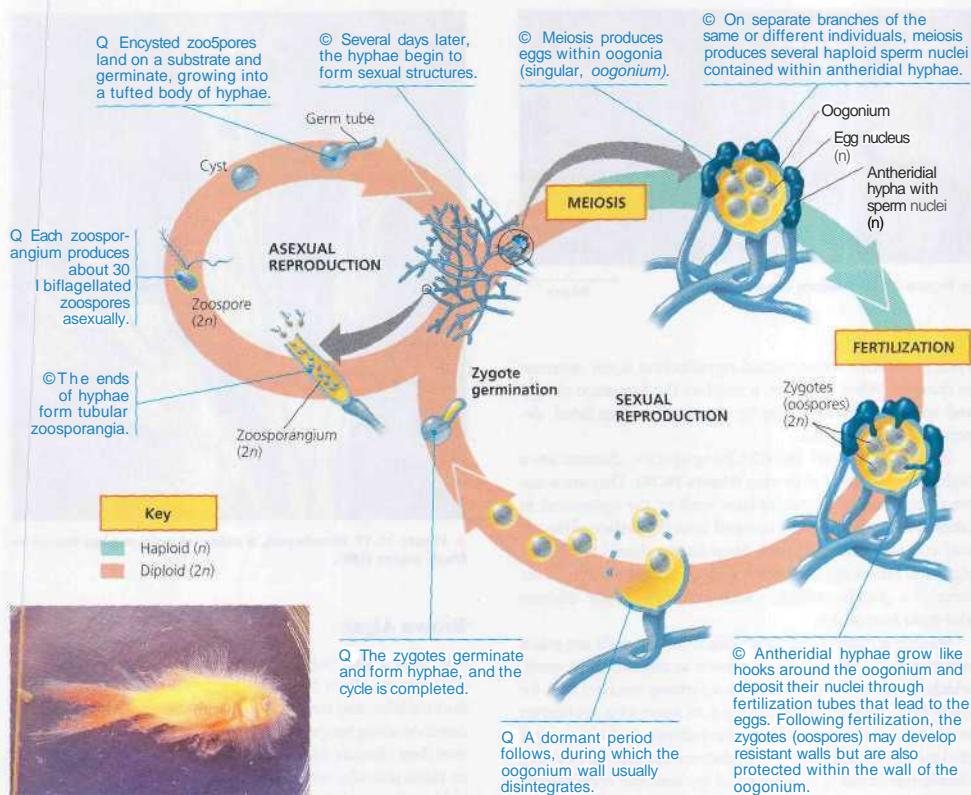

Figure 23.14 The life cycle of a water mold. Water molds help decompose dead insects, fishes, and other animals in fresh water. (Note the hyphal mass on the goldfish in the inset.)

Diatoms

Diatoms (also called bacillariophytes) are unicellular algae that have a unique glass-like wall made of hydrated silica embedded in an organic matrix. The wall consists of two parts that overlap like a shoe box and its lid (**Figure 28.15**). These walls provide effective protection from the crushing jaws of predators: In 2003, German researchers discovered that live diatoms can withstand pressures of up to $1.4 \text{ million kg/m}^2$, equal to the pressure under each leg of a table supporting an elephant! Much of the strength of diatoms comes from the delicate lacework of holes and grooves in their walls—if the walls were smooth, it would take 60% less force to crush them.

Most of the year, diatoms reproduce asexually by mitosis, with each daughter cell receiving half of the parental cell wall and generating a new half that fits inside it. Some species form

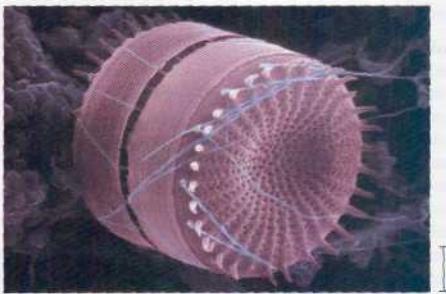

Figure 28.15 A freshwater diatom (colorized SEM).

▲ Figure 28.16 Diatom diversity (LM).

50 µm

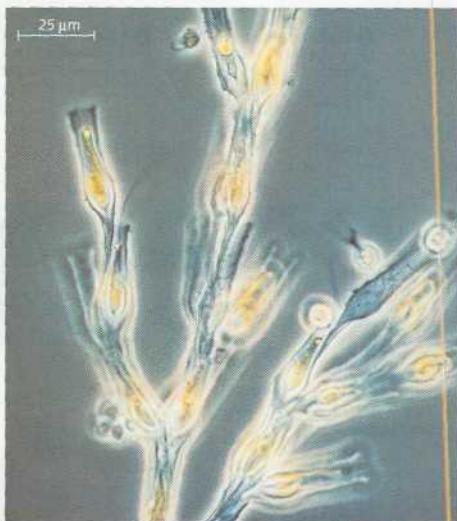

cysts as resistant stages. Sexual reproduction is not common in diatoms. When it occurs, it involves the formation of eggs and sperm; sperm cells may be amoeboid or flagellated, depending on the species.

With an estimated 100,000 living species, diatoms are a highly diverse group of protists (Figure 28.16). They are a major component of phytoplankton both in the ocean and in lakes: One bucket of water scooped from the surface of the sea may contain millions of these microscopic algae. Like golden algae and brown algae, diatoms store their food reserves in the form of a glucose polymer called laminarin. Some diatoms also store food as oil.

Massive accumulations of fossilized diatom walls are major constituents of the sediments known as diatomaceous earth, which is mined for its quality as a filtering medium and for many other uses. Diatoms also have an interesting application in the field of nanotechnology—the fashioning of microscopic devices. In building their shells, diatoms perform an intricate, three-dimensional self-assembly of microscopic components. Nano-engineers are studying this process as a model for the manufacture of miniature motors, lasers, and medicine-delivery systems. They are even exploring the idea of modifying diatom DNA to produce specific structures for humans.

Golden Algae

Golden algae, or chrysophytes (from the Greek *chrysos*, golden), are named for their color, which results from their yellow and brown carotenoids. The cells of golden algae are typically biflagellated, with both flagella attached near one end of the cell. Many golden algae are components of freshwater and marine plankton. While all golden algae are photosynthetic, some species are mixotrophic, and can also absorb dissolved organic compounds or ingest food particles and prokaryotes by phagocytosis. Most species are unicellular, but some, such as the freshwater genus *Dinobryon*, are colonial (Figure 28.17). If cell density exceeds a certain level, many species form resistant cysts that can survive for decades.

A Figure 28.17 *Dinobryon*, a colonial golden alga found in fresh water (LM).

Brown Algae

The largest and most complex algae are **brown algae**, or phaeophytes (from the Greek *phaios*, dusky, brown). All are multicellular, and most are marine. Brown algae are especially common along temperate coasts, where the water is cool. They owe their characteristic brown or olive color to the carotenoids; in their plastids, which are homologous to the plastids of green algae and diatoms.

Brown algae include many of the species commonly called seaweeds. (Some large, multicellular species of red and green algae are also referred to as seaweeds. We will examine them later in this chapter.) Seaweeds have the most complex multicellular anatomy of all algae. Some even have specialized tissues and organs that resemble those in plants. But various evidence indicates that the similarities evolved independently in the algal and plant lineages and are thus analogous, not homologous.

The term **thallus** (plural, *thalli*; from the Greek *thallos*, sprout) refers to a seaweed body that is plant-like. Unlike the body of a plant, however, a thallus lacks true roots, stems, and leaves. A typical seaweed thallus consists of a rootlike **holdfast**, which anchors the alga, and a stemlike **stipe**, which supports leaflike **blades** (Figure 28.18). The blades provide most of the surface for photosynthesis. Some brown algae are equipped with floats, which keep the blades near the water surface. Beyond the intertidal zone in deeper waters live giant seaweeds

JFigure 28.18 Seaweeds: adapted to life at the ocean's margins. The sea palm (*Postelsia*) lives on rocks along the coast of the northwestern United States and western Canada. The thallus of this brown alga is well adapted to maintaining a firm foothold despite the crashing surf.

(a) The seaweed is grown on nets in shallow coastal waters.

(b) A worker spreads the harvested seaweed on bamboo screens to dry.

(c) Paper-thin, glossy sheets of nori make a mineral-rich wrap for rice, seafood, and vegetables in sushi.

& Figure 28.20 Edible seaweed. Nori is a traditional Japanese food made from the seaweed *Porphyra* (a red alga, which we discuss in more detail later in the chapter).

A Figure 28.19 A kelp forest. The great kelp beds of temperate coastal waters provide habitat and food for a variety of organisms, including many fish species caught by humans. *Macrocystis*, a kelp common along the Pacific coast of the United States, can grow more than 60 m in a single season, the fastest linear growth recorded in any organism.

known as kelps (Figure 28.19). The stipes of these brown algae may be as long as 60 m.

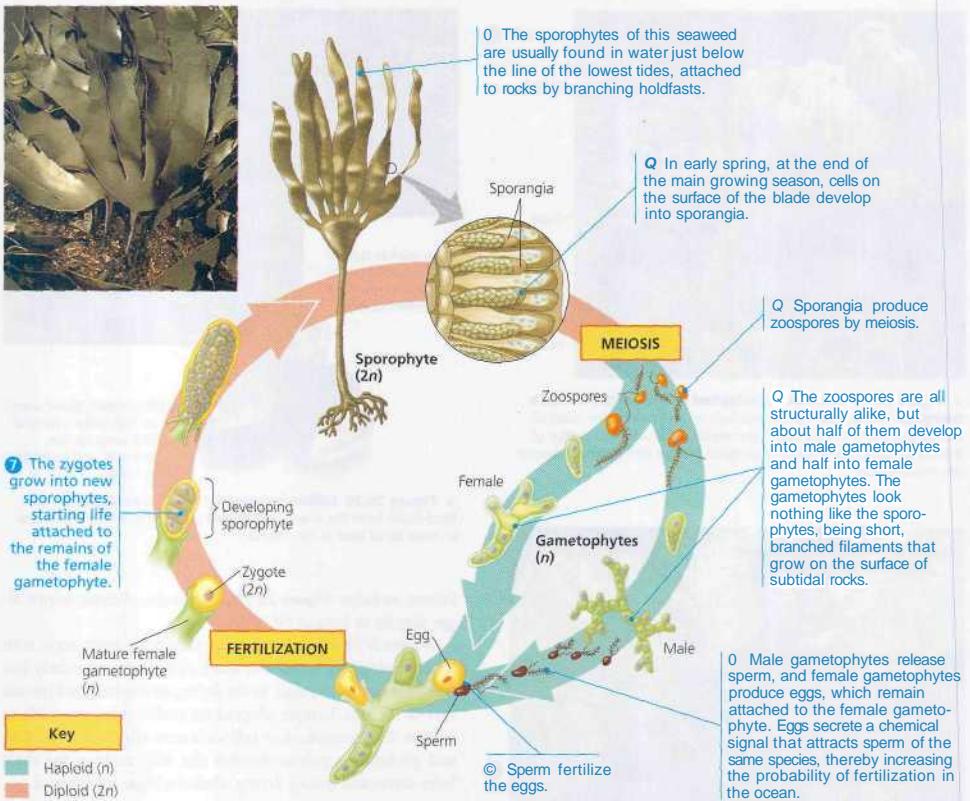

Seaweeds that inhabit the intertidal zone must cope with water churned by waves and wind, along with twice-daily low tides that expose the algae to the drying atmosphere and intense rays of the sun. Unique adaptations enable these seaweeds to survive. For example, their cell walls are composed of cellulose and gel-forming polysaccharides that help cushion the thalli from waves and reduce drying when the algae are exposed.

Human Uses of Seaweeds

Seaweeds—brown algae as well as large, multicellular red and green algae, which we discuss later in the chapter—are important commodities for humans. Many seaweeds are harvested for food. For example, the brown alga *Laminaria* (Japanese "kombu") is used in soups, and the red alga *Porphyra* (Japanese "nori") is eaten as crispy sheets or used to wrap sushi (Figure 28.20). The gel-forming substances in the cell walls of algae (algin in brown algae, agar and carrageenan in red algae) are also used to thicken many processed foods, such as pudding, ice cream, and salad dressing.

Alternation of Generations

A variety of life cycles have evolved among the multicellular algae. The most complex life cycles include an **alternation of generations**, the alternation of multicellular haploid and diploid forms. Although haploid and diploid conditions

A Figure 28.21 The life cycle of *Laminaria*: an example of alternation of generations.

alternate in *all* sexual life cycles—human gametes, for example, are haploid—the term alternation of generations applies only to life cycles in which both haploid and diploid stages are multicellular. As you will read in Chapter 29, alternation of generations also evolved in the life cycles of all plants.

The complex life cycle of the brown alga *Laminaria* is an example of alternation of generations (Figure 28.21). The diploid individual is called the sporophyte because it produces reproductive cells called zoospores. The zoospores develop into haploid male and female gametophytes, which produce gametes. The union of two gametes (fertilization, or syngamy) results in a diploid zygote, which gives rise to a new sporophyte.

In *Laminaria*, the two generations are heteromorphic, meaning that the sporophytes and gametophytes are structurally different. Other algal life cycles have an alternation of

isomorphic generations, in which the sporophytes and gametophytes look similar to each other, although they differ in chromosome number.

Concept Check 28.5

- What unique cellular feature is common to all stramenopiles?
- Compare the nutrition of oomycetes with that of golden algae.
- How is the structure of a brown alga such as *Laminaria* well suited to its intertidal zone habitat?

For suggested answers, see Appendix A.

Concept 28.6

Cercozoans and radiolarians have threadlike pseudopodia

A newly recognized clade, Cercozoa (the cercozoans), contains a diversity of species that are among the organisms referred to as amoebas. Amoebas were formerly defined as protists that move and feed by means of pseudopodia, extensions that may bulge from virtually anywhere on the cell surface. When an amoeba moves, it extends a pseudopodium and anchors the tip, and then more cytoplasm streams into the pseudopodium. However, based on molecular systematics, it is now clear that amoebas do not constitute a monophyletic group but are dispersed across many distantly related eukaryotic taxa. Those that belong to the clade Cercozoa are distinguished morphologically from most other amoebas by their threadlike pseudopodia. Cercozoans include chlorarachniophytes (mentioned earlier in this chapter in the discussion of secondary endosymbiosis) and foraminiferans. Protists in another clade, Radiolaria (the radiolarians), also have threadlike pseudopodia and are closely related to cercozoans.

Foraminiferans (Forams)

Foraminiferans (from the Latin *foramen*, little hole, and *erre*, to bear, or forams, are named for their porous shells, called tests (Figure 28.22). Foram tests are generally multichambered and consist of organic material hardened with calcium carbonate. The pseudopodia that extend through the pores function in swimming, test formation, and feeding. Many forams also

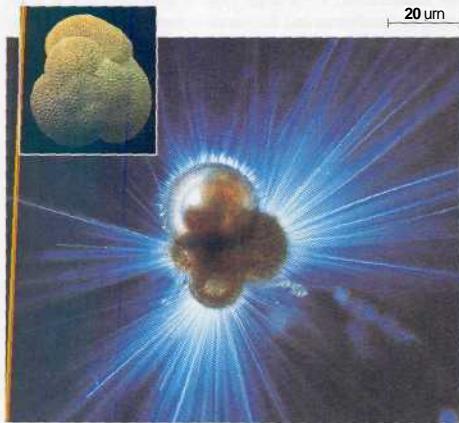

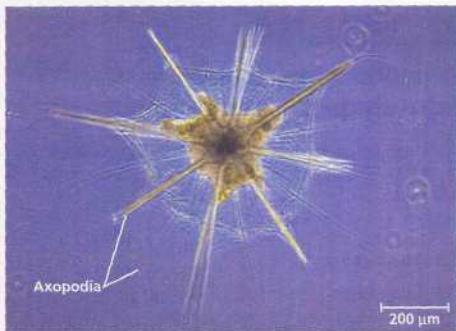

Figure 28.22 *Globigerina*, a foram with a snail-like test. Threadlike pseudopodia extend through pores in the test (LM). The inset SEM shows a calcareous foram test.

A. Figure 28.23 A radiolarian. Numerous threadlike axopodia radiate from the central body of this radiolarian, which is found in the Red Sea (LM).

derive nourishment from the photosynthesis of symbiotic algae that live within the tests.

Forams are found in both the ocean and fresh water. Most species live in the sand or attach themselves to rocks or algae, but some are abundant in plankton. The largest forams, though single-celled, grow to a diameter of several centimeters.

Ninety percent of all identified species of forams are known from fossils. Along with the calcareous remains of other protists, the fossilized tests of forams are components of marine sediments, including sedimentary rocks that are now land formations. Foram fossils are excellent markers for correlating the ages of sedimentary rocks in different parts of the world.

Radiolarians

Radiolarians are mostly marine protists whose tests are fused into one delicate piece, which is generally made of silica. The pseudopodia of radiolarians, known as axopodia, radiate from the central body and are reinforced by bundles of microtubules (Figure 28.23). The microtubules are covered by a thin layer of cytoplasm, which surrounds through phagocytosis smaller microorganisms that become attached to the axopodia. Cytoplasmic streaming then carries the engulfed prey into the main part of the cell. After radiolarians die, their tests settle to the seafloor, where they have accumulated as an ooze that is hundreds of meters thick in some locations.

Concept Check 28.6

1. Why do forams have such a well-preserved fossil record?
2. Compare feeding in forams and radiolarians.

For suggested answers, see Appendix A.

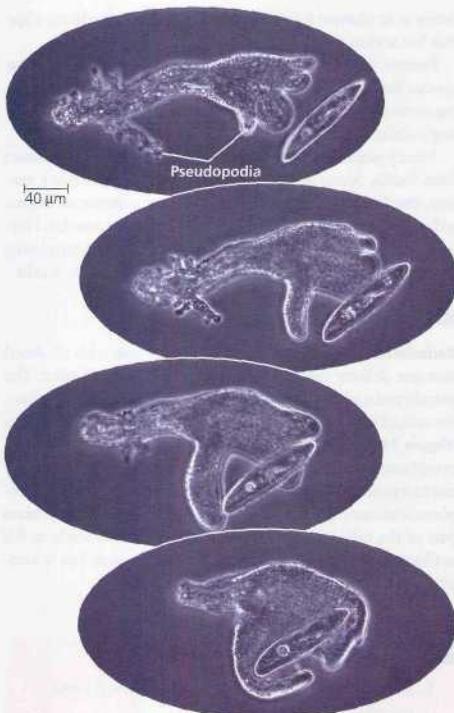

Concept 28.7

Amoebozoans have lobe-shaped pseudopodia

Many species of amoebas that have lobe-shaped, rather than threadlike, pseudopodia belong to the clade Amoebozoa (the amoebozoans). Amoebozoans include gymnamoebas, entamoebas, and slime molds.

Gymnamoebas

Gymnamoebas constitute a large and varied group of amoebas. These unicellular protists are ubiquitous in soil as well as freshwater and marine environments. Most are heterotrophs that actively seek and consume bacteria and other protists (Figure 28.24). Some gymnamoebas also feed on detritus (non-living organic matter).

• **Figure 28.24** A gymnamoeba feeding. In this series of images selected from a video, a gymnamoeba (*Amoeba* sp.) uses its lobe-shaped pseudopodia to engulf its prey, a eukaryote.

Entamoebas

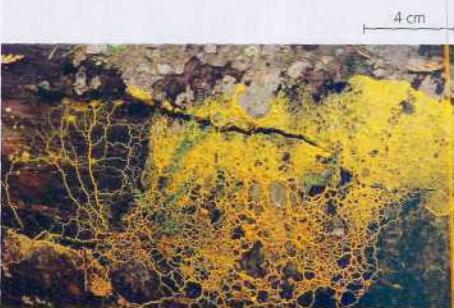

Whereas most amoebozoans are free-living, those that belong to the genus *Entamoeba* are parasites that infect all classes of vertebrates as well as some invertebrates. Humans host at least six species of *Entamoeba*, but only one, *E. histolytica*, is known to be pathogenic. *E. histolytica* causes amebic dysentery and is spread via contaminated drinking water, food, or eating utensils. Responsible for up to 100,000 deaths worldwide every year, the disease is the third-leading cause of death due to parasites, after malaria and schistosomiasis (see Chapter 33).

Slime Molds

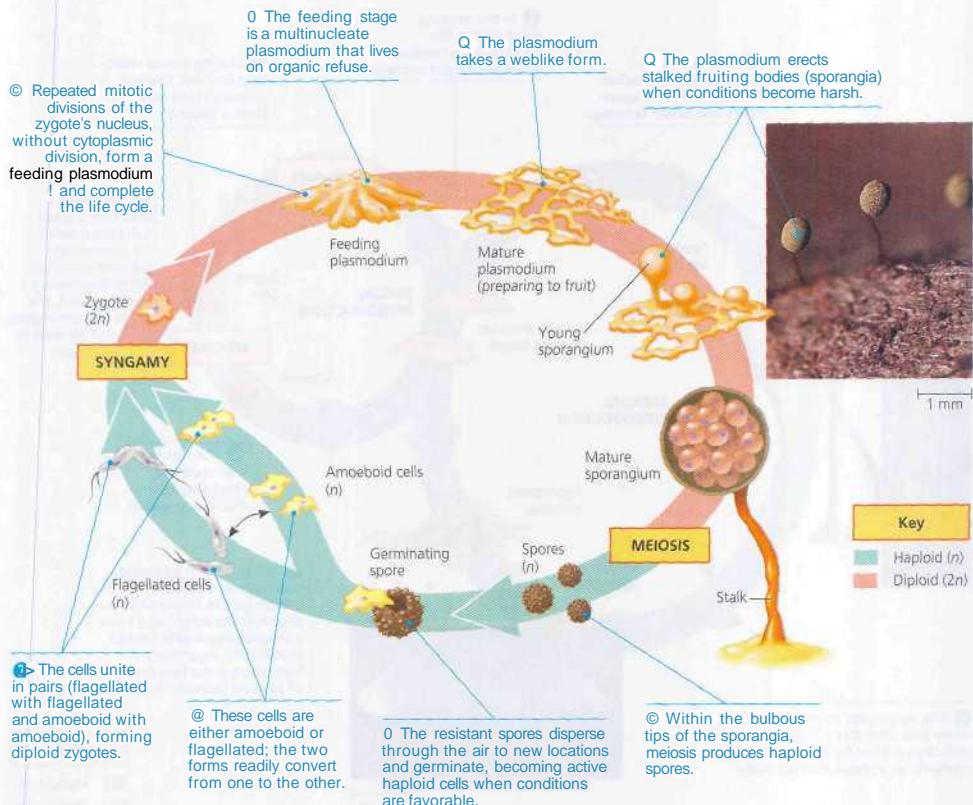

Slime molds, or mycetozoans (from the Latin meaning "fungus animals"), were once thought to be fungi because, like fungi, they produce fruiting bodies that aid in spore dispersal. However, the resemblance between mycetozoans and fungi appears to be another example of evolutionary convergence. Molecular systematics places slime molds in the clade Amoebozoa and suggests that they descended from unicellular, gymnamoeba-like ancestors. Slime molds have diverged into two main branches, plasmodial slime molds and cellular slime molds, which are distinguished in part by their distinctive life cycles.

Plasmodial Slime Molds

Many species of plasmodial slime molds are brightly pigmented, usually yellow or orange (Figure 28.25). At one stage in their life cycle, they form a mass called a plasmodium, which may grow to a diameter of many centimeters (Figure 28.26). (Don't confuse a slime mold! plasmodium with the apicomplexan parasite *Plasmodium*.) Despite its size, the plasmodium is not multicellular; it is a single mass of cytoplasm that is undivided by membranes and that contains many diploid nuclei. This "supercell" is the product of mitotic nuclear divisions that are not followed by cytokinesis, the division of cytoplasm. In most species, the mitotic divisions are synchronous, meaning that

A **Figure 28.25** *Physarum polycephalum*, a plasmodial slime mold.

▲ Figure 28.26 The life cycle of a plasmodial slime mold.

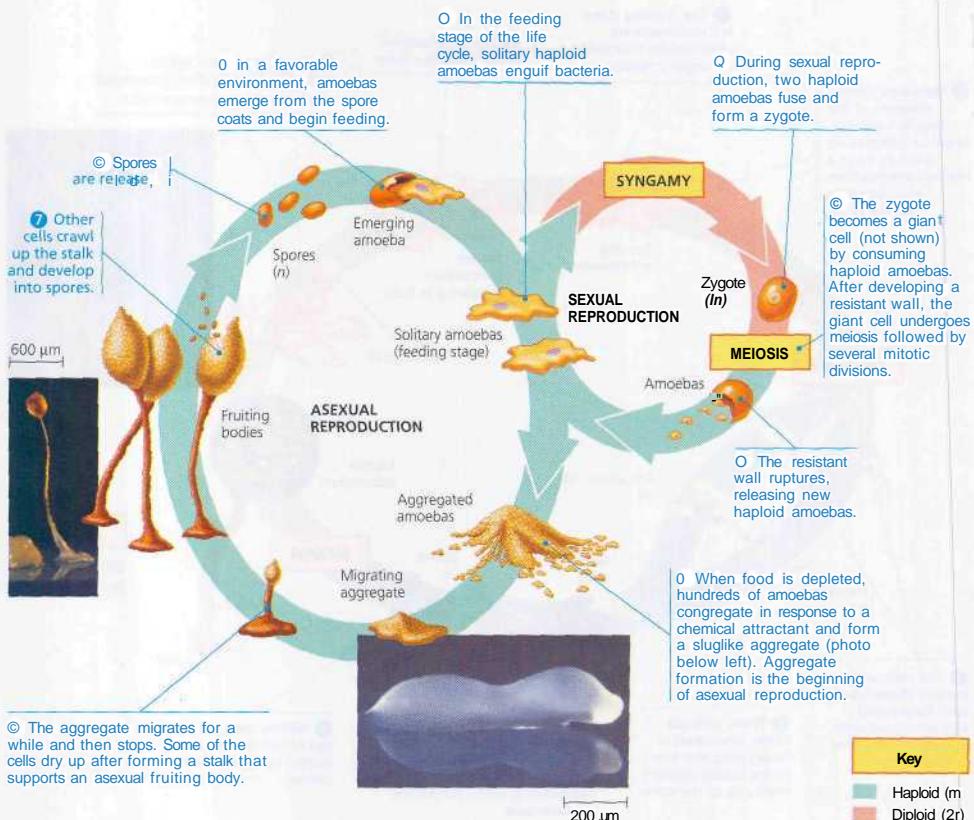

thousands of nuclei go through each phase of mitosis at the same time. Because of this characteristic, plasmodial slime molds have been used to study the molecular details of the cell cycle.

Within the line channels of the plasmodium, cytoplasm streams first one way, then the other, in pulsing flows that are beautiful to watch through a microscope. This cytoplasmic Streaming apparently helps distribute nutrients and oxygen. The plasmodium extends pseudopodia through moist soil, leaf mulch, or rotting logs, engulfing food particles by phagocytosis as it grows. If the habitat begins to dry up or there is no food left, the plasmodium stops growing and differentiates into a stage of the life cycle that produces fruiting bodies, which function in sexual reproduction. In most plasmodial slime molds, the diploid condition is the predominant part of the life cycle.

Cellular Slime Molds

Cellular slime molds pose a semantic question about what it means to be an individual organism. The feeding stage of the life cycle consists of solitary cells that function individually but when food is depleted the cells form an aggregate that functions as a unit (Figure 28.27, on the next page). Although this mass of cells superficially resembles a plasmodial slime mold, the cells remain separated by their membranes.

Cellular slime molds also differ from plasmodial slime molds in being haploid organisms (only the zygote is diploid) and in having fruiting bodies that function in asexual rather than sexual reproduction. Furthermore, cellular slime molds have no flagellated stages.

A Figure 28.27 The life cycle of *Dictyostelium*, a cellular slime mold.

Dictyostelium discoideum, a common cellular slime mold on forest floors, has become a model organism for addressing the evolution of multicellularity. One line of research has focused on the fruiting body stage. During this stage, the cells that form the stalk die as they dry out, while the spore cells at the top survive and have the potential to reproduce. Scientists have found that mutations to a single gene can turn individual *Dictyostelium* cells into "cheaters" that never become part of the stalk. Since these mutants gain a strong reproductive advantage over noncheaters, it is puzzling that all *Dictyostelium* cells are not cheaters.

In 2003, scientists at Rice University and the University of Turin, Italy discovered why most of the cells do not cheat. Cheating mutants lack a protein on their cell surface, and noncheating cells can recognize this difference. Noncheaters preferentially aggregate with other noncheaters, thus depriving

cheaters of the opportunity to exploit them. Such a recognition system may have been important in the evolution of multicellular eukaryotes such as animals and plants.

Concept Check 28.7

1. Contrast the pseudopodia of amoebozoans and forams.
2. In what sense is "fungus animal" a fitting description of a slime mold? In what sense is it not a fitting description?
3. Does cooperation between cells exist in amoebozoans? Explain.

For suggested answers, see Appendix A.

Concept 28.8

Red algae and green algae are the closest relatives of land plants

As we described in Chapter 26, molecular systematics and studies of cell structure support this phylogenetic scenario: More than a billion years ago, a heterotrophic protist acquired a cyanobacterial endosymbiont, and the photosynthetic descendants of this ancient protist evolved into red algae and green algae (see Figure 28.3). At least 475 million years ago, the lineage that produced green algae gave rise to land plants. We will examine land plants in Chapters 29 and 30; here we will look at the diversity of their closest algal relatives, red algae and green algae.

Red Algae

Many of the 6,000 known species of **red algae** (rhodophytes, from the Greek *rhos*, red) are reddish, owing to an accessory pigment called phycocerythrin, which masks the green of chlorophyll. However, species adapted to shallower water have less phycocerythrin. As a result, red algae species may be almost black in deep water, bright red at more moderate depths, and greenish in very shallow water. Some species lack pigmentation altogether and function heterotrophically as parasites on other red algae.

Red algae are the most abundant large algae in the warm coastal waters of tropical oceans. Their accessory pigments allow them to absorb blue and green light, which penetrate relatively far into the water. A species of red alga has recently been

discovered living near the Bahamas at a depth of more than 260 m. There are also some freshwater and terrestrial species.

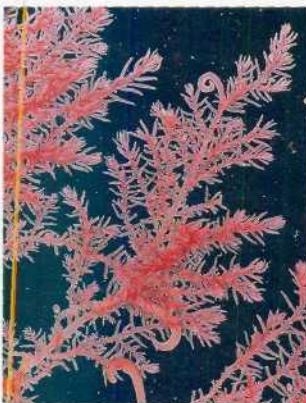

Most red algae are multicellular, and the largest are included in the informal designation "seaweeds" (Figure 28.28), although no red algae are as big as the giant brown kelps. The thalli of many red algae are filamentous, often branched and interwoven in lacy patterns. The base of the thallus is usually differentiated as a simple holdfast.

Red algae have especially diverse life cycles, and alternation of generations is common. But unlike other algae, they have no flagellated stages in their life cycle and depend on water currents to bring gametes together for fertilization.

Green Algae

Green algae are named for their grass-green chloroplasts. In their ultrastructure and pigment composition, these chloroplasts are much like those of organisms we traditionally call plants. Molecular systematics and cellular morphology leave little doubt that green algae and land plants are closely related. In fact, some systematists now advocate the inclusion of green algae in an expanded "plant" kingdom, Viridiplantae (from the Latin *viridis*, green).

Green algae are divided into two main groups, chlorophytes (from the Greek *chloros*, green) and charophyceans (see Figure 28.4). More than 7,000 species of chlorophytes have been identified. Most live in fresh water, but there are also many marine species. The simplest chlorophytes are biflagellated unicellular organisms such as *Chlamydomonas*, which resemble the gametes and zoospores of more complex chlorophytes. Various species of unicellular chlorophytes exist as

(a) *Bonnemaisonia hamifera*. This red alga has a filamentous form.

(b) *Dulse* (*Palmaria palmata*). This edible species has a "leafy" form.

(c) A coralline alga. The cell walls of coralline algae are hardened by calcium carbonate. Some coralline algae are members of the biological communities around coral reefs.

▲ Figure 28.28 Red algae.

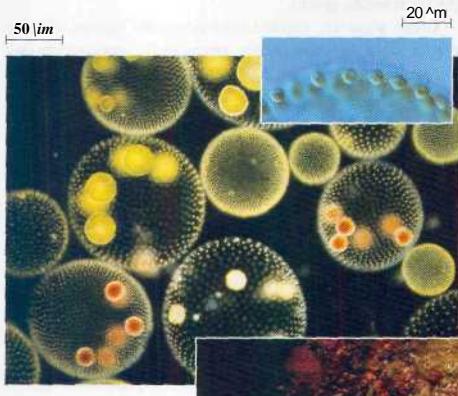

plankton or inhabit damp soil; some live symbiotically within other eukaryotes, contributing part of their photosynthetic output to the food supply of their hosts. Chlorophytes are among the algae that live symbiotically with fungi in the associations called lichens (see Figure 31.24). Some chlorophytes have even adapted to one of the last places on Earth you might expect to find them: snow. For example, *Chlamydomonas nivalis* can form dense algal blooms on high-altitude glaciers and snowfields, where its reddish pigments produce an effect known as "watermelon snow" (Figure 28.29). These chlorophytes carry out photosynthesis despite subfreezing temperatures and intense visible and ultraviolet radiation. They are protected by radiation-blocking compounds in their cytoplasm and by the snow itself, which acts as a shield.

Larger size and greater complexity evolved in chlorophytes by three different mechanisms: (1) the formation of colonies of individual cells, as seen in *Volvox* (Figure 28.30a) and in filamentous forms that contribute to the stringy masses known as pond scum; (2) the repeated division of nuclei with no

• **Figure 28.29 Watermelon snow.** Carotenoids in some snow-dwelling chlorophytes, such as *Chlamydomonas nivalis*, turn the snow red.

f **Figure 28.30 Colonial and multicellular chlorophytes.**

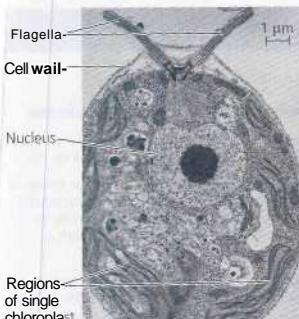

(b) *Caulerpa*, an intertidal chlorophyte. The branched filaments lack cross-walls and thus are multinucleate. In effect the thallus is one huge "supercell."

(c) *Ulva*, or sea lettuce. This edible seaweed has a multicellular thallus differentiated into leaflike blades and a rootlike holdfast that anchors the alga against turbulent waves and tides.

(a) *Volvox*, a colonial freshwater chlorophyte. The colony is a hollow ball whose wall is composed of hundreds or thousands of biflagellated cells (see inset LM) embedded in a gelatinous matrix. The cells are usually connected by strands of cytoplasm; if isolated, these cells cannot reproduce. The large colonies seen here will eventually release the small "daughter" colonies within them (LM).

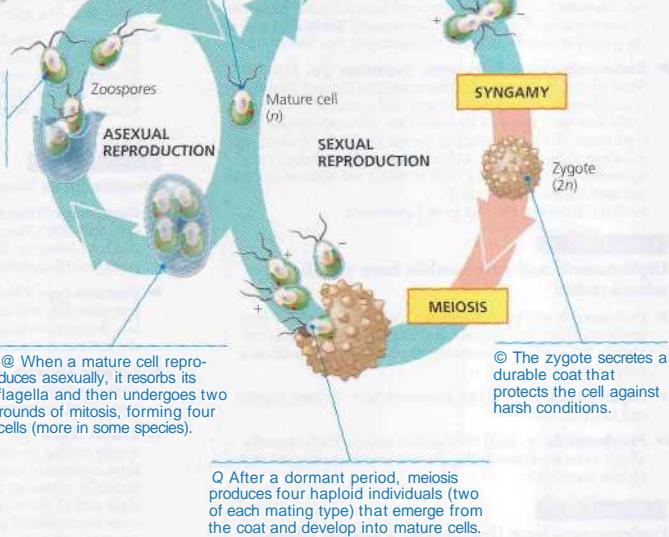

Q These daughter cells develop flagella and cell walls and then emerge as swimming zoospores from the wall of the parent cell that had enclosed them. The zoospores grow into mature haploid cells, completing the asexual life cycle.

O In *Chlamydomonas*, mature cells are haploid and contain a single cup-shaped chloroplast (see TEM at left).

O In response to a shortage of nutrients, drying of the pond, or some other stress, cells develop into gametes.

Q Gametes of opposite mating types (designated + and -) pair off and cling together. Fusion of the gametes (syngamy) forms a diploid zygote.

Key

- Haploid (n)
- Diploid ($2n$)

▲ Figure 28.31 The life cycle of *Chlamydomonas*, a unicellular chlorophyte.

cytoplasmic division, as seen in the multinucleate filaments of *Caulerpa* (Figure 28.30b); and (3) the formation of true multicellular forms by cell division and cell differentiation, as in *Ulva* (Figure 28.30c). Some multicellular marine chlorophytes are large and complex enough to qualify as seaweeds.

Most chlorophytes have complex life cycles, with both sexual and asexual reproductive stages. Nearly all reproduce sexually by means of biflagellated gametes that have cup-shaped chloroplasts (Figure 28.31). The exceptions are the conjugating algae, such as *Spirogyra* (see Figure 28.2d), which produce amoeboid gametes. Alternation of generations evolved in the life cycles of some green algae, including *Ulva*, in which alternate generations are isomorphic.

The other main group of green algae, the charophyceans, are the most closely related to land plants. For that reason, we will discuss them along with plants in Chapter 29.

Concept Check 28.8

1. Identify two ways in which red algae are different from brown algae.
2. Why is it accurate to say that *Ulva* has true multicellularity but *CMukrpa* does not?

For suggested answers, see Appendix A.

Chapter 28 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 28.1

Protists are an extremely diverse assortment of eukaryotes

- Protists are more diverse than all other eukaryotes and are no longer classified in a single kingdom. Most protists are unicellular; some are colonial or multicellular. Protists include photoautotrophs, heterotrophs, and mixotrophs. Most species are aquatic, but others are found in moist terrestrial habitats. Some species are exclusively asexual; others reproduce sexually. Table 28.1 reviews the groups of protists surveyed in this chapter (pp. 549–550).
- Endosymbiosis in Eukaryotic Evolution** (pp. 550–551) Some biologists hypothesize that mitochondria and plastids are descendants of alpha-proteobacteria and cyanobacteria, respectively that were engulfed by eukaryotic cells and became endosymbionts. The plastid-bearing lineage eventually evolved into red algae and green algae. Other protist groups evolved from secondary endosymbiotic events in which red algae or green algae were themselves engulfed.

Activity *Tentative Phylogeny of Eukaryotes*

Concept 28.2

Diplomonads and parabasalids have modified mitochondria

- Diplomonads and parabasalids are adapted to anaerobic environments. They lack plastids, and their mitochondria do not contain DNA, an electron transport chain, or citric-acid cycle enzymes (p. 552).
- Diplomonads** (p. 552) Diplomonads have multiple flagella and two nuclei.
- Parabasalids** (p. 553) Parabasalids include trichomonads, which move by means of flagella and an undulating part of the plasma membrane.

Concept 28.3

Euglenozoans have flagella with a unique internal structure

- Euglenozoans have a spiral or crystalline rod inside their flagella, and most have disk-shaped mitochondrial cristae. They include autotrophs, predatory heterotrophs, and parasites (p. 553).
- Kinetoplastids** (pp. 553–554) Kinetoplastids have a kinetoplast, an organized mass of DNA within a large mitochondrion. Parasitic kinetoplastids cause sleeping sickness and Chagas' disease.
- **Euglenids** (p. 554) Euglenids have one or two flagella that emerge from a pocket at one end of the cell. These protists store the glucose polymer paramylon. Some species of *Euglena* can switch from autotrophy to heterotrophy when sunlight is unavailable.

Concept 28.4

Alveolates have sacs beneath the plasma membrane

- Alveoli, membrane-bound sacs beneath the plasma membrane, distinguish alveolates from other protists (p. 555).
- Dinoflagellates** (p. 555) Dinoflagellates are a diverse group of aquatic photoautotrophs and heterotrophs. Their characteristic spinning movements are produced by two flagella that lie in perpendicular grooves in their cell surface. Rapid growth of some dinoflagellate populations causes red tides.
- Apicomplexans** (pp. 555–556) Apicomplexans are parasites that have an apical complex of organelles specialized for invading host cells. They also have a nonphotosynthetic plastid, th: apicoplast. The apicomplexan *Plasmodium* causes malaria.
- Ciliates** (pp. 556–558) Ciliates use cilia to move and feed. They have large macronuclei and small micronuclei. The micronuclei function during conjugation, a sexual process that produces genetic variation. Conjugation is separate from reproduction, which generally occurs by binary fission.

Concept 28.5

Stramenopiles have "hairy" and smooth flagella

- Oomycetes (Water Molds and Their Relatives)** (pp. 558–559) Most oomycetes are decomposers or parasites and have filaments (hyphae) that facilitate nutrient uptake. The oomycete *Phytophthora infestans* causes potato late blight.
- Diatoms** (pp. 559–560) Diatoms are surrounded by a two-part glass-like wall and are a major component of phytoplankton. Accumulations of fossilized diatom walls comprise much of the sediments known as diatomaceous earth.
- Golden Algae** (p. 560) Golden algae typically have two flagella attached near one end of the cell. Many species are planktonic. Their color results from the carotenoids they contain.
- Brown Algae** (pp. 560–562) Brown algae are multicellular, mostly marine protists. They include some of the most complex algae commonly known as seaweeds, many of which are commercially important to humans. Like some red algae and green algae and all plants, some brown algae have a life cycle that features alternation of generations: A multicellular diploid form alternates with a multicellular haploid form.

Concept 28.6

Cercozoans and radiolarians have threadlike pseudopodia

- Foraminiferans (Forams)** (p. 563) Forams are marine and freshwater amoebas with porous, generally multichambered shells (tests) made of organic material and calcium carbonate. Pseudopodia extend through the pores. Foram tests in marine sediments form an extensive fossil record.
- Radiolarians** (p. 563) Radiolarians have fused tests usually made of silica. They ingest microorganisms by phagocytosis using their pseudopodia, which radiate from their central body.

Table 28.1 A Sample of Protist Diversity

| Major Clade | Key Characteristics | Examples from Chapter |
|---|--|---|
| Diplomonadida (diplomonads) | Two equal-sized nuclei; modified mitochondria | <i>Giardia</i> |
| Parabasala (parabasalids) | Undulating membrane; modified mitochondria | <i>Trichomonas</i> |
| Euglenozoa (euglenozoans) | Spiral or crystalline rod inside flagella | |
| Kinetoplastida (kinetoplastids) | Kinoplasma (DNA in mitochondrion) | <i>Trypanosoma</i> |
| Euglenophyta (euglenids) | Paramylon as storage molecule. | <i>Euglena</i> |
| Aweolata (alveolates) | Alveoli beneath plasma membrane | |
| Dinoflagellata (dinoflagellates) | Armor of cellulose plates | <i>Ceratium, Pfiesteria</i> |
| Apicomplexa (apicomplexans) | Apical complex of organelles | <i>Plasmodium</i> |
| Ciliophora (ciliates) | Cilia used in movement and feeding; macro- and micronuclei | <i>Paramecium, Stenidium</i> |
| Stramenopiles (stramenopiles) | Hairy and smooth, flagella | |
| Oomycota (oomycetes) | Hypphae that absorb nutrients | Water molds, white rusts, downy mildews |
| Bacillariophyta (diatoms) | Glassy, two-part wall | |
| Chrysophyta (golden algae) | Flagella attached near one end of cell | <i>Dinobryon</i> |
| Phaeophyta (brown algae) | All multicellular, some with alternation of generations | <i>Laminaria, Macrocytis, Postsdia</i> |
| Cercozoa (cercozoans) and Radiolaria (radiolarians) | Amoebas with threadlike pseudopodia | |
| Foraminifera (forams) | Porous shell | <i>Globigerina</i> |
| Radiolaria (radiolarians) | Pseudopodia radiating from central body | |
| Amoebozoa (amoebozoans) | Amoebas with lobe-shaped pseudopodia | |
| Gymnamoeba (gymnamoebas) | Soil-dwelling, freshwater, or marine | <i>Amoeba</i> |
| Entamoeba (entamoebas) | Parasites | <i>Entamoeba</i> |
| Myxogastria (plasmoidal slime molds) | Multinucleate plasmodium; fruiting bodies that function in sexual reproduction | <i>Physarum</i> |
| Dictyosteliida (cellular slime molds) | Multicellular aggregate that bears asexual fruiting bodies | <i>Dictyostelium</i> |
| Rhodophyta (red algae) | Phycocyanin (accessory pigment); no flagellated stages | <i>Bonnemaisonia, Deleviana, D'almariella</i> |
| Chlorophyta (one group of green algae) | Plant-type chloroplasts | <i>Caulerpa, Chlamydomonas, Spirogyra, Ulva, Volvox</i> |

Concept 28.7

Amoebozoans have lobe-shaped pseudopodia

- **Gymnamoebas** (p. 564) Gymnamoebas are common unicellular amoebozoans in soil as well as freshwater and marine environments. Most are heterotrophs.
- **Entamoebas** (p. 564) Entamoebas are parasites of vertebrates and some invertebrates. *Entamoeba histolytica* causes amoebic dysentery in humans,
- **Slime Molds** (pp. 564–566) Plasmoidal slime molds aggregate into a plasmodium, a multinucleate mass of cytoplasm undivided by membranes. The plasmodium extends pseudopodia through decomposing material, engulfing food by phagocytosis. Cellular slime molds form multicellular aggregates in which the cells remain separated by their membranes. The cellular slime mold *Dictyostelium discoideum* has become an experimental model for studying the evolution of multicellularity.

Concept 28.8

Red algae and green algae are the closest relatives of land plants

- **Red Algae** (p. 567) Red algae have colors ranging from green to black, owing to varying amounts of the accessory pigment phycocyanin. Most red algae are multicellular; the largest are seaweeds. They are the most abundant large algae in coastal waters of the tropics.
- **Green Algae** (pp. 567–569) Green algae (chlorophytes and charophyceans) are closely related to land plants. Most chlorophytes live in fresh water, although many are marine; others live in damp soil, in snow, or as symbionts in lichens. Chlorophytes include unicellular, colonial, and multicellular forms. Most have complex life cycles.

Science, Technology, and Society

Evolution Connection

Explain why systematists consider the kingdom Protista to be an obsolete taxon.

Scientific Inquiry

Applying the "If . . . then" logic of science (see Chapter 1), what are a few of the predictions that arise from the hypothesis that plants evolved from green algae? Put another way, how could you test this hypothesis?

Investigation *What Kinds of Protists Do Various Habitats Support?*

The ability of the pathogen *Plasmodium* to evade the human immune system is one reason developing a malaria vaccine is so difficult. Another reason is that less money is spent on malaria research than on research into diseases that affect far fewer people, such as cystic fibrosis. What are the possible reasons for this imbalance in research effort?

29

Plant Diversity I How Plants Colonized Land

A Figure 29.1 Tree ferns and a moss-covered log.

Key Concepts

- 29.1 Land plants evolved from green algae
- 29.2 Land plants possess a set of derived terrestrial adaptations
- 29.3 The life cycles of mosses and other bryophytes are dominated by the gametophyte stage
- 29.4 Ferns and other seedless vascular plants formed the first forests

Overview

1 The Greening of Earth

Looking at a lush landscape, such as the forest scene in **Figure 29.1**, it is difficult to imagine the land without many plants or other organisms. Yet for more than the first 3 billion years of Earth's history, the terrestrial surface was lifeless. Geochemical evidence suggests that thin coatings of cyanobacteria existed on land about 1.2 billion years ago. But it was only about 500 million years ago that plants, fungi, and animals joined them ashore.

In this chapter, we will focus on land plants and how they evolved from aquatic green algae. Although some plant species, such as sea grasses, returned to aquatic habitats during their evolution, most plants live in terrestrial environments. Therefore, we will refer to all plants as *land* plants, even those that are now aquatic, to distinguish them from algae, which are photosynthetic protists. Since colonizing land, plants have diversified into roughly 290,000 living species inhabiting all but the harshest environments, such as some mountaintops and some desert and polar regions. The presence of plants has enabled other life-forms—including humans—to survive on land. Plant roots have created habitats for other organisms by stabilizing landscapes. More

importantly, plants are the source of oxygen and the ultimate provider of food for land animals.

In this chapter, we will trace the first 100 million years of plant evolution, including the emergence of seedless plants such as mosses and ferns. In Chapter 30, we will examine the later evolution of seed plants.

Concept 29.1

Land plants evolved from green algae

As you read in Chapter 28, researchers have identified green algae called charophyceans as the closest relatives of land plants. Here we will examine the evidence of this relationship and consider what it suggests about how the algal ancestors of land plants might have been well suited to make the move to land.

Morphological and Biochemical Evidence

Many key characteristics of land plants also appear in a variety of protists, primarily algae. For example, plants are multicellular, eukaryotic, photosynthetic autotrophs, as are brown, red, and certain green algae (see Chapter 28). Plants have cell walls made of cellulose, and so do green algae, di flagellates, and brown algae. And chloroplasts with chlorophylls *a* and *b* are present in green algae, euglenids, and a few dinoflagellates, as well as in plants.

Figure 29.2 Rosette cellulose-synthesizing complexes. These distinctively rose-shaped arrays of proteins are found only in land plants and charophycean algae, suggesting their close kinship (SEM).

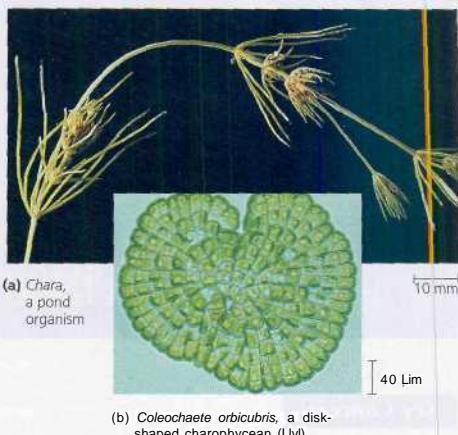

30 nm

There are four key traits, however, that land plants share only with the charophyceans, strongly suggesting a close relationship between the two groups:

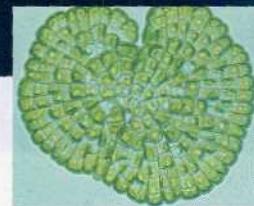

- Rose-shaped complexes for cellulose synthesis.** The cells of both land plants and charophyceans have **rosette cellulose-synthesizing complexes**. These are rose-shaped arrays of proteins in the plasma membrane that synthesize the cellulose microfibrils of the cell walls (**Figure 29.2**). In contrast, linear arrays of proteins synthesize cellulose in noncharophycean algae. Also, the cell walls of plants and charophyceans contain a higher percentage of cellulose than the cell walls of noncharophycean algae. These differences indicate that the cellulose walls in plants and charophyceans evolved independently of those in other algae.
- Peroxisome enzymes.** The peroxisomes (see Figure 6.19) of both land plants and charophyceans contain enzymes that help minimize the loss of organic products as a result of photorespiration (see Chapter 10). The peroxisomes of other algae lack these enzymes.
- Structure of flagellated sperm.** In species of land plants that have flagellated sperm, the structure of the sperm closely resembles that of charophycean sperm.
- Formation of a phragmoplast.** Certain details of cell division occur only in land plants and certain charophyceans, including the genera *Chara* and *Coleochaete*. For example, the synthesis of new cross-walls (cell plates) during cell division involves the formation of a **phragmoplast**, an alignment of cytoskeletal elements and Golgi-derived vesicles across the midline of the dividing cell (see Figure 12.10).

Genetic Evidence

Over the past decade, researchers involved in an international initiative called "Deep Green" have conducted a large-scale study of major transitions in plant evolution, analyzing genes from a wide range of plant and algal species. Comparisons of both nuclear and chloroplast genes agree with the morphological and biochemical data in pointing to charophyceans—particularly *Chara* and *Coleochaete*—as the closest living relatives of land plants (**Figure 29.3**). Note that this does not mean that these *living* algae are the ancestors of plants; however, they do offer a glimpse of what those ancestors might have been like.

(a) *Chara*,
a pond
organism

(b) *Coleochaete orbiculata*, a disk-
shaped charophycean (Llv)

A Figure 29.3 Examples of charophyceans, the closest algal relatives of land plants.

Adaptations Enabling the Move to Land

Many species of charophycean algae inhabit shallow waters around the edges of ponds and lakes, where they are subject to occasional drying. In such environments, natural selection favors individual algae that can survive periods when they are not submerged in water. In charophyceans, a layer of a durable polymer called **sporopollenin** prevents exposed zygotes from drying out. An ancestral form of this chemical adaptation may have also been the precursor to the tough sporopollenin walls that encase plant spores.

It is likely that the accumulation of such traits by at least one population of charophycean ancestors enabled their descendants—the first land plants—to live permanently above the waterline. These evolutionary novelties opened an expanse of terrestrial habitat, a new frontier that offered enormous benefits. The bright sunlight was unfiltered by water and plankton; the atmosphere had an abundance of CO_2 ; the soil was rich in mineral nutrients; and initially there were relatively few herbivores and pathogens. Benefiting from these environmental opportunities became possible as adaptations evolved in plants that allowed them to survive and reproduce on land.

Concept Check 29.1

- Describe the evidence linking plants to a charophycean ancestry.

For suggested answers, see Appendix A.

Concept 29.2

Land plants possess a set of derived terrestrial adaptations

Many of the adaptations that emerged after land plants diverged from their charophycean relatives facilitated survival and reproduction on dry land. We will explore the most important derived traits of plants. We will then examine some fossil evidence of the divergence of land plants from charophyceans and survey main groups within the plant kingdom.

Defining the Plant Kingdom

Where exactly is the line dividing land plants from algae? Systematists are currently debating the boundaries of the plant kingdom (**Figure 29.4**). The traditional scheme equates the kingdom Plantae with embryophytes (plants with embryos; *phyte* is from the Greek word for plant). Some plant biologists now propose that the boundaries of the plant kingdom should be expanded to include the green algae most closely related to plants—the charophyceans and a few related groups—and named kingdom Streptophyta. Others suggest an even broader definition of plants that also includes chlorophytes (the non-charophycean green algae) in a kingdom Viridiplantae (see Chapter 28). Since the debate is ongoing, this text retains the embryophyte definition of the plant kingdom and uses kingdom Plantae as the formal name for the taxon.

Derived Traits of Plants

Five key traits appear in nearly all land plants but are absent in the charophyceans: apical meristems; alternation of generations; walled spores produced in sporangia; multicellular gametangia; and multicellular, dependent embryos. **Figure 29.5**, on the next two pages, depicts these traits. We can infer that these traits were absent in the ancestor common to land plants and charophyceans but instead evolved independently as derived traits of land plants. Some of these traits are not unique to plants, having evolved separately in other lineages, and some traits have been lost in certain lineages of plants. However, these key traits set the first land plants apart from their closest algal relatives.

Additional derived traits that relate to terrestrial life have evolved in many plant species. Permanently exposed to the air, land plants run a far greater risk of desiccation (drying out) than their algal ancestors. The epidermis in many species has a covering, known as a cuticle, that consists of polymers called polyesters and waxes. The cuticle acts as waterproofing, helping prevent excessive water loss from the above-ground plant organs, while also providing some protection from microbial attack.

Many land plants produce molecules called *secondary compounds*, so named because they are products of secondary metabolic pathways—side branches off the primary metabolic

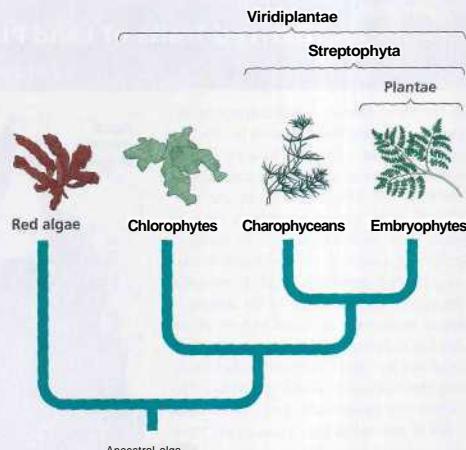

Figure 29.4 Three clades that are candidates for designation as the plant kingdom. This textbook adopts the embryophyte definition of plants and uses the name Plantae for the kingdom.

pathways that produce the lipids, carbohydrates, amino acids, and other compounds common to all organisms. Secondary compounds include alkaloids, terpenes, tannins, and phenolics such as flavonoids. Various alkaloids, terpenes, and tannins have a bitter taste, strong odor, or toxic effect that helps defend against herbivores and parasites. Flavonoids absorb harmful UV radiation and may act as signals in symbiotic relationships with beneficial soil microbes. Some phenolics deter attack by pathogenic microbes. As you survey the major groups of land plants, note how secondary compounds aid their survival. Humans also benefit from secondary compounds; just one example is use of the alkaloid quinines antimicrobial properties to fight malaria.

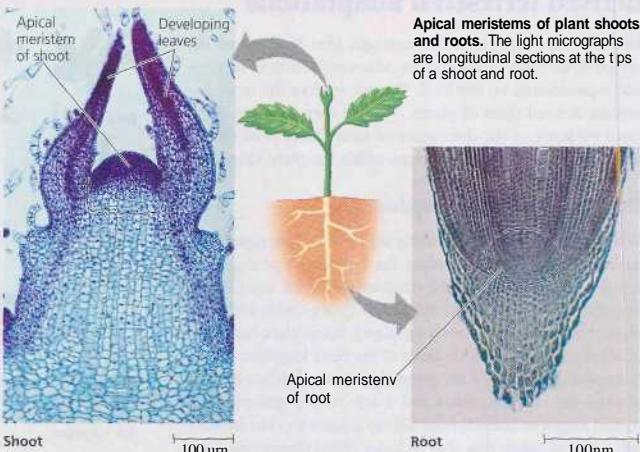

The Origin and Diversification of Plants

Paleobotanists seeking the evolutionary origin of plants have long debated what constitutes the oldest fossil evidence of land plants. In the 1970s, researchers found fossil spores dating to the Ordovician period, up to 475 million years old. Although the fossil spores resemble those of living plants, they also have some striking differences. For example, spores of living plants are typically dispersed as single grains, but the fossil spores are fused together in groups of two or four. This difference raises the possibility that the fossil spores were not produced by plants, but by some extinct algal relative. Furthermore, the oldest known fragments of plant tissue are 50 million years younger than the puzzling spores.

Figure 29.5
Exploring Derived Traits of Land Plants

In terrestrial habitats, a photosynthetic organism finds essential resources in two very different places. Light and CO_2 are mainly available above-ground; water and mineral nutrients are found mainly in the soil. Though plants cannot move from place to place, their roots and shoots can elongate, increasing exposure to environmental resources. This growth in length is sustained throughout the plant's life by the activity of **apical meristems**, localized regions of cell division at the tips of shoots and roots. Cells produced by apical meristems differentiate into various tissues, including a surface epidermis that protects the body and several types of internal tissues. Shoot apical meristems also generate leaves in most plants. Thus, the complex bodies of plants show structural specialization for subterranean and aerial organs—roots and leaf-bearing shoots, respectively, in most plants.

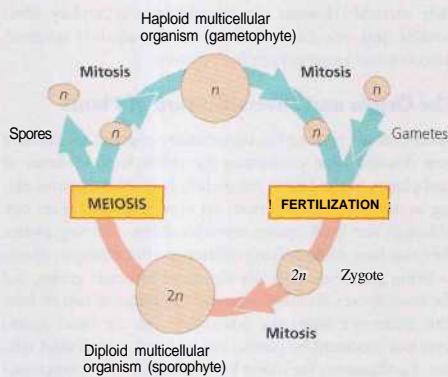

APICAL MERISTEMS

Apical meristems of plant shoots and roots. The light micrographs are longitudinal sections at the tips of a shoot and root.

ALTERNATION OF GENERATIONS

The life cycles of all land plants alternate between two different multicellular bodies, with each **form** producing the other. This type of reproductive cycle, called **alternation of generations**, also evolved in various groups of algae but does not occur in the charophyceans, the algae most closely related to land plants. We can infer that alternation of generations is a derived characteristic of land plants—it was not present in the ancestor common to land plants and charophyceans.

Alternation of generations: a generalized scheme

Take care not to confuse the alternation of generations in plants with the haploid and diploid stages in the life cycles of *all* sexually reproducing organisms (see Figure 13.6). In humans, for example, meiosis in the gonads (ovaries and testes) produces haploid gametes that unite, forming diploid zygotes that divide and become multicellular. The haploid stage is represented only by single-celled gametes. In contrast, alternation of generations is distinguished by the fact that there are both multicellular haploid and multicellular diploid stages in the life cycle.

The two multicellular body forms that alternate in the life cycles of land plants are the gametophyte and sporophyte generations. The cells of the **gametophyte** are haploid, meaning they have a single set of chromosomes. The gametophyte is named for its production by mitosis of haploid gametes—eggs and sperm—that fuse during fertilization, forming diploid zygotes. Mitotic division of the zygote produces the multicellular sporophyte, the spore-producing generation. Thus, the cells of the sporophyte are diploid, having two sets of chromosomes—one from each gamete. Meiosis in a mature sporophyte produces haploid **spores**, reproductive cells that can develop into a new organism without fusing with another cell. In contrast, gametes cannot develop directly into a multicellular organism but instead must fuse and form a zygote. Mitotic division of a plant spore produces a new multicellular gametophyte. And so the alternation of generations continues, with sporophytes producing spores that develop into gametophytes, and gametophytes producing gametes that unite, forming the zygotes that develop into sporophytes.

WALLED SPORES PRODUCED IN SPORANGIA

Plant spores are haploid reproductive cells that have the potential to grow into multicellular, haploid gametophytes by mitosis. The polymer sporopollenin makes the walls of plant spores very tough and resistant to harsh environments. This chemical adaptation makes it possible for spores to be dispersed through dry air without harm.

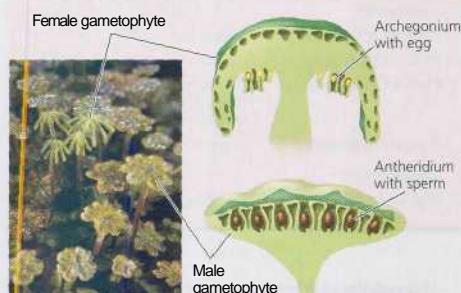

The sporophyte has multicellular organs called sporangia (singular, *sporangium*) that produce plant spores. Within a sporangium, diploid cells called sporocytes, also known as spore mother cells, undergo meiosis and generate the haploid spores. The outer tissues of the sporangium protect the developing spores until they are released into the air.

Multicellular sporangia that produce spores with sporopollenin-enriched walls are key terrestrial adaptations of land plants. Although charophyceans produce spores, these algae lack multicellular sporangia, and their flagellated, water-dispersed spores lack sporopollenin.

MULTICELLULAR GAMETANGIA

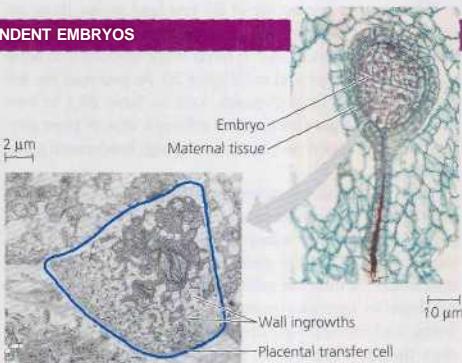

Archegonia and antheridia of *Marchantia* (a liverwort)

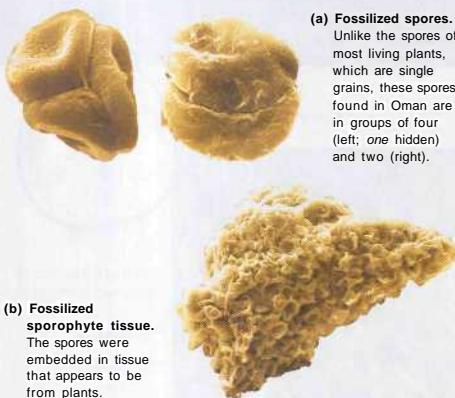

Another feature distinguishing early land plants from their algal ancestors was the production of gametes within multicellular organs called gametangia. The female gametangia are called archegonia (singular, *archegonium*), each of which is a vase-shaped organ that produces a single egg retained within the base of the organ. Male gametangia, called antheridia (singular, *antheridium*), produce and release sperm into the environment. In many major groups of living plants, the sperm have flagella and swim to the eggs through water droplets or water films. Each egg is fertilized within an archegonium, where the zygote develops into an embryo. As you will see in Chapter 30, the gametophytes of seed plants are so reduced in size that the archegonia and antheridia have been lost in some lineages.

MULTICELLULAR, DEPENDENT EMBRYOS

Multicellular plant embryos develop from zygotes that are retained within tissues of the female parent. The parental tissues provide the developing embryo with nutrients, such as sugars and amino acids. The embryo has specialized placental transfer cells, sometimes present in the adjacent maternal tissue as well, which enhance the transfer of nutrients from parent to embryo through elaborate ingrowths of the wall surface (plasma membrane and cell wall). This interface is analogous to the nutrient-transferring embryo-mother interface of eutherian (placental) mammals. The multicellular, dependent embryo of land plants is such a significant derived trait that land plants are also known as embryophytes.

Embryo and placental transfer cell of *Marchantia*

A Figure 29.6 Ancient plant spores and tissue.

In 2003, scientists from Britain and Oman shed some light on this mystery when they extracted spores from 475-million-year-old rocks from the Middle Eastern country of Oman (**Figure 29.6a**). Unlike previously discovered spores of this age, these were embedded in plant cuticle material that is similar to spore-bearing tissue in living plants (**Figure 29.6b**). After finding other small fragments of tissue that clearly belonged to plants, the scientists concluded that the Oman spores represent fossil plants rather than algae.

A 2001 "molecular clock" study (see Chapter 25) of plants suggested that the common ancestor of living plants existed 700 million years ago. If this is true, then the fossil record is missing the first 225 million years of plant evolution. In 2003, however, Michael Sanderson of the University of California reported an estimate based on molecular data of 490 to 425 million years, roughly the age of the spores discovered in Oman.

Whatever the precise age of the first land plants, those ancestral species gave rise to the vast diversity of living plants. **Table 29.1** summarizes the 10 phyla in the taxonomic scheme used in this chapter and in Chapter 30. As you read the following overview of land plants, look at Table 29.1 in conjunction with **Figure 29.7**, which reflects a view of plant phylogeny that is based on plant morphology, biochemistry, and genetics.

Land plants can be informally grouped based on the presence or absence of an extensive system of vascular tissue, cells joined into tubes that transport water and nutrients throughout the plant body. Most plants have a complex vascular tissue system and are therefore called vascular plants. Plants that do not have an extensive transport system—liverworts, hornworts, and mosses—are described as "nonvascular" plants, even though some mosses do have simple vascular tissue. Nonvascular plants are often informally called bryophytes (from the Greek *bryon*, moss, and *phyton*, plant).

[Table 29.1 Ten Phyla of Extant Plants

| | Common Name | Approximate Number of Extant Species |
|--|---|--------------------------------------|
| Bryophytes (nonvascular plants) | | |
| Phylum Hepaticophyta | Liverworts | 9,000 |
| Phylum Anthocerophyta | Hornworts | 100 |
| Phylum Bryophyta | Mosses | 15,000 |
| Vascular Plants | | |
| Seedless Vascular Plants: | | |
| Phylum Lycophyta | Lycophytes (club mosses, spike mosses, and quillworts) | 1,200 |
| Phylum Pterophyta | Pterophytes (ferns, horsetails, and whisk ferns) | 12,000 |
| Seed Plants | | |
| <i>Gymnosperms</i> | | |
| Phylum Ginkgophyta | Ginkgo | 1 |
| Phylum Cycadophyta | Cycads | 130 |
| Phylum Gnetaophyta | Gnetaophytes (<i>Gneciu</i> n, <i>Ephedra</i> , and <i>Welwitschia</i>) | 75 |
| Phylum Coniferophyta | Conifers | 600 |
| <i>Angiosperms</i> | | |
| Phylum Anthophyta | Flowering plants | 250,000 |

Although the term *bryophyte* is still commonly used to refer to all nonvascular plants, debate continues over the relationships of liverworts, hornworts, and mosses to each other and to vascular plants. Whereas some molecular studies have concluded that bryophytes are not monophyletic, a recent analysis of amino acid sequences in chloroplasts asserts that bryophytes form a clade. The broken lines in Figure 29.7 reflect the current uncertainty regarding bryophyte phylogeny. Whether or not bryophytes are monophyletic, they share some derived traits with vascular plants, such as multicellular embryos and apical meristems, while lacking many innovations of vascular plants, such as roots and true leaves.

Vascular plants form a clade, consisting of about 93% of all plant species. Vascular plants can be categorized further into three smaller clades. Two of these clades are the lycophytes (club mosses and their relatives) and the pterophytes (ferns and their relatives). Each of these clades lacks seeds, which is why collectively the two clades are often informally called seedless vascular plants. However, notice in Figure 29.7 that seedless vascular plants are not monophyletic. The third clade

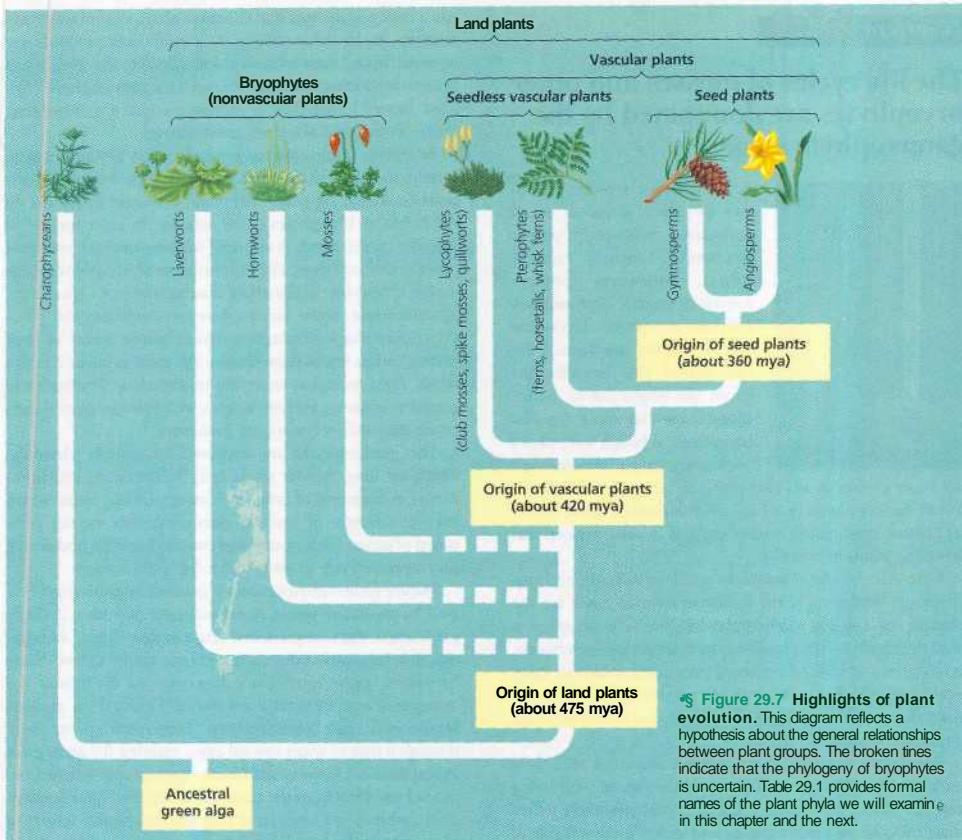

Figure 29.7 Highlights of plant evolution. This diagram reflects a hypothesis about the general relationships between plant groups. The broken lines indicate that the phylogeny of bryophytes is uncertain. Table 29.1 provides formal names of the plant phyla we will examine in this chapter and the next.

If vascular plants consists of seed plants, the vast majority of living plant species. A **seed** is an embryo packaged with a supply of nutrients inside a protective coat. Seed plants can be divided into two groups, gymnosperms and angiosperms, based on the absence or presence of enclosed chambers in which seeds mature. **Gymnosperms** (from the Greek *gymnos*, naked, and *sperm*, seed) are grouped together as "naked seed" plants because their seeds are not enclosed in chambers. Surviving gymnosperm species, which consist primarily of conifers, probably form a clade. **Angiosperms** (from the Greek *an\$on*, container) are a huge clade consisting of all flowering plants. Angiosperm seeds develop inside chambers called ovaries, which originate within flowers and mature into fruits.

Note that the phylogeny depicted in Figure 29.7 focuses only on the relationships between extant plant lineages—

those that have surviving members in addition to extinct members. Paleobotanists have also discovered fossils belonging to extinct plant lineages. Many of these fossils reveal the intermediate steps leading to the distinctive plant groups found on Earth today.

Concept Check 29.2

- Identify three derived traits that distinguish plants from charophyceans and facilitate life on land. Explain.
- Identify each structure as either haploid or diploid; (a) sporophyte; (b) spore; (c) gametophyte; (d) zygote; (e) sperm; (f) egg.

For suggested answers, see Appendix A.

Concept 29.3

The life cycles of mosses and other bryophytes are dominated by the gametophyte stage

Bryophytes are represented today by three phyla of small herbaceous (nonwoody) plants: **liverworts** (phylum Hepaticophyta), **hornworts** (phylum Anthocerophyta), and mosses (phylum Bryophyta). Liverworts and hornworts are named for their shapes, plus the suffix *wort* (from the Anglo-Saxon, *herb*). Mosses are the most familiar bryophytes, although some plants commonly called "mosses" are

not really mosses at all. These include Irish moss (a red seaweed), reindeer moss (a lichen), club mosses (seedless vascular plants), and Spanish mosses (lichens in some regions and flowering plants in others).

Note that the terms *Bryophyta* and *bryophyte* are not synonymous. *Bryophyta* is the formal taxonomic name for the phylum that consists solely of mosses. The term *bryophyte* is used informally to refer to *all* nonvascular plants—liverworts, hornworts, and mosses. As noted previously, it has not been established whether these three groups form a clade. Systematists also continue to debate the sequence in which the three phyla of bryophytes evolved.

Bryophytes acquired many unique adaptations after their evolutionary split from the ancestors they share with living vascular plants. Nevertheless, living bryophytes likely reflect some traits of the earliest plants. The oldest known fossils of plant fragments, for example, include tissues that look very much like the interior of liverworts. Researchers are eager to discover more parts of these ancient plants to see if this resemblance is reflected more broadly.

Bryophyte Gametophytes

Unlike vascular plants, in all three bryophyte phyla the gametophytes are larger and longer-living than sporophytes, as shown in the moss life cycle in **Figure 29.8**. Sporophytes are typically present only part of the time.

If bryophyte spores are dispersed to a favorable habitat, such as moist soil or tree bark, they may germinate and grow into gametophytes. Germinating moss spores, for example, characteristically produce a mass of green, branched, one-cell-thick filaments known as a **protonema** (plural, *protonemata*; from the Greek *proto*, first, and *nema*, threads). A protonema

has a large surface area that enhances absorption of water and minerals. In favorable conditions, a protonema produces one or more "buds," each with an apical meristem that generates a gamete-producing structure known as a **gametophore** ("gamete bearer"). Together, a protonema and a gametophore make up the body of a moss gametophyte.

Bryophyte gametophytes generally form ground-hugging carpets and are at most only a few cells thick. Such thin body parts could not support a tall plant. A second constraint on the height of bryophytes is the absence, in most species of vascular tissue, which is required for long-distance transport of water and nutrients. The thin structure of bryophyte organs makes it possible to distribute materials without specialized vascular tissue. Some mosses, however, including the genus *Volvicularium*, have conducting tissues in the center of their "stems," and a few of these mosses can grow as tall as 2 m as a result. Plant biologists are trying to determine whether these conducting tissues are homologous with vascular plant tissues or are the result of convergent evolution.

The gametophytes are anchored by delicate rhizoids, which are long, tubular single cells (in liverworts and hornworts) or filaments of cells (in mosses). Unlike roots, which are characteristic of vascular plants, rhizoids are not composed of tissues, lack specialized conducting cells, and do not play a primary role in water and mineral absorption.

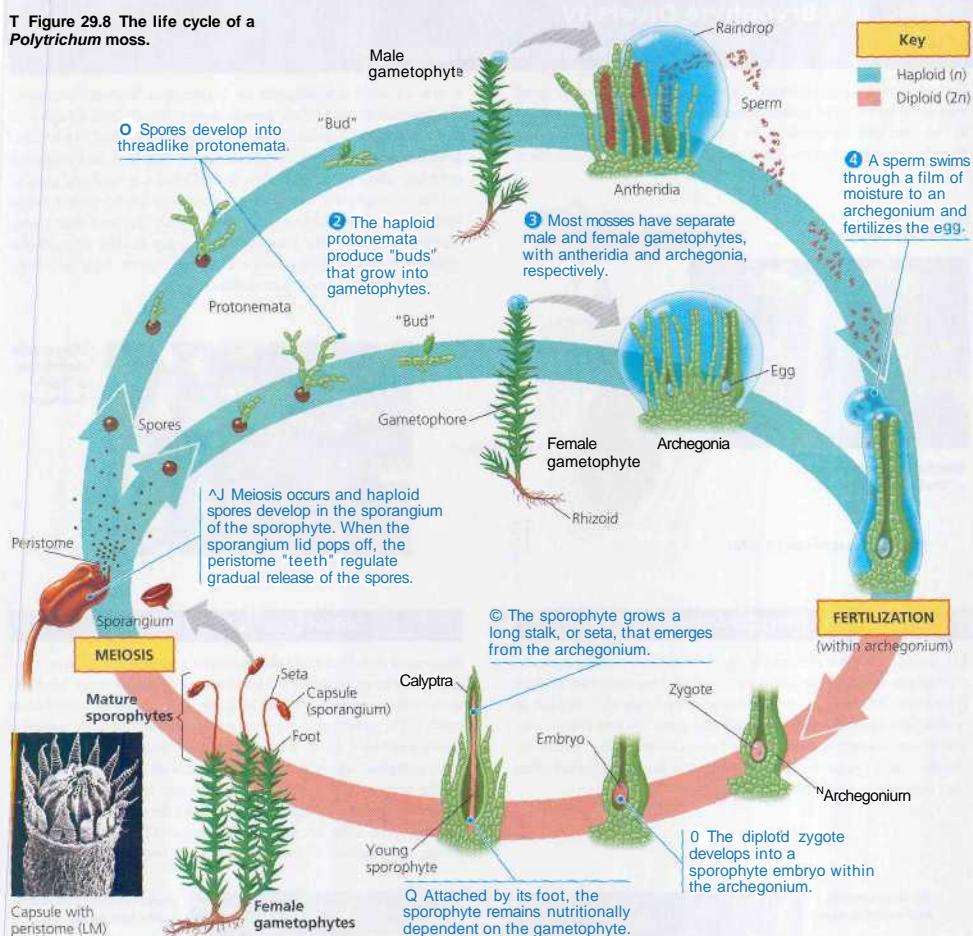

Mature gametophytes produce gametes in gametangia covered by protective tissue. A gametophyte may have multiple gametangia. Eggs are produced singly in vase-shaped archegonia, whereas antheridia each produce many sperm. Some bryophyte gametophytes are bisexual, but in mosses the archegonia and antheridia are typically carried on separate female and male gametophytes. Flagellated sperm swim through a film of water toward eggs, entering the archegonia in response to chemical attractants. Eggs are not released but instead remain within the bases of archegonia. After fertilization, embryos are retained within the archegonia. Layers of placental transfer cells help transport nutrients to the embryos as they develop into sporophytes.

Bryophyte Sporophytes

Although bryophyte sporophytes are usually green and photosynthetic when young, they cannot live independently. They remain attached to their parental gametophytes, from which they absorb sugars, amino acids, minerals, and water.

Bryophytes have the smallest and simplest sporophytes of all extant plant groups, consistent with the hypothesis that larger and more complex sporophytes evolved only later in vascular plants. A typical sporophyte consists of a foot, a seta, and a sporangium. Embedded in the archegonium, the **foot** absorbs nutrients from the gametophyte. The **seta** (plural, *setae*), or stalk, conducts these materials to the sporangium, also called a **capsule**, which uses them to produce spores by meiosis. One capsule can generate up to 50 million spores.

T Figure 29.8 The life cycle of a *Polytrichum* moss.

In most mosses, the seta becomes elongated, enhancing spore dispersal by elevating the capsule. An immature capsule has a protective cap of gametophyte tissue called the **calyptra**, which is shed when the capsule is mature. In most moss species, the upper part of the capsule features a ring of toothlike structures known as the **peristome** (see Figure 29.8). The peristome is specialized for gradual spore discharge, taking advantage of periodic wind gusts that can carry spores long distances.

Hornwort and moss sporophytes are larger and more complex than those of liverworts. Both hornwort and moss spor-

phytes also have specialized pores called **stomata** (singular, *stoma*), which are also found in all vascular plants. These pores support photosynthesis by allowing the exchange of CO_2 and O_2 between the outside air and the sporophyte interior (see Figure 10.3). Stomata are the main avenues by which water evaporates from the sporophyte. In hot, dry conditions, the stomata can close, minimizing water loss.

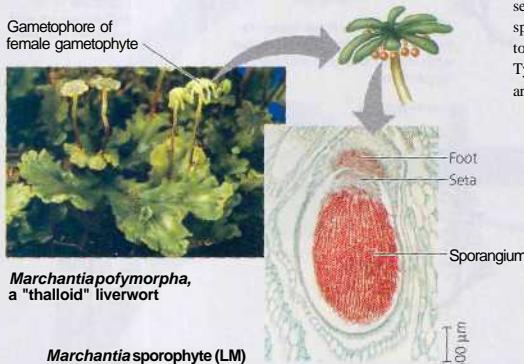

The fact that stomata are present in mosses and horworts but absent in liverworts suggests three possible hypotheses for their evolution. If liverworts are the deepest-branching lineage

Figure 29.9

Exploring Bryophyte Diversity

LIVERWORTS (PHYLUM HEPATOPHYTA)

The common name and scientific name (from the Latin *hepaticus*, liver) refer to the liver-shaped gametophytes of *Marchantia*, a genus common in the Northern Hemisphere. In medieval times, their shape was thought to be a sign that the plants could help treat liver diseases. Some

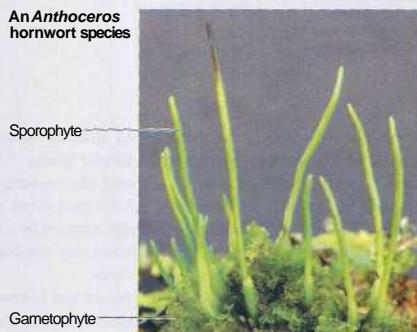

liverworts, such as *Marchantia*, are described as "thalloid" because of the flattened shape of their gametophytes. (Recall from Chapter 28 that the body of a multicellular alga is called a thallus.) *Marchantia* gametangia are elevated on gametophores that look like miniature trees (see also Figure 29.5). You would need a magnifying glass to see the sporophytes, which have a short seta (stalk) with a round sporangium. Some liverworts are called "leafy" because their gametophytes have stemlike structures with many leaflike appendages. Typically found in tropical and subtropical regions, leafy liverworts are much more common than thalloid species.

HORNWORTS (PHYLUM ANTHOCEROPHYTA)

The common name and scientific name (from the Greek *kerns*, horn) refer to the shape of the sporophyte, which also resembles a small grass blade. A typical sporophyte can grow up to about 5 cm high. A sporangium extends along its length and splits open to release mature spores, starting at the tip of the horn. Gametophytes, which are usually 1 to 2 cm in diameter, grow mostly horizontally and often have multiple sporophytes attached.

MOSSES (PHYLUM BRYOPHYTA)

In contrast with liverworts and hornworts, moss gametophytes typically grow more vertically than horizontally. Heights range from less than a millimeter to more than 50 cm but are less than 15 cm in most species. The gametophytes are the structures that primarily comprise a carpet of moss. Their "leaves" are usually only one cell thick, but more complex "leaves" with ridges coated with cuticle can be found on the common hairy-cap moss and its close relatives. Moss sporophytes are typically elongated and visible to the naked eye, with sizes ranging up to about 20 cm. Though green and photosynthetic when young, they turn tan or brownish red when ready to release spores.

of land plants, then stomata evolved once in the ancestor of hornworts, mosses, and vascular plants. If hornworts are the deepest-branched lineage, then stomata may have evolved once and then been lost in the liverwort lineage. Or perhaps hornworts acquired stomata independently of mosses and vascular plants. This question is important to understanding plant evolution because stomata play a crucial role in the success of vascular plants, as you will see in Chapter 36.

Figure 29.9, on the facing page, illustrates examples of gametophytes and sporophytes in the three bryophyte phyla.

Ecological and Economic Importance of Mosses

Wind dispersal of lightweight spores has distributed mosses around the world. These plants are particularly common and diverse in moist forests and wetlands, where they form habitats for tiny animals. Some moss species even inhabit such extreme environments as mountaintops, tundra, and deserts (see Chapter 50). Many mosses exist in very cold or dry habitats because they can survive the loss of most of their body water, then rehydrate when moisture is available. Few vascular plants can survive the same degree of desiccation. Moreover, phenolic compounds in moss cell walls absorb damaging levels of radiation present in deserts or at high altitudes and latitudes.

One wetland moss genus, *Sphagnum*, or "peat moss," is especially widespread, forming extensive deposits of partially decayed organic material known as peat (**Figure 29.10**). Boggy regions dominated by this moss are called peat bogs. Because of the resistant phenolic compounds embedded in its cell walls, *Sphagnum* does not decay readily. In addition, it secretes compounds that may reduce bacterial activity. Low temperatures and nutrient levels in peat bogs also inhibit decay. As a result, peat bogs can preserve mummified corpses for thousands of years.

Worldwide, an estimated 400 billion tons of organic carbon are stored in peat. These carbon reservoirs help stabilize global atmospheric CO₂ concentrations (see Chapter 54).

Peat has long been a fuel source in Europe and Asia, and it is still harvested for fuel today, notably in Ireland and Canada. Because peat moss has large dead cells that can absorb some 20 times the moss's weight in water, it also serves as a soil conditioner and is used for packing plant roots during shipment. Current overharvesting of *Sphagnum* may reduce its beneficial ecological effects.

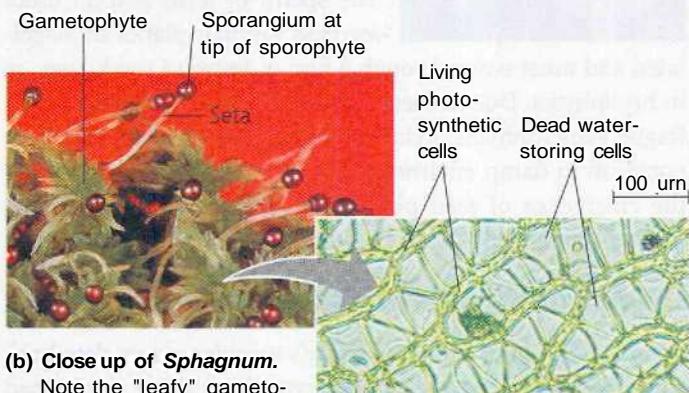

Concept Check #29.3

- How do bryophytes differ from other plants?
- Give three examples of how structure fits function in bryophytes.

For suggested answers, see Appendix A.

Concept 29.4

Ferns and other seedless vascular plants formed the first forests

Whereas bryophytes or bryophyte-like plants were the prevalent vegetation during the first 100 million years of plant evolution, vascular plants dominate most landscapes today. Living seedless vascular plants provide insights into plant evolution during the Carboniferous period, when vascular plants began to diversify but most groups of seed plants had not yet evolved. The sperm of ferns and all other seedless vascular plants are flagellated and must swim through a film of water to reach eggs, as in bryophytes. Due to these swimming sperm, as well as their fragile gametophytes, living seedless vascular plants are most common in damp environments. Thus it is likely that before the emergence of seed plants, most plant life on Earth was limited to relatively damp habitats.

Origins and Traits of Vascular Plants

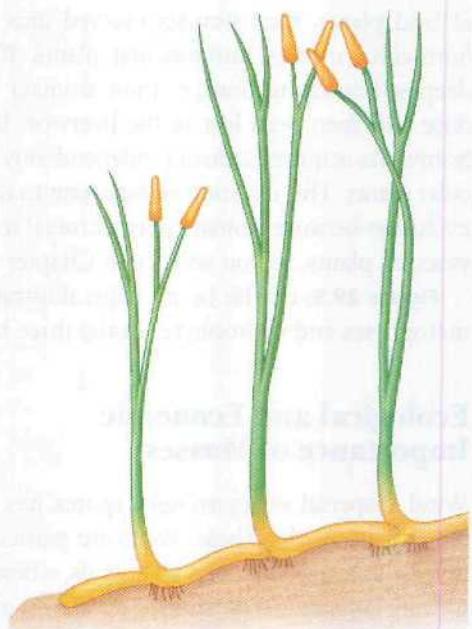

Fossils of the forerunners of today's vascular plants date back about 420 million years. Unlike bryophytes, these species had branched sporophytes that were not dependent on gametophytes for growth (**Figure 29.11**). Although these plants grew no taller than about 50 cm, their branching made possible more complex bodies with multiple sporangia. This evolutionary development facilitated greater production of spores and increased survival despite herbivory, for even if some sporangia were eaten, others might survive.

The ancestors of vascular plants already displayed some derived traits of living vascular plants, but they lacked other key adaptations that evolved later. This section describes the main traits that characterize living vascular plants: life cycles with dominant sporophytes, transport in vascular tissues called xylem and phloem, and the presence of roots and leaves, including spore-bearing leaves called sporophylls.

Life Cycles with Dominant Sporophytes

Fossils suggest that the ancestors of vascular plants had life cycles characterized by gametophytes and sporophytes that were about equal in size. Among extant vascular plants, however, the sporophyte (diploid) generation is the larger and more complex plant in the alternation of generations. In ferns, for example, the familiar leafy plants are the sporophytes. You would have to get down on your hands and knees and search the ground carefully to find fern gametophytes, which are tiny structures that grow

*- **Figure 29.11**
Aglaophyton major, an ancient relative of modern vascular plants. This reconstruction from fossils dating to about 420 million years ago exhibits dichotomous (Y-shaped) branching and terminal sporangia. These traits characterize living vascular plants but are lacking in bryophytes (nonvascular plants).

on or just below the soil surface. Until you have a chance to do that, you can study the sporophyte-dominant life cycle of seedless vascular plants in **Figure 29.12**, which uses a fern as an example. Then, for review, compare this life cycle with Figure 29.8, which represents a typical gametophyte-dominated life cycle of mosses and other nonvascular plants. In Chapter 30, you will see that gametophytes became even more reduced during the evolution of seed plants.

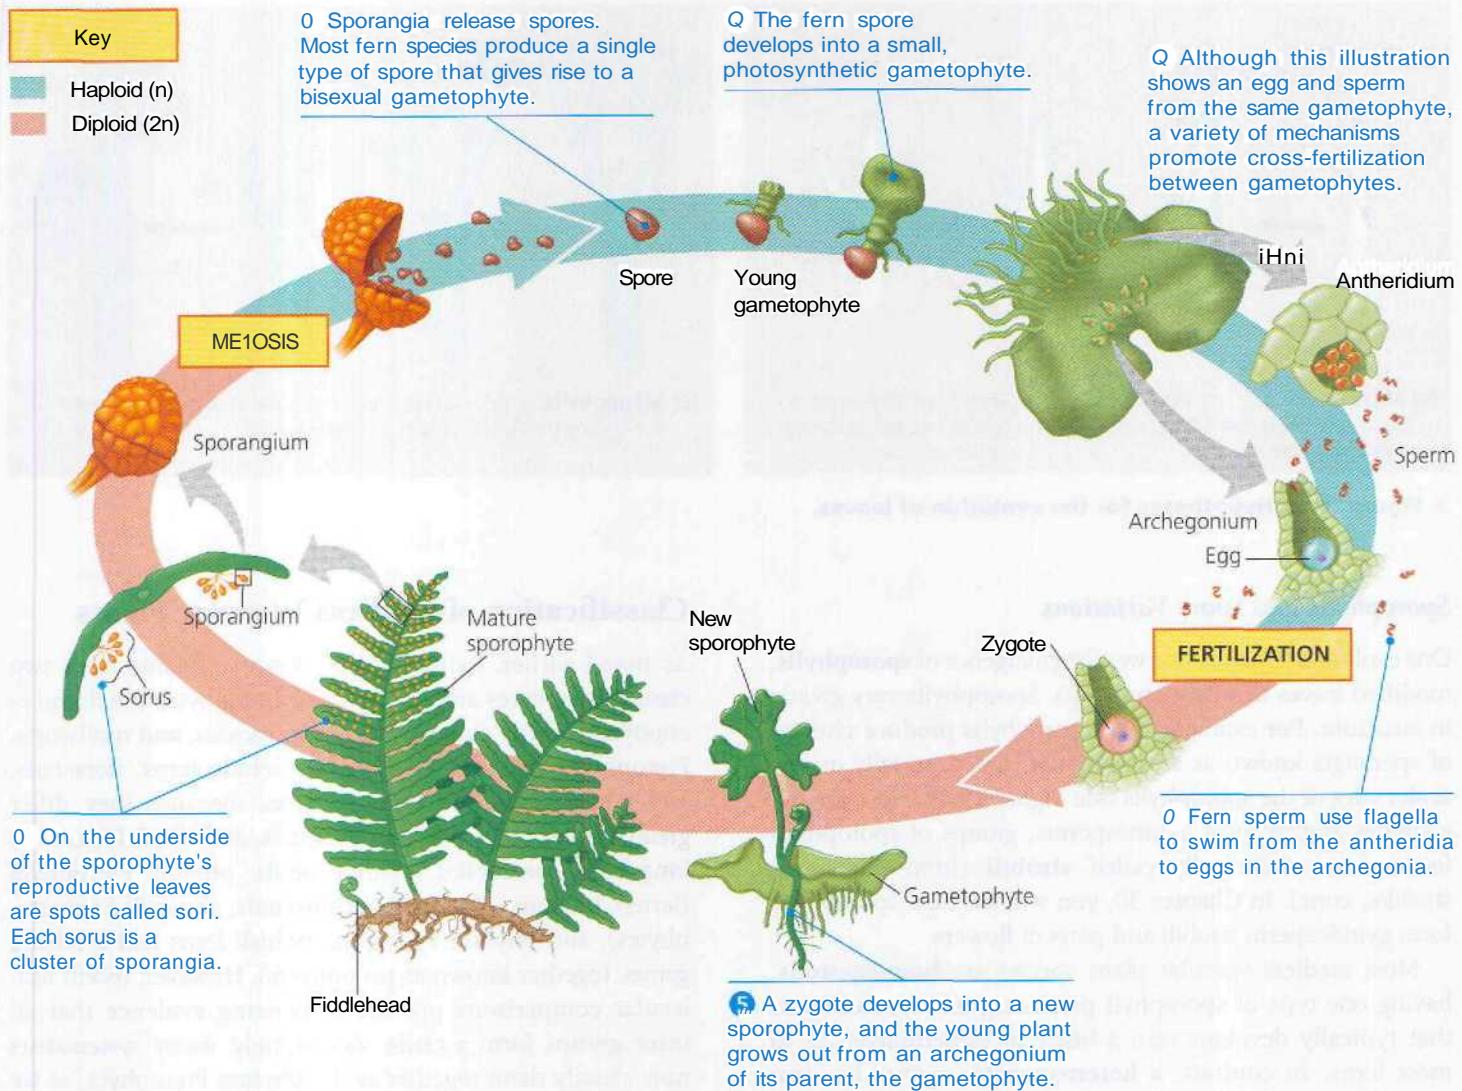

Transport in Xylem and Phloem

Vascular plants have two types of vascular tissue: xylem and phloem. Xylem conducts most of the water and minerals. The xylem of all vascular plants includes tracheids, tube-shaped cells that carry water and minerals up from roots (see Figure 35.9). Because nonvascular plants lack tracheids, vascular plants are sometimes referred to as tracheophytes. Tracheids are actually dead cells—only their walls remain and provide a system of microscopic water pipes. The water-conducting cells in vascular plants are *lignified*; that is, their cell walls are strengthened by the phenolic polymer lignin. The tissue called phloem includes living sugar-conducting cells arranged into tubes that distribute sugars, amino acids, and other organic products (see Figure 35.9).

Lignified vascular tissue permitted vascular plants to grow to greater heights than bryophytes. Their stems became strong enough to withstand drooping, and they could transport water and mineral nutrients high above the ground,

Evolution of Roots

Lignified vascular tissue also provides benefits below-ground. Instead of the rhizoids seen in bryophytes, roots evolved in almost all vascular plants. Roots are organs that anchor vascular plants and enable them to absorb water and nutrients from the soil. Roots also allow the shoot system to grow taller.

A **Figure 29.12** The life cycle of a fern.

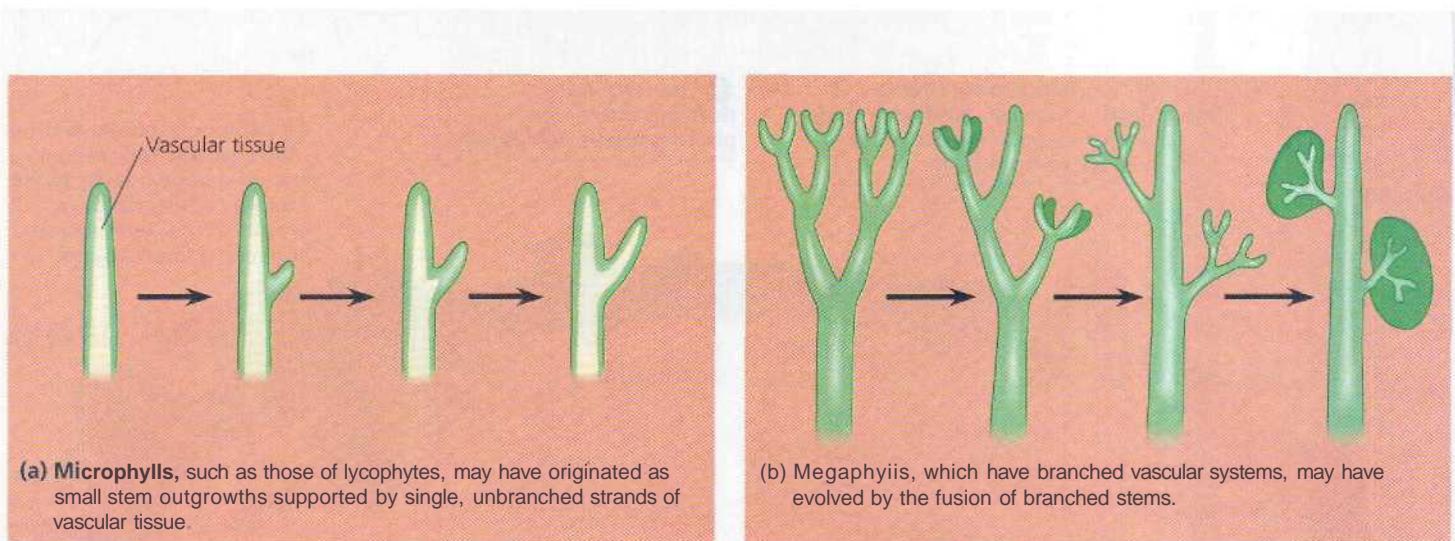

Root tissues of living plants closely resemble stem tissues of early vascular plants preserved in fossils. This suggests that roots may have evolved from the lowermost, subterranean portions of stems in ancient vascular plants. It is not clear whether roots evolved only once in the common ancestor of all vascular plants or independently in different lineages. Although the roots of living members of these lineages of vascular plants share many similarities, the fossil evidence hints at convergent evolution. The oldest lycophyte fossils, for example, already displayed simple roots 400 million years ago, when the ancestors of ferns and seed plants still had none. Studying genes that control root development in different vascular plant species may help resolve this controversy.

Evolution of Leaves

Leaves are organs that increase the surface area of vascular plants, thereby capturing more solar energy for photosynthesis. In terms of size and complexity, leaves can be classified as

either microphylls or megaphylls. All lycophytes (the oldest lineage of modern vascular plants) have microphylls, small, usually spine-shaped leaves with a single vein. Almost all other vascular plants have megaphylls, leaves with a highly branched vascular system. So named because they are typically larger than microphylls, megaphylls support greater photosynthetic productivity than microphylls as a result of their greater surface area served by a network of veins. Microphylls first appear in the fossil record 410 million years ago, but megaphylls do not emerge until about 370 million years ago, near the end of the Devonian period.

According to one model of leaf evolution, microphylls originated as small outgrowths of stems. These outgrowths were supported by single strands of vascular tissue (Figure 29.13a). Megaphylls, by contrast, may have evolved from a series of branches lying close together on a stem, which became flattened and developed webbing that joined branches together (Figure 29.13b). To better understand the origin of leaves, scientists are exploring genetic control of leaf development.

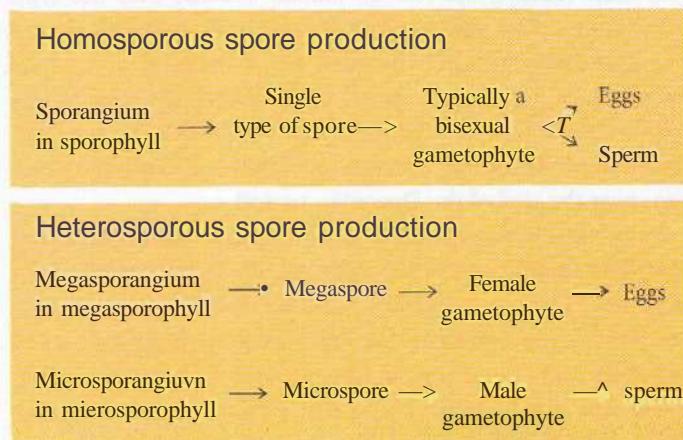

A Figure 29.13 Hypotheses for the evolution of leaves.

Sporophylls and Spore Variations

One evolutionary milestone was the emergence of **sporophylls**, modified leaves that bear sporangia. Sporophylls vary greatly in structure. For example, fern sporophylls produce clusters of sporangia known as **sori** (singular, sorus), usually on the undersides of the sporophylls (see Figure 29.12). In many lycophytes and in most gymnosperms, groups of sporophylls form cones, technically called **strobili** (from the Greek *strobilos*, cone). In Chapter 30, you will see how sporophylls form gymnosperm strobili and parts of flowers.

Most seedless vascular plant species are **homosporous**, having one type of sporophyll producing one type of spore that typically develops into a bisexual gametophyte, as in most ferns. In contrast, a **heterosporous** species has two types of sporophylls and produces two kinds of spores. Megasporangia in megasporophylls produce, megaspores, which develop into female gametophytes. Microsporangia in microsporophylls produce **microspores**, which develop into male gametophytes. All seed plants and a few seedless vascular plants are heterosporous. The following diagram compares the two conditions:

Classification of Seedless Vascular Plants

As noted earlier, living seedless vascular plants form two clades: lycophytes and pterophytes. Lycophytes (phylum Lycophyta) include club mosses, spike mosses, and quillworts. Pterophytes (phylum Pterophyta) include ferns, horsetails, and whisk ferns and their relatives. Because they differ greatly in appearance, ferns, horsetails, and whisk ferns have long been considered separate phyla: phylum Pterophyta (ferns), phylum Sphenophyta (horsetails, also called sphenophytes), and phylum Psilophyta (whisk ferns and a related genus, together known as psilophytes). However, recent molecular comparisons provide convincing evidence that all three groups form a clade. Accordingly many systematists now classify them together as the phylum Pterophyta, as we do in this chapter. Others refer to them as three separate phyla within a clade.

Figure 29.14, on the facing page, describes the general groups of seedless vascular plants.

Phylum Lycophyta: Club Mosses, Spike Mosses, and Quillworts

Modern species of lycophytes—the most primitive group of vascular plants—are relicts of a far more eminent past. By the Carboniferous period, there were two evolutionary lines—one composed of small herbaceous plants and another line of giant woody trees with diameters of more than 2 m and heights of more than 40 m. The giant lycophytes thrived for millions of years in warm, moist swamps, but they became extinct when the climate became cooler and drier at the end of the Carboniferous period. The small lycophytes survived, represented today by about 1,200 species. Though some are commonly called club mosses and spike mosses, they are not true mosses, which are bryophytes.

Figure 29.14

Exploring Seedless Vascular Plant Diversity

LYCOPHYTES (PHYLUM LYCOPHYTA)

Many lycophytes grow on tropical trees as epiphytes, plants that use oilier plants as a substrate but are not parasites. Other species grow on temperate forest floors. In some species, the tiny gametophytes live above-ground and are photosynthetic. Others live underground, nurtured by symbiotic fungi.

Sporophytes have upright stems with many small leaves, as well as ground-hugging stems that produce dichotomously branching roots. In club mosses, sporophylls are clustered into club-shaped cones (strobili). Spike mosses are usually smaller and often grow horizontally. Quillworts, named for their leaf shape, are a single genus that lives in marshy areas. Club mosses are all homosporous, whereas spike mosses and quillworts are all heterosporous. Spores are released in clouds and are so rich in oil that magicians and photographers once ignited them to create smoke or flashes of light.

PTEROPHYTES (PHYLUM PTEROPHYTA)

Psilotum nudum, a whisk fern

Equisetum arvense, field horsetail
Vegetative stem
Strobilus on fertile stem

Athyrium filix-femina, lady fern

WHISK FERNS AND RELATIVES

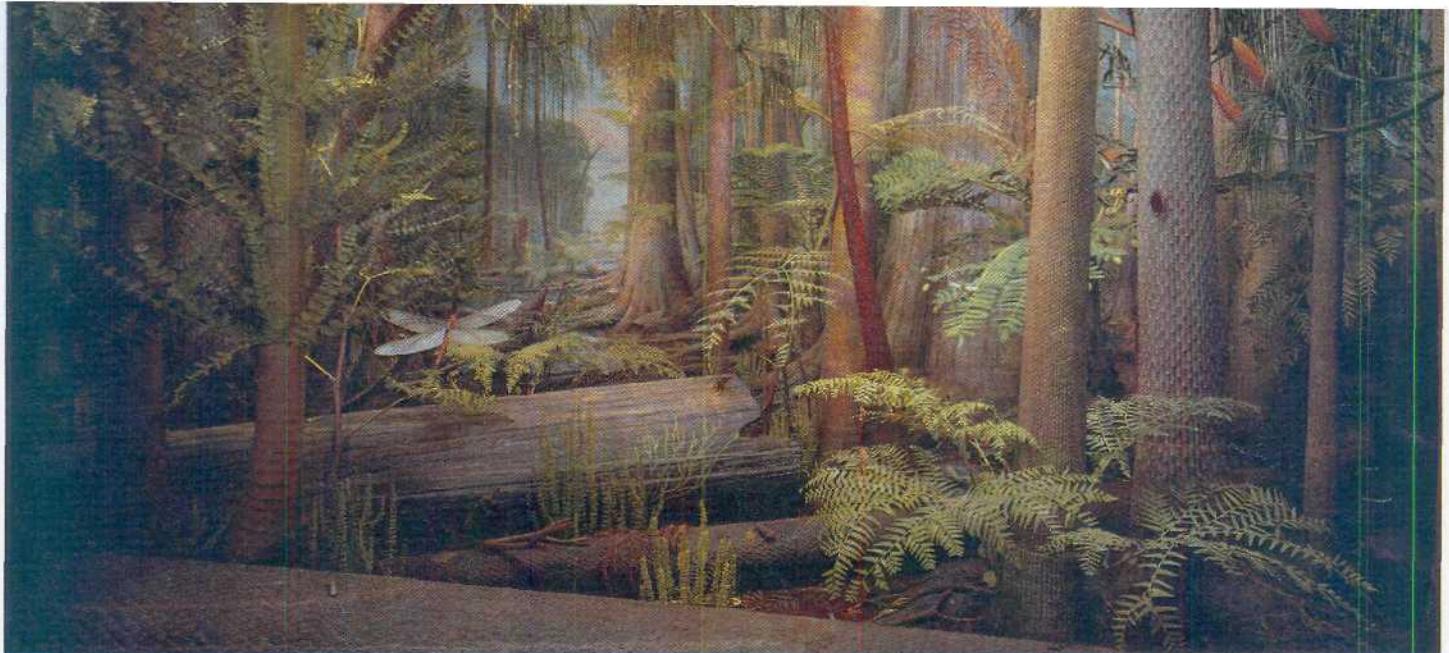

Like primitive vascular plant fossils, the sporophytes of whisk ferns (*Psilotum*) have dichotomously branching stems but no roots. Stems have scale-like outgrowths that lack vascular tissue and may have evolved as very reduced leaves. Each yellow knob on a stem consists of three fused sporangia. Species of the genus *Tmesipteris*, closely related to whisk ferns and found only in the South Pacific, also lack roots but have small, leaflike outgrowths in their stems, giving them a vinelike appearance. Both genera are homosporous, with spores giving rise to bisexual gametophytes that grow underground and are only about a centimeter long.

The name refers to the brushy appearance of the stems, which have a gritty texture that made them historically useful as "scouring rushes" to scrub pots and pans. Some species have separate fertile (cone-bearing) and vegetative stems. Horsetails are homosporous, with cones releasing spores that give rise to tiny male or bisexual gametophytes.

Horsetails are also called arthropophytes ("jointed plants") because their stems have joints. Rings of small leaves or branches emerge from each joint, but the stem is the main photosynthetic organ. Large air canals carry oxygen to the roots, which often grow in waterlogged soil.

Unlike most other seedless vascular plants, ferns have megaphylls (see Figure 29.13b). Sporophytes typically have horizontal stems that give rise to large leaves called fronds, often divided into leaflets. A frond grows as its coiled tip, the fiddlehead, unfurls (see the cover of this textbook).

Almost all species are homosporous. The gametophyte shrivels and dies after the young sporophyte detaches itself. In most species, sporophytes have stalked sporangia with spring-like devices that catapult spores several meters. Airborne spores can be carried far from their origin. Some species produce more than a trillion spores in a plant's lifetime.

A Figure 29.15 Artist's conception of a Carboniferous forest based on fossil evidence. Most of the large trees with straight trunks are lycophytes. The tree on the left with feathery branches is a horsetail. Tree ferns, not shown here, were also abundant in the "coal forests" of the Carboniferous. Animals, including giant dragonflies, also thrived.

Phylum Pterophyta: Ferns, Horsetails, and Whisk Ferns and Relatives

Ferns radiated extensively from their Devonian origins and grew alongside tree lycophytes and horsetails in the great Carboniferous swamp forests. Today ferns are by far the most widespread seedless vascular plants, numbering more than 12,000 species. Though most diverse in the tropics, many ferns thrive in temperate forests, and some species are even adapted to arid habitats.

Horsetails were very diverse during the Carboniferous period, some growing as tall as 15 m. However, today only about 15 species survive as a single, widely distributed genus, *Equisetum*, found in marshy places or along streams.

Psilotum (whisk ferns) and a closely related genus, *Tmesipteris*, form a clade consisting mainly of tropical epiphytes. Whisk ferns, the only vascular plants lacking true roots and leaves, are called "living fossils" because of their striking resemblance to fossils of ancient relatives of living vascular plants (see Figures 29.11 and 29.14). However, much evidence, including analyses of DNA sequences and sperm structure, indicates that *Psilotum* and *Tmesipteris* are closely related to ferns. This hypothesis suggests that their ancestor's true roots and leaves were lost during evolution.

The Significance of Seedless Vascular Plants

The ancestors of living lycophytes, horsetails, and ferns, along with their seedless vascular relatives, grew to great heights during the Carboniferous, forming the first forests (Figure 29.15). With the evolution of vascular tissue, roots, and leaves, these plants accelerated their rate of photosynthesis, dramatically

increasing the removal of CO₂ from the atmosphere. Scientists estimate that CO₂ levels dropped by as much as a factor of five during the Carboniferous, causing global cooling that resulted in widespread glacier formation.

The seedless vascular plants that formed the first forests eventually became coal. In the stagnant waters of Carboniferous swamps, dead plants did not completely decay. This organic material turned to thick layers of peat, later covered by the sea. Marine sediments piled on top, and over millions of years, heat and pressure converted the peat to coal. In fact, Carboniferous coal deposits are the most extensive ever formed. Coal was crucial to the Industrial Revolution, and people worldwide still burn 6 billion tons a year. It is ironic that coal, formed from plants that contributed to a global cooling, now contributes to global warming by returning carbon to the atmosphere (see Chapter 54).

Growing along with the seedless plants in Carboniferous swamps were primitive seed plants. Though seed plants were not dominant at that time, they rose to prominence after the swamps began to dry up at the end of the Carboniferous period. The next chapter traces the origin and diversification of seed plants, continuing our theme of terrestrial adaptation.

Concept Check 29.4

- What are a few key differences between seedless vascular plants and bryophytes?
- What is the major difference between most lycophytes and most ferns and their relatives?

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 29.1

Land plants evolved from green algae

- **Morphological and Biochemical Evidence** (pp. 573-574) The traits shared by plants and charophyceans include rosette cellulose-synthesizing complexes, peroxisome enzymes, similarities in flagellated sperm structure, and formation of phragmoplasts during cell division.
- **Genetic Evidence** (p. 574) Similarities in nuclear and chloroplast genes suggest that charophyceans are the closest living relatives of land plants.
- **Adaptations Enabling the Move to Land** (p. 574) Traits such as sporopollenin allow charophyceans to withstand occasional drying along the edges of ponds and lakes. These traits may have enabled the algal ancestors of plants to survive in terrestrial conditions, opening the way to the colonization of dry land.

Concept 29.2

Land plants possess a set of derived terrestrial adaptations

- **Defining the Plant Kingdom** (p. 575) Some biologists think that the plant kingdom should be expanded to include some or all green algae. Until this phylogenetic debate is resolved, this textbook retains the embryophyte definition of kingdom Plantae, which includes all land plants and their closest algal relatives.
- **Derived Traits of Plants** (pp. 575-577) Derived traits that distinguish the clade of land plants from charophyceans, their closest algal relatives, include apical meristems, alternation of generations, walled spores in sporangia, multicellular gametangia, and multicellular, dependent embryos. Additional derived traits, such as the cuticle and secondary compounds, evolved in many plant species.

Activity Terrestrial Adaptations of Plants

- **The Origin and Diversification of Plants** (pp. 575, 578-579) Fossil evidence indicates that plants were on land at least 475 million years ago. Subsequently, plants diverged into several major groups, including bryophytes (nonvascular plants); seedless vascular plants, such as lycophytes and ferns; and the two groups of seed plants: gymnosperms and angiosperms (flowering plants). Most systematists divide plants into ten phyla.

Activity Highlights of Plant Phylogeny

Concept 29.3

The life cycles of mosses and other bryophytes are dominated by the gametophyte stage

- The three phyla of bryophytes—liverworts, hornworts, and mosses—may not form a clade. Debate continues over the sequence of their evolution (p. 580).
- **Bryophyte Gametophytes** (p. 580) Liverwort and hornwort gametophytes grow more horizontally, whereas those of mosses are more vertical. Gametophytes are the dominant generation and are typically most visible, such as a mat of moss. Rhizoids

anchor gametophytes to the surface. The flagellated sperm produced by antheridia require a film of water to travel to the eggs in archegonia.

- **Bryophyte Sporophytes** (pp. 580-583) Sporophytes grow out of archegonia and are dependent on the haploid gametophytes for nourishment. Smaller and simpler than vascular plant sporophytes, they typically consist of a foot, seta (stalk), and sporangium. Hornwort and moss sporophytes have stomata.

Activity Moss Life Cycle

- **Ecological and Economic Importance of Mosses** (p. 583) *Sphagnum* covers great expanses of land as peat bogs and peat lands, playing an important role in the carbon cycle.

Concept 29.4

Ferns and other seedless vascular plants formed the first forests

- **Origins and Traits of Vascular Plants** (pp. 584-586) Fossils of the forerunners of today's vascular plants date back about 420 million years ago and show that these tiny plants had independent, branching sporophytes but lacked other derived traits of vascular plants, such as xylem and phloem, roots, and leaves.

Life Cycles with Dominant Sporophytes. In contrast with bryophytes, sporophytes of seedless vascular plants are the larger generation, as in the example of the familiar leafy fern plant. The gametophytes are tiny plants that grow on or below the surface.

Activity Fern Life Cycle

Investigation What Are the Different Stages of a Fern Life Cycle?

Transport in Xylem and Phloem. Vascular plants have two vascular tissues: xylem and phloem. Xylem conducts most of the water and minerals. Xylem of all vascular plants includes dead cells called tracheids. The lignin in xylem enables most vascular plants to grow taller than bryophytes. Phloem, a living tissue, conducts sugars and other organic nutrients.

Evolution of Roots. Unlike the rhizoids of bryophytes, roots play an important role in absorbing water and nutrients. Roots may have evolved from subterranean stems. It is unclear whether roots evolved independently in different lineages.

Evolution of Leaves. In terms of evolution, leaves are categorized into two types: microphylls and megaphylls. Microphylls, leaves with a single vein, evolved first and are typical of lycophytes. Almost all other vascular plants have megaphylls, leaves with a highly branched vascular system. Megaphylls are usually larger, which increases photosynthetic productivity.

Sporophylls and Spore Variations. Sporophylls are modified leaves with sporangia. Most seedless vascular plant species are homosporous, producing one type of spore, which usually develops into a bisexual gametophyte. All seed plants and some seedless vascular plant species are heterosporous, having two types of spores that give rise to male and female gametophytes.

- **Classification of Seedless Vascular Plants** (pp. 586-588) Seedless vascular plants include the phylum Lycophtya (club mosses, spike mosses, and quillworts) and the phylum Pterophyta (ferns, horsetails, and whisk ferns and relatives). Ancient lycophytes included woody and herbaceous plants that dominated the first forests. Modern lycophytes are small herbaceous plants. Lycophtya sporophytes have upright stems bearing many microphylls and horizontal stems that grow along the surface. Ferns are the most diverse seedless vascular plants. Most fern species are homosporous and produce clusters of sporangia known as sori. Horsetails and whisk ferns are actually close relatives of ferns.

- **The Significance of Seedless Vascular Plants** (p. 588)
Seedless vascular plants dominated the earliest forests. Their growth may have helped produce the major global cooling that characterized the end of the Carboniferous period. The decaying remnants of the first forests eventually became coal.

TESTING YOUR KNOWLEDGE

Evolution Connection

Draw a cladogram that includes a moss, a fern, and a gymnosperm. Use a charophycean alga as the outgroup. (See Chapter 25 to review cladistics.) Label each branch of the cladogram with at least one derived characteristic unique to that clade.

Scientific Inquiry

In April 1986, an accident at a nuclear power plant in Chernobyl, Ukraine, scattered radioactive fallout for hundreds of miles. In assessing the biological effects of the radiation, researchers found mosses to be especially valuable as organisms for monitoring the damage. Radiation damages organisms by causing mutations. Explain why the genetic effects of radiation can be observed sooner in bryophytes than in plants from other groups. Imagine that you are conducting tests shortly after a nuclear accident. Using potted moss plants as your experimental organisms, design an experiment to test the hypothesis that the frequency of mutations decreases with the organisms distance from the source of radiation.

Investigation *What Are the Different Stages of a Fern Life Cycle?*

Science, Technology, and Society

Bryophytes (nonvascular plants) and seedless vascular plants are common, and several of them have important economic and ecological uses. Nevertheless, very few are important agriculturally. Why? What attributes do they lack that would make a plant useful in agriculture? What attributes limit their agricultural utility?

30

Plant Diversity II The Evolution of Seed Plants

A Figure 30.1 An ancient squash seed.

Key Concepts

- 30.1 The reduced gametophytes of seed plants are protected in ovules and pollen grains
- 30.2 Gymnosperms bear "naked" seeds, typically on cones
- 30.3 The reproductive adaptations of angiosperms include flowers and fruits
- 30.4 Human welfare depends greatly on seed plants

Overview

Feeding the World

Continuing the saga of how plants transformed Earth, this chapter follows the emergence and diversification of seed plants. Fossils and comparative studies of living plants offer clues about the origin of seed plants some 360 million years ago. Seeds changed the course of plant evolution, enabling their bearers to become the dominant producers in most of the terrestrial ecosystems and to make up the vast majority of plant biodiversity.

Seed plants have also had an enormous impact on human society. Starting about 13,000 years ago, humans began to domesticate wheat, maize (commonly called corn in the United States), bananas, and other wild seed plants. This practice emerged separately in various regions of the world, including the Near East, East Asia, Africa, and the Americas. One piece of evidence, the well-preserved squash seed in **Figure 30.1**, was found in a cave in Mexico and dates from between 8,000 and 10,000 years ago. This seed differs from wild squash seeds, suggesting that squash was being cultivated by that time. The domestication of seed plants, particularly angiosperms, produced the most important cultural change in

human history, transforming most human societies from roving bands of hunter-gatherers to permanent settlements anchored by agriculture.

In this chapter, we will first examine the general characteristics of seed plants. Then we will look at the distinguishing features and evolution of gymnosperms and angiosperms.

Concept 30.1

The reduced gametophytes of seed plants are protected in ovules and pollen grains

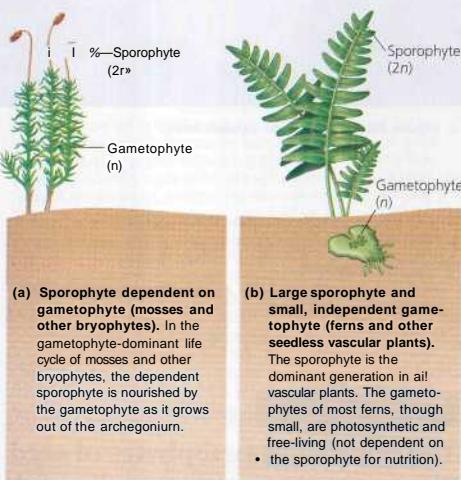

We begin with an overview of key terrestrial adaptations that seed plants added to those already present in bryophytes and seedless vascular plants (see Chapter 29). In addition to seeds, the following are common to all seed plants: reduced gametophytes, heterospory, ovules, and pollen. Seedless plants lack these adaptations, except for a few species that exhibit heterospory.

Advantages of Reduced Gametophytes

Mosses and other bryophytes have life cycles dominated by gametophytes, whereas ferns and other seedless vascular plants have sporophyte-dominated life cycles. The evolutionary trend of gametophyte reduction continued further in the vascular plant lineage that led to seed plants. While the gametophytes of seedless vascular plants are visible to the naked eye, the gametophytes of seed plants are mostly microscopic.

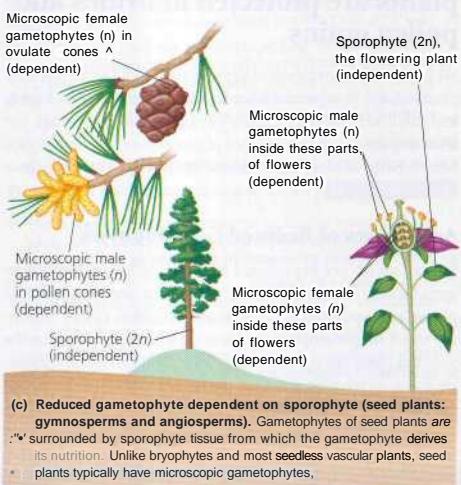

This miniaturization allowed for an important evolutionary innovation in seed plants: Their tiny gametophytes can develop from spores retained within the sporangia of the parental sporophyte. This arrangement protects the delicate female

(egg-containing) gametophytes from environmental stresses. The moist reproductive tissues of the sporophyte shield the gametophytes from drought conditions and from UV radiation. This relationship also enables the dependent gametophytes to obtain nutrients from the sporophyte. In contrast, the free-living gametophytes of seedless plants must fend for themselves. **Figure 30.2** contrasts the sporophyte-gametophyte relationships in bryophytes, seedless vascular plants, and seed plants.

(b) Large sporophyte and small, independent gametophyte (ferns and other seedless vascular plants). The sporophyte is the dominant generation in all vascular plants. The gametophytes of most ferns, though small, are photosynthetic and free-living (not dependent on the sporophyte for nutrition).

Diagram showing a large green fern leaf labeled "Sporophyte (2n)" above a small green heart-shaped gametophyte labeled "Gametophyte (n)".

A Figure 30.2 Gametophyte/sporophyte relationships.

Heterospory: The Rule Among Seed Plants

You read in Chapter 29 that nearly all seedless plants are homosporous—they produce one kind of spore, which usually gives rise to a bisexual gametophyte. The closest relatives of seed plants are all homosporous, suggesting that seed plants also had homosporous ancestors. At some point, seed plants or their ancestors became heterosporous: Megasporangia in megasporophylls produce megaspores that give rise to female gametophytes, and microsporangia in microsporophylls produce microspores that give rise to male gametophytes. Each megasporangium has a single functional megaspore, whereas each microsporangium contains vast numbers of microspores.

As we noted previously, the miniaturization of seed plant gametophytes contributed to the great success of this clade. Next we will look at the development of the female gametophyte within an ovule and the development of the male gametophyte in a pollen grain. Then we will follow the transformation of the ovule into a seed after fertilization.

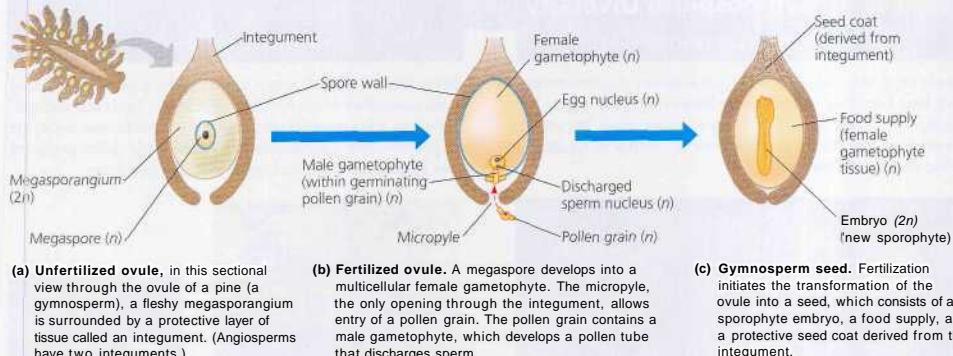

Ovules and Production of Eggs

Although a few species of seedless plants are heterosporous, seed plants are unique in retaining the megaspore within the parent sporophyte (see Figure 30.2c). Layers of sporophyte tissue called **integuments** envelop and protect the megasporangium. Gymnosperm megaspores are surrounded by one integument, whereas those in angiosperms usually have two integuments! The whole structure—megasporangium, megaspore, and their integument(s)—is called an ovule (**Figure 30.3a**). Inside each ovule (from the Latin *ovulum*, little egg), a female gametophyte develops from a megasporangium and produces one or more egg cells.

Pollen and Production of Sperm

Microspores develop into pollen grains, which contain the male gametophytes of seed plants. Protected by a tough coat containing the polymer sporopollenin, pollen grains can be carried away from their parent plant by wind or by hitchhiking on the body of an animal that visits the plant to feed. This transfer of pollen to the part of a seed plant containing the ovules is called **pollination**. If a pollen grain germinates (begins growing), it gives rise to a pollen tube that discharges two sperm into the female gametophyte within the ovule, as shown in **Figure 30.3b**.

Recall that in bryophytes and seedless vascular plants such as ferns, free-living gametophytes release flagellated sperm that must swim through a film of water to reach egg cells. The distance for this sperm transport rarely exceeds a few centimeters. In seed plants, by contrast, the female gametophyte never leaves the sporophyte ovule, and the male gametophytes in pollen grains are durable travelers that can be carried long distances by the wind or by pollinators, depending on the species. Living gymnosperms provide evidence of this evolutionary transition. The sperm of some gymnosperm

A **Figure 30.3** From ovule to seed.

species retain the ancient flagellated condition, but flagella have been lost in the sperm of most gymnosperms and all angiosperms. The sperm of seed plants do not require water or naotility because the pollen is carried to the pollen tube, which then conveys the sperm to the ovule.

The Evolutionary Advantage of Seeds

We have been discussing characteristics of seed plants, but what exactly is a seed? If a sperm fertilizes an egg of a seed plant, the zygote grows into a sporophyte embryo. As shown in **Figure 30.3c**, the whole ovule develops into a seed, which consists of the embryo, along with a food supply, packaged within a protective coat derived from the integument(s).

The evolution of seeds enabled plants bearing them to better resist harsh environments and to disperse offspring more widely. Until the advent of seeds, the spore was the only protective stage in any plant life cycle. For example, moss spores may survive even if the local environment becomes too cold, too hot, or too dry for the mosses themselves to live. Their tiny size enables the moss spores to be dispersed in a dormant state to a new area, where they can germinate and give rise to new moss gametophytes if and when the environment is favorable enough for them to break dormancy. Spores were the main way that mosses and other seedless plants spread over Earth for the first 100 million years of plant life on land, in contrast to a spore, which is single-celled, a seed is a multicellular structure that is much more resistant and complex. Its protective coat is derived from the integument(s) of the ovule. After being released from the parent plant, a seed may remain dormant for days, months, or even years. Under favorable conditions, it can then germinate, with the sporophyte embryo emerging as a seedling. Some seeds drop close to their parent sporophyte plant; others are carried far by the wind or animals.

Concept Check 30.1

1. Contrast sperm delivery in seedless plants with sperm delivery in seed plants.
2. What additional features of seed plants, not present in seedless plants, contributed to their enormous success on land?

For suggested answers, see Appendix A.

Concept 30.2

Gymnosperms bear "naked" seeds, typically on cones

Recall from Chapter 29 that gymnosperms are plants that have "naked" seeds that are not enclosed in ovaries. Their seeds are exposed on modified leaves that usually form cones (strobili). In contrast, angiosperm seeds are enclosed in fruits, which are mature ovaries. Among the gymnosperms are many well-known varieties of conifers, or cone-bearing trees, including pine, fir, and redwood. Of the ten plant phyla in the taxonomic scheme adopted by this textbook (see Table 29.1), four are gymnosperms: Cycadophyta, Ginkgophyta, Gnetaophyta, and Coniferophyta. The relationships of these four phyla to each other are uncertain. **Figure 30.4**, on the next two pages, surveys the diversity of extant gymnosperms.

Figure 30.4
Exploring Gymnosperm Diversity

PHYLUM CYCADOPHYTA

Cycads are the next largest group of gymnosperms after the conifers. They have large cones and palmlike leaves (true palm species are angiosperms). Only about 130 species survive today, but cycads thrived during the Mesozoic era, known as the "Age of Cycads" as well as the "Age of Dinosaurs."

Cycas revoluta

PHYLUM GINKGOPHYTA

Ginkgo biloba is the only extant species of this phylum. Also known as the maidenhair tree, it has deciduous fanlike leaves that turn gold in autumn. It is a popular ornamental tree in cities because it tolerates air pollution well. Landscapers usually plant only pollen-producing trees because the fleshy seeds smell rancid as they decay.

PHYLUM GNETOPHYTA

Plants in the phylum Gnetaophyta, called gnethophytes, consist of three genera: *Gnetum*, *Ephedra*, and *Welwitschia*. Some species are tropical, whereas others live in deserts. Although very different in appearance, the genera are grouped together based on molecular data.

Welwitschia.
This genus consists of one species,
Welwitschia mirabilis, a plant that lives only in the deserts of southwestern Africa. Its strap-like leaves are among the largest leaves known.

Ovulate cones

***Gnetum*.** This genus includes about 35 species of tropical trees, shrubs, and vines, mainly native to Africa and Asia. Their leaves look similar to those of flowering plants, and their seeds took somewhat like fruits.

***Ephedra*.** This genus includes about 40 species that inhabit arid regions worldwide. These desert shrubs, commonly called "Mormon tea," produce the compound ephedrine, which is used medicinally as a decongestant.

PHYLUM CONIFEROphyta

Phylum Coniferophyta is by far the largest of the gymnosperm phyla, consisting of about 600 species of conifers (from the Latin *conus*, cone, and *ferre*, to carry). Many are large trees, such as cypresses and redwoods. A few conifer species dominate vast forested regions of the Northern Hemisphere, where the growing season is relatively short because of latitude or altitude.

Douglas fir. "Doug fir" (*Pseudotsuga menziesii*) provides more timber than any other North American tree species. Some uses include house framing, plywood, pulpwood for paper, railroad ties, and boxes and crates.

Pacific yew. The bark of Pacific yew (*Taxus brevifolia*) is a source of taxol, a compound used to treat women with ovarian cancer. The leaves of a European yew species produce a similar compound, which can be harvested without destroying the plants. Pharmaceutical companies are continuing to develop techniques for synthesizing drugs with taxol-like properties.

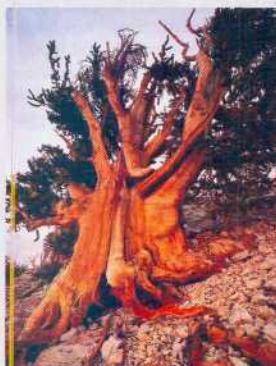

Most conifers are evergreens; they retain their leaves throughout the year. Even during winter, a limited amount of photosynthesis occurs on sunny days. When spring comes, conifers already have fully developed leaves that can take advantage of the sunnier, warmer days. Some conifers, such as the dawn redwood, tamarack, and larch, are deciduous trees that lose leaves each autumn.

Common juniper. The "berries" of the common juniper (*Juniperus communis*) are actually ovule-producing cones consisting of fleshy sporophylls.

Wollemia pine. Survivors of a conifer group once known only from fossils, living Wollemi pines (*Wollemia nobilis*) were discovered in 1994 in a national park only 150 kilometers from Sydney, Australia. The species consists of just 40 known individuals in two small groves. The inset photo compares the leaves of this "living fossil" with actual fossils.

Bristlecone pine. This species (*Pinus longaeva*), which is found in the White Mountains of California, includes some of the oldest living organisms, reaching ages of more than 4,600 years. One tree (not shown here) is called Methuselah because it may be the world's oldest living tree, in order to protect the tree, scientists keep its location a secret.

Sequoia. This giant sequoia (*Sequoiadendron giganteum*) in California's Sequoia National Park weighs about 2,500 metric tons, equivalent to about 24 blue whales (the largest animals), or 40,000 people. The giant sequoia is one of the largest living organisms and also among the most ancient, with some individuals estimated to be between 1,800 and 2,700 years old. Their cousins, the coast redwoods (*Sequoia sempervirens*), grow to heights of more than 110 meters (taller than the Statue of Liberty) and are found only in a narrow coastal strip of northern California and southern Oregon.

Gymnosperm Evolution

Fossil evidence reveals that by the late Devonian period, some plants had begun to acquire some adaptations that characterize seed plants. For example, *Archaeopteris* was a heterosporous tree that produced wood (Figure 30.5). It did not, however, bear seeds. Such transitional species of seedless vascular plants are sometimes called progymnosperms.

The first seed-bearing plants to appear in the fossil record were gymnosperms dating from around 360 million years ago, more than 200 million years before the first angiosperm fossils. These early gymnosperm species became extinct, along with several later gymnosperm lineages. Although the relationships between extinct and surviving lineages of seed plants remain uncertain, morphological and molecular evidence places surviving lineages of seed plants into two clades: the gymnosperms and the angiosperms (see Figure 29.7).

Early gymnosperms lived in Carboniferous ecosystems still dominated by lycophytes, horsetails, ferns, and other seedless vascular plants. As the Carboniferous period gave way to the Permian, markedly warmer and drier climatic conditions favored the spread of gymnosperms. The flora and fauna changed dramatically, as many groups of organisms disappeared and others became prominent (see Chapter 26). Though most pronounced in the seas, the changeover also affected terrestrial life. For example, in the animal kingdom, amphibians decreased in diversity and were replaced by reptiles, which were especially well adapted to the arid conditions. Similarly, the lycophytes, horsetails, and ferns that dominated the Carboniferous swamps were largely replaced by gymnosperms, which were more suited to the drier climate. In such gymnosperms as pines and firs, among the adaptations to arid conditions are their needle-shaped leaves, which have thick cuticles and relatively small surface areas.

• **Figure 30.5 A progymnosperm.** *Archaeopteris*, which lived 360 million years ago, produced wood and was heterosporous, but did not produce seeds. Growing up to 20 m tall, it had fernlike leaves.

Geologists consider the end of the Permian period, about 251 million years ago, to be the boundary between the Paleozoic ("old life") and Mesozoic ("new life") eras. Life changed profoundly as gymnosperms dominated terrestrial ecosystems throughout the Mesozoic, serving as the food supply for giant herbivorous dinosaurs. The Mesozoic era ended with mass extinctions of the dinosaurs and many other groups, and the planet gradually cooled. Although angiosperms now dominate most terrestrial ecosystems, many gymnosperms remain an important part of Earth's flora.

A Closer Look at the Life Cycle of a Pine

As you read earlier in the chapter, the evolution of seed plants included three key reproductive adaptations: the increasing dominance of the sporophyte generation; the advent of the seed as a resistant, dispersible stage in the life cycle; and the evolution of pollen as an airborne agent that brings gametes together. To reinforce your understanding of these adaptations, study Figure 30.6, which shows the life cycle of a pine, one of the most familiar gymnosperms.

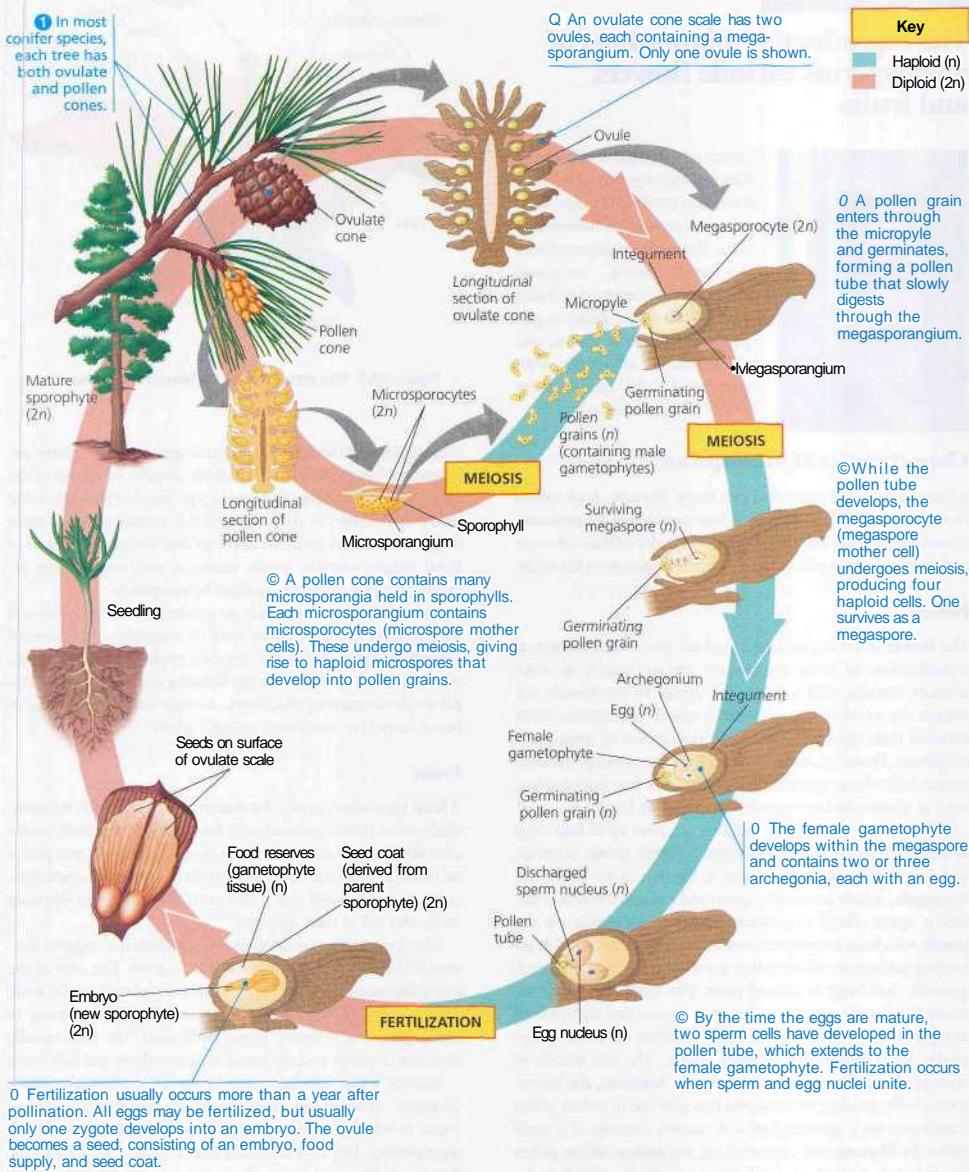

The pine tree is the sporophyte; its sporangia are located on scalelike structures packed densely in cones. Like all seed plants, conifers are heterosporous. In conifers, the two types of spores are produced by separate cones: small pollen cones and large ovulate cones. In most pine species, each tree has both types of cones. In pollen cones, microsporocytes (microspore mother cells) undergo meiosis and produce haploid microspores. Each microspore develops into a pollen grain containing a male gametophyte. In pines and other conifers, the yellow pollen is released in large amounts and carried by the wind, dusting everything in its path. Meanwhile, in ovulate cones, megasporocytes (megaspore mother cells) undergo meiosis and produce haploid megaspores. Surviving megasporocytes develop into female gametophytes, which are retained within the sporangia. From the time young pollen and ovulate cones appear on the tree, it takes nearly three years for the male and female gametophytes to be produced and brought together, and for mature seeds to form from the fertilized ovules. The scales of each ovulate cone then separate, and the seeds travel on the wind. A seed that lands in a habitable place germinates, its embryo emerging as a pine seedling.

Concept Check 30.2

- Based on Figure 30.4, explain why the various types of gymnosperms can be described as being similar yet distinctive.
- Explain how the pine life cycle (see Figure 30.6) reflects basic characteristics of seed plants.

For suggested answers, see Appendix A.

• Figure 30.6 The life cycle of a pine.

Concept 30.3

The reproductive adaptations of angiosperms include flowers and fruits

Commonly known as flowering plants, angiosperms are seed plants that produce the reproductive structures called (flowers and fruits). The name *angiosperm* (from the Greek *angion*, container) refers to seeds contained in fruits, the mature ovaries. Today, angiosperms are the most diverse and widespread of all plants, with more than 250,000 species (about 90% of all plant species).

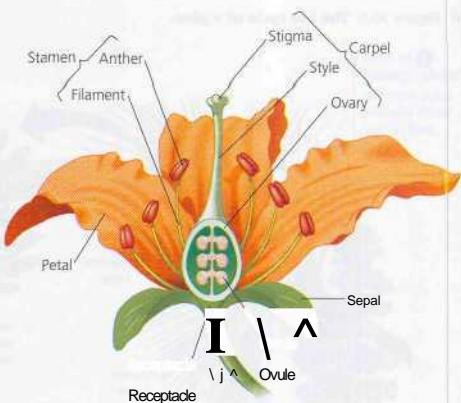

Characteristics of Angiosperms

All angiosperms are classified in a single phylum, Anthophyta (from the Greek *anthos*, flower). Before considering the evolution of angiosperms, we will examine their key adaptations—flowers and fruits—and the roles they play in the angiosperm life cycle.

Flowers

The flower is an angiosperm structure specialized for sexual reproduction. In many angiosperm species, insects or other animals transfer pollen from one flower to the female sex organs on another flower, which makes pollination more directed than the wind-dependent pollination of most gymnosperms. However, some angiosperms are wind-pollinated, particularly those species that occur in dense populations, such as grasses and tree species in temperate forests.

A flower is a specialized shoot that can have up to four rings of modified leaves called floral organs: sepals, petals, stamens, and carpels (Figure 30.7). Starting at the base of the flower are the sepals, which are usually green and enclose the flower before it opens (think of a rosebud). Above the sepals are the petals, which are brightly colored in most flowers and aid in attracting pollinators. Flowers that are wind-pollinated, however, generally lack brightly colored parts. The sepals and petals are sterile floral organs, meaning that they are not directly involved in reproduction. Within the whorl of petals are the fertile sporophylls, floral organs that produce spores. The two whorls of sporophylls are the stamens and carpels. Stamens, the microsporophylls, produce microspores that give rise to pollen grains containing male gametophytes. A stamen consists of a stalk called the filament and a terminal sac, the anther, where pollen is produced. Carpels are the megasporophylls, which make

& Figure 30.7 The structure of an idealized flower.

megaspores and their products, female gametophytes. Many angiosperms have flowers with multiple carpels. At the tip of the carpel is a sticky stigma that receives pollen. A style leads to the ovary at the base of the carpel, which contains one or more ovules. If fertilized, an ovule develops into a seed. The whorls of floral organs—sepals, petals, stamens, and carpels—are attached to a part of the stem called the receptacle.

Some angiosperms, such as garden peas, have flowerets with a single carpel. Others, such as magnolias, have several separate carpels. Still other species, such as lilies, have two or more fused carpels, usually forming an ovary with multiple ovule-containing chambers. A single carpel or a group of fused carpels is sometimes called a **pistil**.

Fruits

A fruit typically consists of a mature ovary, although it can include other flower parts as well. As seeds develop from ovules after fertilization, the wall of the ovary thickens. A pea pod is an example of a fruit, with seeds (mature ovules, the peas) encased in the ripened ovary (the pod). Fruits protect dormant seeds and aid in their dispersal.

The fruit begins to develop after pollination triggers hormonal changes that cause the ovary to grow. The wall of the ovary becomes the pericarp, the thickened wall of the fruit. As the ovary grows, the other flower parts wither away in many plants. If a flower is not pollinated, the fruit usually does not develop, and the entire flower withers and falls away.

Mature fruits can be either fleshy or dry (Figure 30.8!). Oranges, strawberries, and grapes are examples of fleshy fruits, in which one or more pericarp layers become soft during ripening. Dry fruits include beans, nuts, and grains. The dry, wind-dispersed fruits of grasses, harvested while on the

(a) Tomato, a fleshy fruit with soft outer and inner layers of pericarp

(b) Ruby grapefruit, a fleshy fruit with a hard outer layer and soft inner layer of pericarp

(c) Nectarine, a fleshy fruit with a soft outer layer and hard inner layer (pit) of pericarp

(d) Milkweed, a dry fruit that splits open at maturity

(e) Walnut, a dry fruit that remains closed at maturity

▲ **Figure 30.8** Some variations in fruit structure.

pliant, are major staple foods for humans. The cereal grains of wheat, rice, maize, and other grasses are easily mistaken for seeds, but each is actually a fruit with a dry pericarp that adheres to the seed coat of the seed within. The ripening of a dry fruit involves the aging and drying out of the fruit tissues.

Fruits can also be categorized according to whether they develop from a single ovary, from multiple ovaries, or even from more than one flower. In Chapter 38, we will examine the transition from flower to fruit in more detail.

Various fruit adaptations help disperse seeds (Figure 30.9). The seeds of some flowering plants, such as dandelions and maples, are contained within fruits that function like kites or propellers, adaptations that enhance dispersal by wind. Some, such as coconuts, are adapted to dispersal by water. And many angiosperms rely on animals to carry seeds. Some of these plants have fruits modified as burrs that cling to animal fur (or tie clothes of humans). Other angiosperms produce edible fruits, which are usually nutritious, sweet tasting, and vividly colored, advertising their ripeness. When an animal eats the fruit, it digests the fruit's fleshy part, but the tough seeds usually pass unharmed through the animal's digestive tract. Animals may deposit the seeds, along with a supply of fertilizer, miles from where the fruit was eaten.

the Angiosperm Life Cycle

An atypical angiosperm life cycle is shown in Figure 30.10, on the next page. The flower of the sporophyte produces microspores

(a) Wings enable maple fruits to be easily carried by the wind.

(b) Seeds within berries and other edible fruits are often dispersed in animal feces.

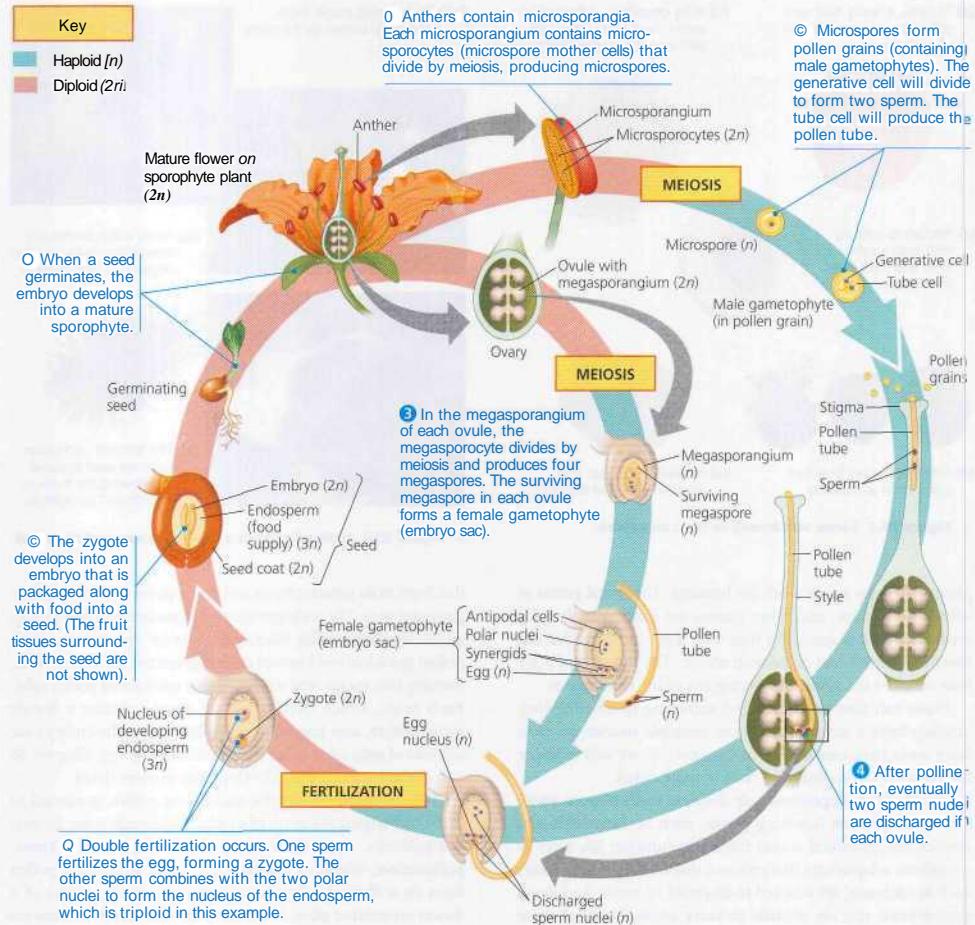

(c) The barbs of cockleburs facilitate seed dispersal by allowing the fruits to "hitchhike" on animals.

▲ **Figure 30.9** Fruit adaptations that enhance seed dispersal.

that form male gametophytes and megasporangia that form female gametophytes. The male gametophytes are in the pollen grains, which develop within microsporangia in the anthers. Each pollen grain has two haploid cells: a generative cell that divides, forming two sperm, and a tube cell that produces a pollen tube. Each ovule, which develops in an ovary, contains a female gametophyte, also known as an embryo sac. The embryo sac consists of only a few cells, one of which is the egg. Chapter 38 will discuss gametophyte development in more detail.

After its release from the anther, the pollen is carried to the sticky stigma at the tip of a carpel. Although some flowers self-pollinate, most have mechanisms that ensure cross-pollination, which in angiosperms is the transfer of pollen from an anther of a flower on one plant to the stigma of a flower on another plant of the same species. Cross-pollination enhances genetic variability. In some cases, stamens and carpels of a single flower may mature at different times, or they may be so arranged that self-pollination is unlikely.

The pollen grain germinates after it adheres to the stigma of a carpel. Now a mature male gametophyte, it extends a pollen tube that grows down within the style of the carpel. After reaching the ovary, the pollen tube penetrates through the micropyle, a pore in the integuments of the ovule, and discharges two sperm cells into the female gametophyte (embryo sac). One sperm fertilizes the egg, forming a diploid zygote. The other sperm fuses with the two nuclei in the large central cell of the female gametophyte. This type of double fertilization is unique to angiosperms.

A Figure 30.10 The life cycle of an angiosperm.

After double fertilization, the ovule matures into a seed. The zygote develops into a sporophyte embryo with a rudimentary root and one or two seed leaves called cotyledons. The nucleus of the central cell of the female gametophyte divides repeatedly and develops into endosperm, tissue rich in starch and other food reserves.

What is the function of double fertilization in angiosperms? One hypothesis is that double fertilization synchronizes the development of food storage in the seed with the development of the embryo. If a particular flower is not pollinated or sperm

cells are not discharged into the embryo sac, fertilization does not occur, and neither endosperm nor embryo forms. So perhaps double fertilization is an adaptation that prevents flowering plants from squandering nutrients on infertile ovules.

Another type of double fertilization occurs in some gymnosperm species belonging to phylum Gnetophyta. However, in these species double fertilization gives rise to two embryos rather than to an embryo and endosperm. This difference indicates that double fertilization evolved independently in angiosperms and gymnosperms.

As you read earlier, the seed consists of the embryo, endosperm, remnants of the sporangium, and a seed coat derived from the integuments. An ovary develops into a fruit as its ovules become seeds. After being dispersed, a seed may germinate if environmental conditions are favorable. The coat ruptures and the embryo emerges as a seedling, using food stored in the endosperm and cotyledons.

Angiosperm Evolution

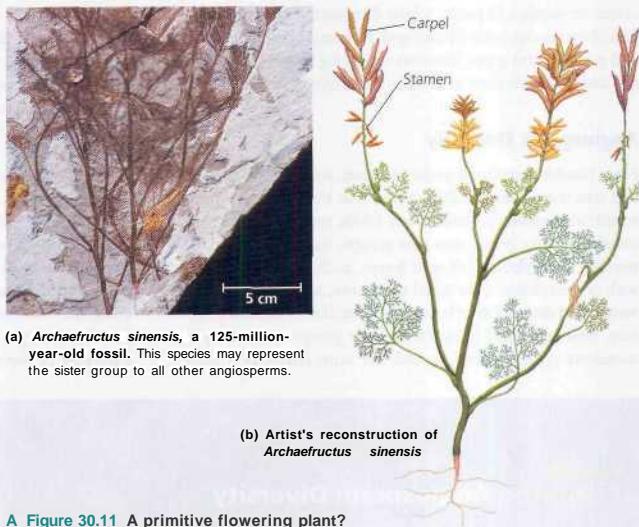

Clarifying the origin and diversification of angiosperms—what Charles Darwin once called an “abominable mystery”—poses fascinating challenges to evolutionary biologists. Angiosperms originated at least 140 million years ago, and during the late Mesozoic, the major branches of the clade diverged from their common ancestor, but it was not until the end of the Mesozoic that angiosperms began to dominate many terrestrial ecosystems. Landscapes changed dramatically as conifers, cycads, and other gymnosperms gave way to flowering plants in many parts of the world.

With their flowers and fruits, angiosperms are profoundly different from living or fossil gymnosperms, which makes their origins puzzling. To understand how the angiosperm body plan emerged, scientists are studying newly discovered fossils and developmental genes that underlie flowers and other angiosperm innovations (see Chapter 35).

Fossil Angiosperms

In the late 1990s, scientists in China discovered some intriguing fossils of 125-million-year-old angiosperms. These fossils, now named *Archaefructus liaoningensis* and *Archaefructus sinensis* (Figure 30.11), display both derived and primitive traits. *A. sinensis*, for example, has anthers and has seeds inside closed carpels but lacks petals and sepals. In 2002, scientists completed a phylogenetic comparison of *A. sinensis* with 173 living plants. (*A. liaoningensis* was not included because its fossils are not as well preserved.) The researchers concluded that among all known plant fossils, *Archaefructus* is the most closely related to all living angiosperms.

If *Archaefructus* is indeed a “proto-angiosperm,” that would suggest that the ancestors of flowering plants were herbaceous rather than woody. *Archaefructus* was discovered along with fish fossils and has bulbous structures that might be aquatic adaptations, implying that perhaps angiosperms originated as aquatic plants. The discoverers of *Archaefructus* have suggested that fast-growing herbaceous plants could have returned to

A Figure 30.11 A primitive flowering plant?

water and thrived there, escaping competition with other seed plants and then later taking over the land.

More recently however, some paleobotanists have disputed this interpretation. More derived lineages of angiosperms also became aquatic, and along the way their flowers became simpler, resembling the “primitive” flowers of *Archaefructus*. Such debates, typical whenever a seemingly transitional fossil is discovered, may be resolved when more fossils and other types of evidence emerge.

An “Evo-Devo” Hypothesis of Flower Origins

Chapter 24 discussed how studying developmental genes informs hypotheses about animal evolution. The same holds true for flowering plants. Botanist Michael Frohlich of the Natural History Museum in London has used the “evo-devo” approach—the synthesis of evolutionary and developmental biology—in hypothesizing how pollen-producing and ovule-producing structures were combined into a single flower. He proposes that the ancestor of angiosperms had separate pollen-producing and ovule-producing structures. Then, as a result of a mutation, ovules developed on some microsporophylls, which evolved into carpels.

Because Frohlich asserts that the flower evolved mainly from the pollen-producing (“male”) reproductive structure of a gymnosperm ancestor, his view is known as the “mostly male” hypothesis. Supporting evidence includes comparisons of genes that give rise to flowers and cones. Flower-development genes are usually related to pollen-producing gymnosperm genes. Also, certain mutations cause flowering plants to grow

ovules on sepals and petals, which demonstrates that the position of ovules can easily be changed. By comparing angiosperm and gymnosperm genes, botanists are testing Froelich's hypothesis and other evo-devo models for the origin of flowers.

Angiosperm Diversity

From humble beginnings in the Mesozoic, angiosperms diversified into more than 250,000 species that now dominate most terrestrial ecosystems. Until the late 1990s, most systematists divided flowering plants into two groups, based partly on the number of cotyledons, or seed leaves, in the embryo. Species with one cotyledon were called **monocots**, and those with two were called **dicots**. Other features, such as flower and leaf structure, were also used to define the two groups. For example, monocots typically have parallel leaf veins (think of a grass

blade), while the veins of most dicots have a netlike pattern (think of an oak leaf). Some examples of monocots are orchids, palms, and grain crops such as maize, wheat, and rice. Some examples of dicots are roses, peas, sunflowers, and maples.

Recent DNA studies, however, indicate that the monocot-dicot distinction likely does not completely reflect evolutionary relationships. Current research supports the view that monocots form a clade but reveals that the remaining angiosperm species are not monophyletic. The vast majority of species traditionally called dicots do form a clade, now known as **eudicots** ("true" dicots), but the others are now divided into several small lineages. Three of these lineages are informally called **basal angiosperms** because they appear to include the flowering plants belonging to the oldest lineages. Another lineage, known as the **magnoliids**, evolved later. Figure 30.12 provides an overview of angiosperm diversity.

Figure 30.12
Exploring Angiosperm Diversity

BASAL ANGIOSPERMS

Surviving basal angiosperms are currently thought to consist of three small lineages, including only about 100 species. The oldest lineage seems to be represented by a single species, *Amborella trichopoda*. Two other surviving lineages diverged later: a clade that includes water lilies and then a clade consisting of the star anise and its relatives.

***Amborella trichopoda*.** This small shrub, found only on the South Pacific island of New Caledonia, may be the sole survivor of a branch at the very base of the angiosperm tree. *Amborella* lacks vessels, which are present in more derived angiosperms. Consisting of xylem cells arranged in continuous tubes, vessels transport water more efficiently than tracheids. Their absence in *Amborella* indicates they evolved after the lineage that gave rise to *Amborella* branched off.

Water lily (*Nymphaea "Rene Gerard"*). Water lilies are living members of a clade that may be predated only by the *Amborella* lineage.

Star anise (*Illicium floridanum*). This species represents a third surviving lineage of basal angiosperms.

HYPOTHETICAL TREE OF FLOWERING PLANTS

MAGNOLIIDS

Magnoliids consist of about 8,000 species, most notably magnolias, laurels, and black pepper plants. They include both woody and herbaceous species. Although they share some primitive traits with basal angiosperms, such as a typically spiral rather than whorled arrangement of flower organs, magnoliids are actually more closely related to monocots and eudicots.

Southern magnolia (*Magnolia grandiflora*). This member of the magnolia family is a woody magnoliid. This variety of southern magnolia, called "Goliath," has flowers that measure up to about a foot across.

MONOCOTS

More than one-quarter of angiosperm species are monocots—about 70,000 species. These examples represent some of the largest families.

Orchid
(*Lemboglossum rossii*)

Pygmy date palm (*Phoenix roebelenii*)

Lily (*Lilium*
"Enchantment")

Barley (*Hordeum vulgare*), a grass

EUDICOTS

More than two-thirds of angiosperm species are eudicots—roughly 170,000 species. Below is a sampling of floral diversity

California
clarkia
californica

Pyrenean oak
(*Quercus*
pyrenaica)

Dog rose (*Rosa canina*), a wild rose

Pea (*Lathyrus*
nervosus,
Lord Anson's
blue pea), a legume

Zucchini
(*Cucurbita*
pepo), female
(left) and
male flowers

Monocot Characteristics

One cotyledon

Veins usually parallel

Vascular tissue scattered

Root system usually fibrous (no main root)

Pollen grain with one opening

Floral organs usually in multiples of three

Eudicot Characteristics

Two cotyledons

Veins usually netlike

Vascular tissue usually arranged in ring

Taproot (main root) usually present

Pollen grain with three openings

Floral organs usually in multiples of four or five

Evolutionary Links Between Angiosperms and Animals

Ever since they colonized land, animals have influenced the evolution of terrestrial plants, and vice versa. Animals crawling on the forest floor created a selective pressure favoring plants that kept their spores and gametophytes off the ground, out of easy reach of most animals. This trend in plants may in turn have favored the evolution of flight in insects.

This type of mutual evolutionary influence between species is often advantageous for both partners. For example, as flowers and fruits evolved in angiosperms, some animals helped plants by dispersing their pollen and seeds. Meanwhile, the animals received a benefit as they ate the plants' nectars, seeds, and fruits.

Plant-pollinator relationships have likely played a role in increasing angiosperm and animal diversity (Figure 30.13). The most extreme of these relationships is between an individual species of flower that can only be pollinated by a single animal species. In Madagascar, for example, one species of orchid has an 18-inch-long nectary, so the nectar can only be consumed by a moth with an 18-inch-long proboscis! Such linked adaptations, involving reciprocal genetic change in two species, are described as *coevolution*, as we will discuss farther in Chapter 53.

Most relationships are less specific, however. For example, the flowers of a particular species may attract insects rather than birds, but many different insect species may serve as pollinators. Conversely, a single animal species—a honeybee species, for

example—may pollinate many plant species. But even in these less specific relationships, flower color, fragrance, and structure often relied specialization for a particular taxonomic group of pollinators, such as diverse species of bees or hummingbirds. Other influences, such as animals that eat flowers while providing no pollination, can also help to shape flower diversity.

Angiosperm evolution has contributed particularly to the variety of insect species. But the expansion of grasslands during the past 65 million years has also increased the diversity of grazing mammals such as horses. Grasses that are C₄ photosynthesizers spread because a decline in the atmospheric CO₂ levels gave a selective advantage to C₄ photosynthesis (see Chapter 10). And as you will read in Chapter 34, the shift from forests to grasslands in Africa between 10 and 2 million years ago was a crucial factor in the evolution of our own lineage.

Concept Check 30.3

- It has been said that an oak is an acorn's way of making more acorns. Write an explanation that includes these terms: sporophyte, gametophyte, ovule, seed, ovary, and fruit.
- Compare and contrast a pine cone and a flower in terms of structure and function.
- Explain the use of the terms *monocot*, *dicot*, and *eudicot*.

For suggested answers, see Appendix A.

(a) A flower pollinated by honeybees. This honeybee is harvesting pollen and nectar (a sugary solution secreted by flower glands) from Scottish broom flower. The flower has a tripping mechanism that arches the stamens over the bee and dusts it with pollen, some of which will rub off onto the stigma of the next flower the bee visits.

(b) A flower pollinated by hummingbirds. The long, thin beak and tongue of this rufous hummingbird enable the animal to probe flowers that secrete nectar deep within floral tubes. Before the hummer leaves, anthers will dust its beak and head feathers with pollen. Many flowers that are pollinated by birds are red or pink, colors to which bird eyes are especially sensitive.

(c) A flower pollinated by nocturnal animals. Some angiosperms, such as this cactus, depend mainly on nocturnal pollinators, including bats. Common adaptations of such plants include large, light-colored, highly fragrant flowers that nighttime pollinators can locate.

A Figure 30.13 Flower-pollinator relationships.

Concept 30.4

Human welfare depends greatly on seed plants

Throughout this unit, we have been highlighting the important ways in which humans depend on various groups of organisms. No group is more important to our survival than seed plants. In fact, forests and on farms, seed plants are key sources of food, fuel, wood products, and medicine. Our reliance on them makes the preservation of plant diversity critical.

Products from Seed Plants

Most of our food comes from angiosperms. Just six crops—wheat, rice, maize, potatoes, cassava, and sweet potatoes—yield 80% of all the calories consumed by humans. We also depend on angiosperms to feed livestock raised for meat: It takes A.8 pounds of grain to produce a pound of grain-fed beef.

Modern crops are the products of a relatively recent burst of genetic change, resulting from artificial selection after humans began domesticating plants approximately 13,000 years ago. To appreciate the scale of the transformation, contrast the sizes of domesticated plants and their smaller wild relatives, as in the case of maize and teosinte (see Figure 38.14). At the genetic level, scientists can also glean information about domestication by comparing the genes of crops with those of wild relatives. With maize, dramatic changes, such as increased cob size and removal of the hard coating round teosinte kernels, may have been initiated by as few as five gene mutations.

How did wild plants change so dramatically in such relatively little time? For thousands of years, farmers have selected the seeds of plants with desirable traits (large fruits, for example) to plant for the next year's crops. But humans may also be domesticating certain other plants unconsciously, as in the case of wild almonds. Almonds contain a bitter compound called amygdalin that repels birds and other animals. Amygdalin breaks down into cyanide, so eating a large number of wild almonds can be fatal. But mutations can reduce the level of amygdalin, making almonds sweet rather than bitter. Wild birds eat almonds from trees with such mutations. According to one hypothesis, humans may have observed birds eating the almonds and then eaten the almonds themselves, passing some seeds in their feces. The seeds germinated around human settlements and grew into plants with sweeter, less dangerous almonds.

In addition to basic crops, flowering plants provide non-tapet foods. Two of the world's most popular beverages come from tea leaves and coffee beans, and you can thank the tropical cacao tree for cocoa and chocolate. Spices are derived from various plant parts, such as flowers (clove, saffron), fruits and seeds (vanilla, black pepper, mustard, cumin), leaves (basil, mint, sage), and even bark (cinnamon).

Many seed plants, both gymnosperms and angiosperms, are sources of wood, which is absent in all living seedless plants. Wood consists of an accumulation of tough-walled xylem cells (see Chapter 35). Wood is the primary source of fuel for much of the world, and wood pulp, typically derived from conifers such as fir and pine, is used to make paper. Worldwide, wood also remains the most widely used construction material.

For centuries, humans have also depended on seed plants for medicines. Many cultures have a long tradition of using herbal remedies, and scientific research has identified the relevant secondary compounds in many of these plants, leading to the synthesis of medicines. Willow leaves and bark, for instance, have been used since ancient times in pain-relieving remedies, including prescriptions by the Greek physician Hippocrates. In the 1800s, scientists traced the willow's medicinal property to the chemical salicin. A synthesized derivative, acetylsalicylic acid, is what we call aspirin. Although modern chemistry facilitates laboratory synthesis, plants remain an important direct source of medicinal compounds. In the United States, for example, about 25% of prescription drugs contain one or more active ingredients extracted or derived from plants, typically from seed plants. Other ingredients were first discovered in seed plants and then synthesized artificially. **Table 30.1** lists some medicinal uses of secondary compounds of seed plants.

Table 30.1 A Sampling of Medicines Derived from Seed Plants

| Compound | Example of Source | Example of Use |
|--------------|---------------------------|--------------------------------|
| Atropine | Belladonna plant | Pupil dilator in eye exams |
| Digitalin | Foxglove | Heart medication |
| Menthol | Eucalyptus tree | Ingredient in cough medicines |
| Morphine | Opium poppy | Pain reliever |
| Quinine | Cinchona tree (see below) | Malaria preventative |
| Taxol | Pacific yew | Ovarian cancer drug |
| Tubocurarine | Curare tree | Muscle relaxant during surgery |
| Vinblastine | Periwinkle | Leukemia drug |

Cinchona bark, source of quinine

Threats to Plant Diversity

Although plants may be a renewable resource, plant diversity is not. The exploding human population and its demand for space and resources are extinguishing plant species at an unprecedented rate. The problem is especially severe in the tropics, where more than half the human population lives and where population growth is fastest. Fifty million acres of tropical rain forest, an area about the size of the state of Washington, are cleared each year, a rate that would completely eliminate Earth's tropical forests within 25 years. The most common cause of this destruction is slash-and-burn clearing of forests for agricultural use (see Chapter 55). As forests disappear, so do thousands of plant species. Once a species becomes extinct, it can never return.

The loss of plant species is often accompanied by the loss of insects and other rain forest animals. Researchers estimate that habitat destruction in rain forests and other ecosystems is claiming hundreds of species each year. This rate is faster than in any other period, even during the extensive Permian and Cretaceous extinctions. While the toll is greatest in the tropics, the threat is global.

Many people have ethical concerns about contributing to the extinction of living forms. But there are also practical reasons to be concerned about the loss of plant diversity. So far, we have explored the potential uses of only a tiny fraction of the more than 290,000 known plant species. For example, almost all our food is based on the cultivation of only about two dozen species of seed plants. And fewer than 5,000 plant species have been studied as potential sources of medicine. The tropical rain forest may be a medicine chest of healing plants that could be extinct before we even know they exist. If we begin to view rain forests and other ecosystems as living treasures that can regenerate only slowly, we may learn to harvest their products at sustainable rates. What else can we do to preserve plant diversity? Few questions are as important.

Concept Check 30.4

- Explain why it is accurate to consider plant diversity to be a nonrenewable resource.

For suggested answers, see Appendix A.

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 30.1

The reduced gametophytes of seed plants are protected in ovules and pollen grains

- Advantages of Reduced Gametophytes** (pp. 591–592) The gametophytes of seed plants develop within the walls of spores retained within tissues of the parent sporophyte, which provides protection and nutrients.
- Heterospory; The Rule Among Seed Plants** (p. 592) Seed plants evolved from plants that had megasporangia (which produce megasporangia that give rise to female gametophytes) and microsporangia (which produce microspores that give rise to male gametophytes).
- Ovules and Production of Eggs** (p. 592) An ovule consists of a megasporangium, megasporangium, and protective integument(s). The female gametophyte develops from the megasporangium and produces one or more eggs.
- Pollen and Production of Sperm** (pp. 592–593) Pollen, which can be dispersed by air or animals, eliminates the water requirement for fertilization.
- The Evolutionary Advantage of Seeds** (p. 593) A seed is a sporophyte embryo, along with its food supply, packaged in a protective coat. Seeds are more resistant than spores and can be distributed widely by wind or animals.

Concept 30.2

Gymnosperms bear "naked" seeds, typically on cones

- Extant gymnosperms include cycads, *Ginkgo biloba*, gnetophytes, and conifers (pp. 593–595).
- Gymnosperm Evolution** (p. 596) Gymnosperms appear early in the plant fossil record and dominated Mesozoic terrestrial ecosystems. Living seed plants can be divided into two groups: gymnosperms and angiosperms.
- A Closer Look at the Life Cycle of a Pine** (pp. 596–597) Dominance of the sporophyte generation, the development of seed from fertilized ovules, and the role of pollen in transferring sperm to ovules are key features of a typical gymnosperm life cycle.

Activity *Pine Life Cycle*

Concept 30.3

The reproductive adaptations of angiosperms include flowers and fruits

- Characteristics of Angiosperms** (pp. 598–601) Flowers generally consist of four whorls of modified leaves: sepals, petals, stamens (which produce pollen), and carpels (which produce ovules). Ovaries ripen into fruits, which are often carried by wind, water, or animals to new locations. In the angiosperm life cycle, double fertilization occurs when a pollen tube discharges two sperm into the female gametophyte (embryo sac) within an ovule. One sperm fertilizes the egg, while the other combines with two nuclei in the center cell of the female gametophyte and initiates development of food-storing endosperm tissue. The endosperm nourishes the developing embryo.

Activity *Angiosperm Life Cycle*

- **Angiosperm Evolution** (pp. 601-602) An adaptive radiation of angiosperms occurred during the late Mesozoic period. Fossils and evo-devo studies offer insights into the origin of flowers.
- **Angiosperm Diversity** (pp. 602-603) The two main groups of angiosperms are monocots and eudicots. Basal angiosperms are less derived. Magnoliids share some traits with basal angiosperms but are more closely related to monocots and eudicots.
Investigation How Are Trees Identified by Their Leaves?
- **Evolutionary Links Between Angiosperms and Animals** (p. 604) Pollination of flowers by animals and transport of seeds by animals are two important relationships in terrestrial ecosystems.

Concept 30.4

- Human welfare depends greatly on seed plants**
- **Products from Seed Plants** (p. 605) Humans depend on seed plants for food, wood, and many medicines.
 - **Threats to Plant Diversity** (p. 606) Destruction of habitat is causing extinction of many plant species and the animal species they support.

TESTING YOUR KNOWLEDGE

Evolution Connection

The history of life has been punctuated by several mass extinctions. For example, the impact of a meteorite may have wiped out the dinosaurs and many forms of marine life at the end of the Cretaceous period (see Chapter 26). Fossils indicate that plants were much less severely affected by this and other mass extinctions. What adaptations may have enabled plants to withstand these disasters better than animals?

Scientific Inquiry

Suggest a way to test the hypothesis that a particular angiosperm species is pollinated exclusively by beetles.

Investigation How Are Trees Identified by Their Leaves?

Science, Technology, and Society

Why are tropical rain forests being destroyed at such an alarming rate? What kinds of social, technological, and economic factors are responsible? Most forests in developed Northern Hemisphere countries have already been cut. Do the developed nations have a right to ask the developing nations in the Southern Hemisphere to slow or stop the destruction of their forests? Defend your answer. What kinds of benefits, incentives, or programs might slow the assault on the rain forests?

31

Fungi

▲ Figure 31.1 Two species of fungi decomposing a log.

Key Concepts

- 31.1** Fungi are heterotrophs that feed by absorption
- 31.2** Fungi produce spores through sexual or asexual life cycles
- 31.3** Fungi descended from an aquatic, single-celled, flagellated protist
- 31.4** Fungi have radiated into a diverse set of lineages
- 31.5** Fungi have a powerful impact on ecosystems and human welfare

Overview

Mighty Mushrooms

If you were to walk through the Malheur National Forest in eastern Oregon, you might notice a few clusters of honey mushrooms (*Armillaria ostoyae*) scattered here and there beneath the towering trees. Though the trees might appear to dwarf the mushrooms, as strange as it sounds, the reverse is actually true. These mushrooms are only the above-ground portion of a single enormous fungus. Its subterranean network of filaments spreads through 890 hectares (2,200 acres) of the forest—more than the area of 1,600 football fields. Based on its current growth rate, scientists estimate that this fungus, which weighs hundreds of tons, has been growing for 2,600 years.

The innocuous honey mushrooms on the forest floor are a fitting symbol of the neglected grandeur of the kingdom Fungi. Most of us are barely aware of these eukaryotes beyond the occasional brush with athlete's foot or spoiled food. Yet fungi are a huge and important component of the biosphere. Their diversity alone is staggering: Although 100,000 species

have been described, it is estimated that there are actually as many as 1.5 million species of fungi. Some fungi are single-celled, but most form complex multicellular bodies, which in many cases include the above-ground structures we know as mushrooms. This diversity has enabled fungi to colonize just about every imaginable terrestrial habitat; airborne spores have even been found 160 km above the ground.

Fungi are not only diverse and widespread, but they are also essential for the well-being of most terrestrial ecosystems. They break down organic material and recycle nutrients (Figure 31.1), allowing other organisms to assimilate essential chemical elements. Almost all plants depend on a symbiotic relationship with fungi that helps their roots absorb minerals from the soil. Humans also benefit from fungi's services to agriculture and forestry as well as their essential role in making products ranging from bread to antibiotics. But it is also true that a tiny fraction of fungi causes diseases in plants and animals.

In this chapter, we will investigate the structure of fungi, survey the members of the kingdom Fungi, and discuss their ecological and commercial significance.

Concept 31.1

Fungi are heterotrophs that feed by absorption

Despite their vast diversity, fungi share some key traits, most importantly the way in which they derive nutrition.

Nutrition and Fungal Lifestyles

Like animals, fungi are heterotrophs—they cannot make their own food as plants and algae can. But unlike animals, fungi do not ingest (eat) their food. Instead, they digest their food while

it is still in the environment by secreting powerful hydrolytic enzymes, called exoenzymes, into their surroundings. Exoenzymes break down complex molecules to smaller organic compounds that the fungi can absorb into their bodies and use.

This absorptive mode of nutrition is related to the diverse lifestyles exhibited by fungi. Among the fungi are species that live as decomposers (also called saprobes), parasites, and mutualistic symbionts. Saprobes fungi break down and absorb nutrients from nonliving organic material, such as fallen logs, animal corpses, and the wastes of living organisms. Parasitic fungi absorb nutrients from the cells of living hosts. Some parasitic fungi are pathogenic, including species that infect human lungs and other species that are responsible for about 6% of plant diseases. Mutualistic fungi also absorb nutrients from a host organism, but the mutualistic fungi reciprocate with functions beneficial to the host in some way such as aiding a plant in the uptake of minerals from the soil.

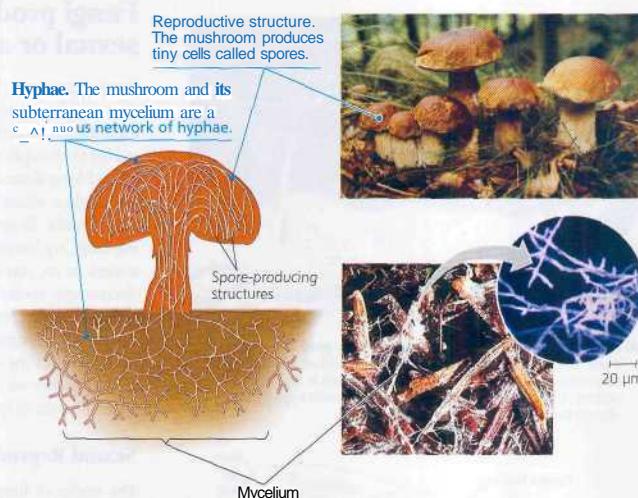

Body Structure

Some fungi exist as single cells and are known as yeasts. However, most species are multicellular. The morphology of multicellular fungi enhances their ability to absorb nutrients from their surroundings (Figure 31.2). The bodies of these fungi typically form a network of tiny filaments called hyphae (singular, *hypha*). Hyphae are composed of tubular cell walls surrounding the plasma membrane and cytoplasm of the cells. Unlike the cellulose walls of plants, fungal cell walls contain chitin, a strong but flexible nitrogen-containing polysaccharide that is also found in the external skeletons of insects and other arthropods.

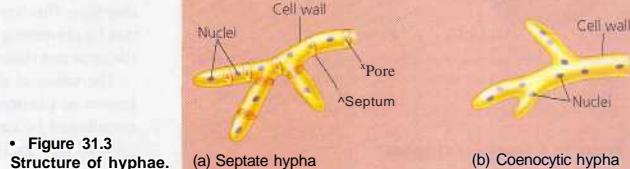

Fungal hyphae form an interwoven mass called a mycelium (plural, *mycelia*) that surrounds and infiltrates the material in which the fungus feeds. The structure of a mycelium maximizes the ratio of its surface area to its volume, making feeding more efficient. Just 1 cm³ of rich organic soil may contain as much as 1 km of hyphae with a total surface area of more than 300 cm² interfacing with the soil. A fungal mycelium grows rapidly, as proteins and other materials synthesized by the fungus are channeled through cytoplasmic streaming to the tips of the extending hyphae. The fungus concentrates its energy and resources on adding hyphal length and thus overall absorptive surface area, rather than on increasing hyphal girth.

Fungal mycelia are nonmotile; they cannot run, swim, or fly in search of food or mates. But the mycelium makes up for its lack of mobility by swiftly extending the tips of its hyphae into new territory.

In most fungi, the hyphae are divided into cells by cross-walls, or septa (singular, septum). Septa generally have pores large enough to allow ribosomes, mitochondria, and even nuclei to flow from cell to cell (Figure 31.3a). Some fungi lack septa. Known as coenocytic fungi, these organisms consist of a continuous cytoplasmic mass containing hundreds or thousands of nuclei (Figure 31.3b). The coenocytic condition results from the repeated division of nuclei without cytoplasmic division. This description may remind you of the plasmodial slime molds you read about in Chapter 28, which also consist of cytoplasmic masses containing many nuclei. This similarity was one reason that slime molds were formerly

A. Figure 31.2 Structure of a multicellular fungus. The top photograph shows the sexual structures, called fruiting bodies, of the penny bun fungus (*Boletus edulis*). The bottom left photograph shows a macroscopic view of a mycelium growing on fallen conifer needles, and the bottom right photograph shows a microscopic view of a mycelium (LM).

• Figure 31.3 Structure of hyphae.

classified as fungi; molecular comparisons have since confirmed that in fact the two clades are not closely related.

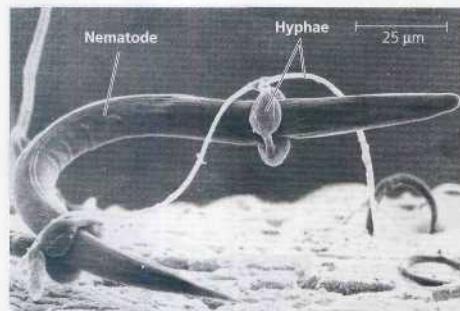

Some fungi have specialized hyphae that allow them to feed on living animals (**Figure 31.4a**). Other species have specialized hyphae called haustoria that enable them to penetrate the tissue of their hosts (**Figure 31.4b**). Mutually beneficial relationships between such fungi and plant roots are called mycorrhizae. (*Mycorrhize* means "fungus roots.") Mycorrhizal fungi (fungi that form mycorrhizae) can deliver phosphate ions and other minerals to plants, which the plants themselves cannot acquire on their own. In exchange, the plants supply the fungi with organic nutrients. There are several different types of mycorrhizal fungi. Ectomycorrhizal fungi (from the Greek *ektos*, out) form sheaths of hyphae over the surface of a root and also grow into the extracellular spaces of the root cortex (see Figure 37.12a). Endomycorrhizal fungi (from

the Greek *entos*, in) extend their hyphae through the root cell wall and into tubes formed by invagination (pushing inward) of the root cell membrane (see Figure 37.12b). You will read more about these types of mycorrhizal fungi later in this chapter.

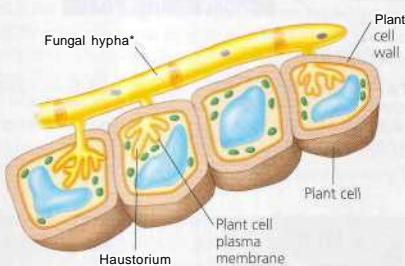

Concept Check 31.1

1. Compare and contrast the nutritional mode of a fungus with your own nutritional mode.
2. Describe how the structure of a fungus is adapted to its nutritional mode.

For suggested answers, see Appendix A.

(a) **Hyphae adapted for trapping and killing prey.** In *Arthrobotrys*, a soil fungus, portions of the hyphae are modified as hoops that can constrict around a nematode (roundworm) in less than a second. The fungus then penetrates its prey with hyphae and digests the prey's inner tissues (SEM).

(b) **Haustoria.** Mutualistic and parasitic fungi grow specialized hyphae called haustoria that can penetrate the cell walls of plants. Haustoria remain separated from a plant cell's cytoplasm by the plasma membrane of the plant cell (dark gold).

A. **Figure 31.4 Specialized hyphae.**

Concept 31.2

Fungi produce spores through sexual or asexual life cycles

Fungi propagate themselves by producing vast numbers of spores, either sexually or asexually. For example, puffballs, the reproductive structures of certain fungi, may release trillions of spores in cloud-like bursts (see Figure 31.18d). Spores can be carried long distances by wind or water, and if they land in a moist place where there is food, they germinate, producing new mycelia. To appreciate how effective spores are at dispersing fungi, try leaving a slice of melon exposed to the air. Within a week or so, you should see fuzzy mycelia growing from the microscopic spores constantly falling onto the melon slice.

Figure 31.5 generalizes the many different life cycles that can produce fungal spores. In this section, we will survey general aspects of the sexual and asexual life cycles of fungi. Later in the chapter we will examine more closely the life cycles of specific phyla of fungi.

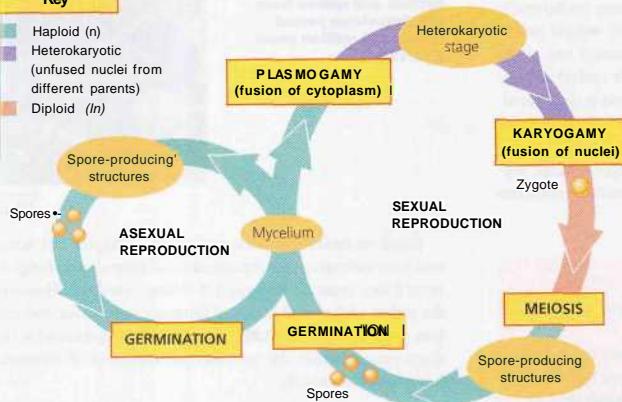

Sexual Reproduction

The nuclei of fungal hyphae and spores of most species are haploid, except for transient diploid stages that form during sexual life cycles. Generally, sexual reproduction in fungi begins when hyphae from two distinct mycelia release sexual signaling molecules called pheromones. If the mycelia are of different mating types, the pheromones from each partner bind to receptors on the surface of the other, and the hyphae extend toward the source of the pheromones. When the hyphae meet, they fuse. This "compatibility test" contributes to genetic variation by preventing hyphae from fusing with other hyphae from the same mycelium or another genetically identical mycelium.

The union of the cytoplasm of the two parent mycelia is known as plasmogamy. In many fungi, the haploid nuclei contributed by each parent do not fuse right away. Instead, parts of the mycelia contain coexisting, genetically different

Key

- Haploid (n)
- Heterokaryotic
(unfused nuclei from different parents)
- Diploid ($2n$)

▲ **Figure 31.5 Generalized life cycle of fungi.** Many—but not all—fungi reproduce both sexually and asexually. Some reproduce only sexually, others only asexually.

nuclei. Such a mycelium is said to be a heterokaryon (meaning "different nuclei"). In some species, heterokaryotic mycelia become mosaics, with different nuclei restricted to different parts of the network; in other species, the different nuclei mingle and may even exchange chromosomes and genes in a process similar to crossing over (see Chapter 13).

In some fungi, the haploid nuclei pair off two to a cell, one from each parent. Such a mycelium is said to be dikaryotic (meaning "two nuclei"). As a dikaryotic mycelium grows, the two nuclei in each cell divide in tandem without fusing.

Hours, days, or even centuries may pass between plasmogamy and the next stage in the sexual cycle, karyogamy. During karyogamy, the haploid nuclei contributed by the two parents fuse, producing diploid cells. Zygotes and other transient structures form during karyogamy, the only stage in which diploidy exists in most fungi. Meiosis restores the haploid condition, and the mycelium then produces specialized reproductive structures that produce and disperse the spores.

The sexual processes of karyogamy and meiosis generate extensive genetic variation, an important prerequisite for adaptive evolution. (See Chapters 13 and 23 to review how sex can increase genetic diversity within a population.) The heterokaryotic condition also offers some of the advantages of haploidy, in that one haploid genome may be able to compensate for harmful mutations in the other.

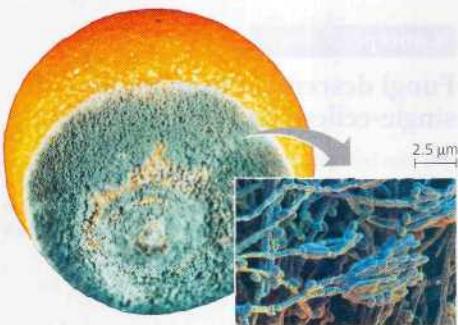

Asexual Reproduction

In addition to sexual reproduction, many fungi can reproduce asexually. Clones are produced by mitotic production of spores, which can be spread by air or water. Some species

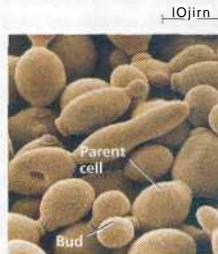

only reproduce asexually. As with sexual reproduction, the processes of asexual reproduction vary widely among fungi.

Some fungi that can reproduce asexually grow as mold. Mold is a familiar sight in the kitchen, where it forms fuzzy carpets on fruit, bread, and other foods (Figure 31.6). Molds grow rapidly as mycelia and produce spores. Many species that can grow as molds can also reproduce sexually if they come in contact with other mating types.

Other asexual fungi are yeasts. Yeasts inhabit liquid or moist habitats, including plant sap and animal tissues. Instead of producing spores, yeasts reproduce asexually by simple cell division or by the pinching of small "bud cells" off a parent cell (Figure 31.7). Some yeast species can also grow as filamentous mycelia, depending on the availability of nutrients. Yeasts sometimes can also reproduce sexually

▲ **Figure 31.6 Penicillium**, a mold commonly encountered as a saprobe on food. The clusters of bead-like structures in the SEM are conidia, involved in asexual reproduction.

► **Figure 31.7 The yeast *Saccharomyces cerevisiae* in various stages of budding (SEM).**

Many molds and yeasts have no known sexual stage. Biologists who study fungi, or mycologists, have traditionally called such fungi deuteromycetes (the suffix *-mycete* means "fungus") or imperfect fungi (from the botanical use of the term *perfect* to refer to the sexual stages of life cycles). Whenever a sexual stage of a so-called deuteromycete is discovered, the species is classified in a particular phylum, depending on the type of sexual structures it forms. In addition to searching for little-known sexual stages of such unassigned fungi, mycologists also can now avail themselves of genetic techniques to identify taxonomic status.

Concept Check 31.2

1. In terms of haploidy versus diploidy, how do the life cycles of humans and fungi differ?
2. Suppose that you sample the DNA of two mushrooms on opposite sides of your yard and find that they are identical. What are two hypotheses that could reasonably account for this result?

For suggested answers, see Appendix A.

► Figure 31.8 Fossil fungal hyphae and spores from the Ordovician period (about 460 million years ago; LM).

Based on molecular clock analysis (see Chapter 25), scientists have estimated that the ancestors of animals and fungi diverged into separate lineages 1.5 billion years ago. However, the oldest undisputed fossils of fungi are only about 460 million years old (Figure 31.8). One possible explanation for this discrepancy is that the microscopic ancestors of terrestrial fungi fossilized poorly.

The Move to Land

Much of the fungal diversity we observe today may have had its phylogenetic origin in an adaptive radiation when life began to colonize land. Fossils of the earliest known vascular plants from the late Silurian period contain evidence of mycorrhizae, the symbiotic relationships between plants and subterranean fungi we discussed earlier. Plants probably existed in this symbiotic relationship from the earliest periods of colonization of land.

Concept 31.3

Fungi descended from an aquatic, single-celled, flagellated protist

Data from both paleontology and molecular systematics offer insights into the early evolution of fungi. Systematists now recognize Fungi and Animalia as sister kingdoms. In other words, fungi and animals are more closely related to each other than they are to plants or other eukaryotes.

The Origin of Fungi

Phylogenetic systematics suggests that fungi evolved from a flagellated ancestor. While the majority of fungi lack flagella, the lineages of fungi thought to be the earliest to diverge (the chytrids, discussed later in this chapter) do have flagella. Moreover, most of the protists that share a close common ancestor with animals and fungi also have flagella. These three groups of eukaryotes—the fungi, animals, and their protistan relatives—are called opistokonts, members of the clade Opisthokonta. This name refers to the posterior (*opisto*) location of the flagellum in these organisms.

Phylogenetic evidence also suggests that the ancestor of fungi was unicellular. The fact that other evidence indicates that animals are more closely related to some unicellular opistokonts than to fungi suggests that animals and fungi must have evolved multicellularity independently from different single-celled ancestors.

Concept Check 31.3

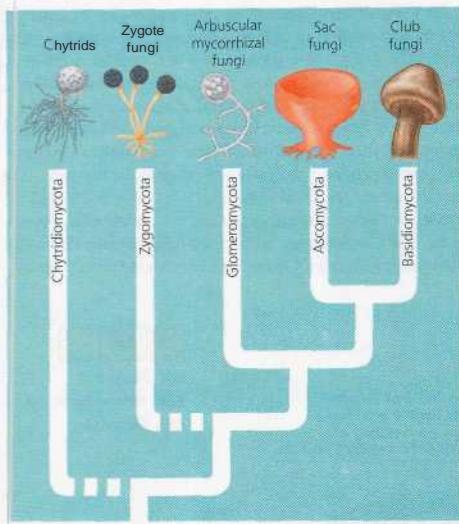

1. Why are fungi classified as opistokonts when most fungi lack flagella?
2. Explain the evolutionary significance of the presence of mycorrhizae in the earliest vascular plants.

For suggested answers, see Appendix A.

Concept 31.4

Fungi have radiated into a diverse set of lineages

The phylogeny of fungi is currently the subject of much research. In the past decade, molecular analysis has helped clarify the evolutionary relationships between fungal groups although there are still areas of uncertainty. Figure 31.9 presents a simplified version of a current hypothesis of fungal phylogeny. In this section, we will survey each of the major fungal groups identified in this phylogenetic tree.

A Figure 31.9 Phylogeny of fungi. Most mycologists currently recognize five phyla of fungi. Molecular systematics is providing information on the relationships between these phyla; the dashed branches indicate groups thought to be paraphyletic (see Figure 31.11).

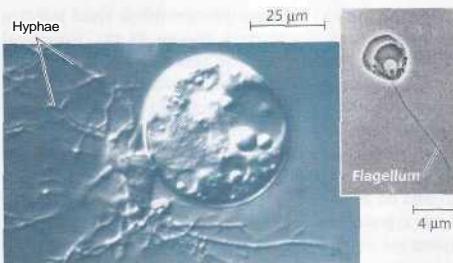

Chytrids

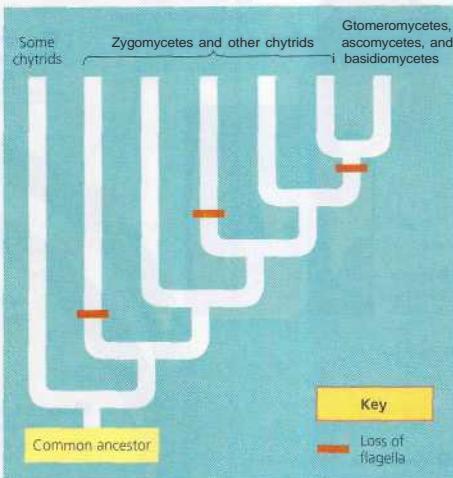

Fungi classified in the phylum Chytridiomycota, called chytrids, are ubiquitous in lakes and soil. Some are saprobes; others parasitize protists, plants, or animals.

Molecular evidence supports the hypothesis that chytrids diverged earliest in fungal evolution. Like other fungi, chytrids have cell walls made of chitin, and they also share certain key enzymes and metabolic pathways with other fungal groups. Some chytrids form colonies with hyphae, while others exist as single spherical cells. But chytrids are unique among fungi in having flagellated spores, called zoospores (**Figure 31.10**).

Until recently systematists thought that fungi lost flagella only once in their history, after chytrids had diverged from other lineages. However, molecular data indicate that some "chytrids" are actually more closely related to another fungal group, the zygomycetes. If this is true, then flagella were lost on more than one occasion during the evolution of fungi (**Figure 31.11**). For this reason, many systematists consider the phyla Chytridiomycota and Zygomycota to be paraphyletic (compare Figures 31.9 and 31.11).

A Figure 31.10 Chytrids. The globular fruiting body of *Chytridium* sprouts branched hyphae (LM). Inset: Chytrids have a flagellated stage called a zoospore (TEM).

A Figure 31.11 Multiple evolutionary losses of flagella. Phylogenetic studies indicate that the common ancestor of fungi had flagella, which have been lost independently in several lineages.

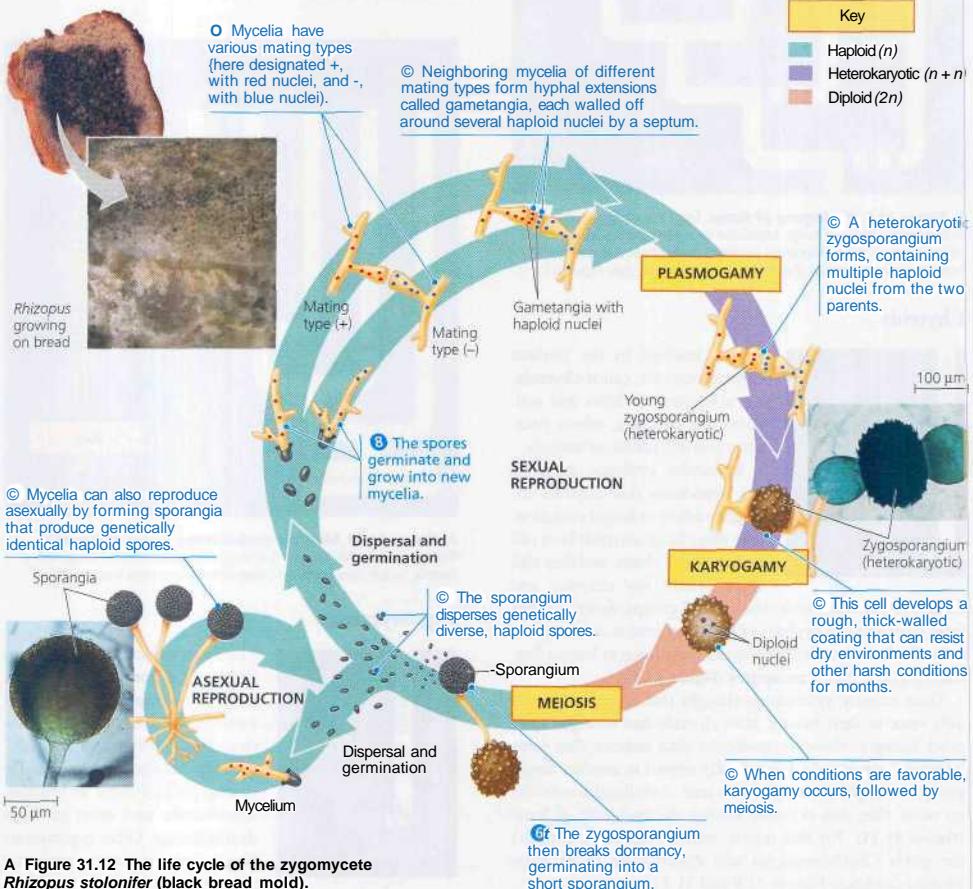

Zygomycetes

The approximately 1,000 known species of zygomycetes (fungi in the phylum Zygomycota) exhibit a considerable diversity of life histories. This phylum includes fast-growing molds responsible for rotting produce such as peaches, strawberries, and sweet potatoes during storage. Other zygomycetes live as parasites or as commensal (neutral) symbionts of animals.

The life cycle of *Rhizopus stolonifer* (black bread mold) is fairly typical of zygomycetes (Figure 31.12). Horizontal hyphae spread out over the food, penetrate it, and absorb nutrients. The hyphae are coenocytic, with septa found only where reproductive cells are formed. In the asexual phase, bulbous black sporangia develop at the tips of upright hyphae. Within each sporangium, hundreds of haploid spores develop and are dispersed through the air. Spores that happen to land on moist food germinate, growing into new mycelia. Some zygomycetes, such as *Pilobohs*, can actually "aim" their sporangia toward conditions associated with good food sources (Figure 31.13).

If environmental conditions deteriorate—for instance, if the mold consumes all its food—*Rhizopus* may reproduce sexually. The parents in a sexual union are mycelia of different mating types that possess different chemical markers, although they may appear identical. Plasmogamy produces a sturdy structure called a syngasporangium, in which karyogamy and then meiosis occur. Note that while a zygosporangium represents the zygote (2n) stage in the life cycle, it is not a zygote in the usual sense (that is, a cell with one diploid nucleus). Rather, a zygosporangium is a multinucleate structure, first heterokaryotic with many haploid nuclei from the two parents, then with many diploid nuclei after karyogamy.

A Figure 31.12 The life cycle of the zygomycete *Rhizopus stolonifer* (black bread mold).

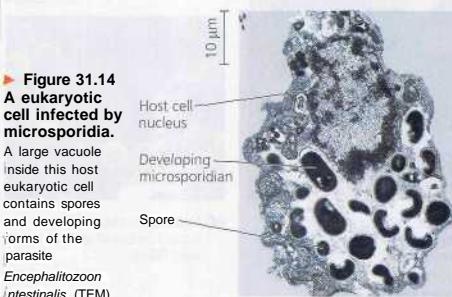

▲ Figure 31.13 *P. ubolus* aiming its sporangia. This zygomycete decomposes animal dung. The mycelium bends its spore-bearing hyphae toward bright light, where grass is likely to be growing. The fungus then shoots its sporangia like cannonballs as far as 2 m. Grazing animals such as cows ingest the fungi with the grass and then scatter the spores in feces.

Zygosporangia are resistant to freezing and drying and are metabolically inactive. When conditions improve, a zygosporangium undergoes meiosis, germinates into a sporangium, and releases genetically diverse haploid spores that may colonize a new substrate.

Microsporidia

Microsporidia are unicellular parasites of animals and protists (Figure 31.14). They are often used in the biological control of insect pests. While microsporidia do not normally infect humans, they do pose a risk to people with HIV and other immune-compromised conditions.

In many ways, microsporidia are unlike most other eukaryotes. They do not have conventional mitochondria, for example. As a result, microsporidia have been something of a taxonomic mystery, thought by some researchers to be an ancient, deep-branching lineage of eukaryotes. In recent

► Figure 31.14 A eukaryotic cell infected by microsporidia.

A large vacuole inside this host eukaryotic cell contains spores and developing forms of the parasite

Encephalitozoon intestinalis (TEM).

years, however, it has become clear that microsporidia are not primitive eukaryotes, but rather are highly derived parasites. In 2002, Bryony Williams and colleagues at the Natural History Museum in London discovered that microsporidia actually have tiny organelles derived from mitochondria. Meanwhile, molecular comparisons have revealed that microsporidia are more closely related to fungi than to any other eukaryotes. A 2003 analysis provided some data suggesting that microsporidia be classified as zygomycetes.

Microsporidia demonstrate the extraordinary changes that can occur as organisms adapt to a parasitic lifestyle. In their case, they lost almost all resemblance to their fungal relatives.

Glomeromycetes

The glomeromycetes, fungi assigned to the phylum Glomeromycota, were formerly considered zygomycetes. But analyses of hundreds of fungal genomes indicate that the glomeromycetes form a separate clade (monophyletic group). Despite their lack of numbers—only 160 species have been identified to date—the glomeromycetes are an ecologically significant group. All glomeromycetes form a distinct type of endomycorrhizae called arbuscular mycorrhizae (Figure 31.15). The tips of the hyphae that push into plant root cells branch into tiny treelike structures known as arbuscules. About 90% of all plants have such symbiotic partnerships with glomeromycetes.

► Figure 31.15 Arbuscular mycorrhizae. Glomeromycetes form endomycorrhizae with plant roots, supplying minerals and other nutrients to the roots. This SEM depicts the branched hyphae—an arbuscule—of *Glomus mosseae* bulging into a root cell by pushing in the membrane (the root has been treated to remove the cytoplasm).

Ascomycetes

Mycologists have described more than 32,000 species of ascomycetes (fungi in the phylum Ascomycota) from a variety of marine, freshwater, and terrestrial habitats. The defining feature of ascomycetes is the production of sexual spores in saclike ascii (singular, *ascus*); thus, they are commonly called sac fungi. Unlike zygomycetes, most ascomycetes bear their sexual stages in fruiting bodies, or ascocarps, which range in size from microscopic to macroscopic. The spore-forming ascii are found in the ascocarps.

Ascomycetes vary in size and complexity from unicellular yeasts to elaborate cup fungi and morels (Figure 31.16). They include some of the most devastating plant pathogens, which will be discussed later in the chapter. However, many ascomycetes are important saprobes, particularly of plant material. More than 40% of all ascomycete species live with green algae or cyanobacteria in symbiotic associations called lichens. Some ascomycetes form mycorrhizae with plants. Still others live between mesophyll cells in leaves, where they release toxic compounds that apparently help protect the plant from insects.

One of the best-studied ascomycetes is *Neurospora crassa*, a bread mold (see Figure 31.1 fid). Though *Neurospora* grows readily on bread, in the wild it is found growing on burned vegetation. As discussed in Chapter 17, biologists in the 1930s used *Neurospora* to formulate the one gene-one enzyme hypothesis. Today, this ascomycete continues to serve as a model organism; in 2003 its entire genome was published. With 10,000 genes, the genome of this tiny fungus is three-fourths the size of the *Drosophila* genome and one-third the size of the human genome! However, the *Neurospora* genome is relatively compact, having few of the stretches of noncoding DNA that occupy much space in the genomes of humans and many other eukaryotes. Biologists have found evidence suggesting that *Neurospora* has a genomic defense

system that prevents "junk DNA" from accumulating to harmful levels.

Although the life cycles of various ascomycete groups differ in the details of their reproductive structures and processes, there are some common elements. Ascomycetes reproduce asexually by producing enormous numbers of asexual spores called conidia (Figure 31.17). Conidia are not formed inside sporangia, as are the asexual spores of most zygomycetes. Rather, they are produced externally at the tips of specialized hyphae called conidiophores, often in clusters or long chains from which they may be dispersed by the wind. Conidia may also be involved in sexual reproduction, fusing with hyphae from a mycelium of a different mating type, as occurs in *Neurospora* (see Figure 31.17).

Following fusion of two different mating types, plasmogamy occurs. The nonseptated bulge, or ascogonium, is now

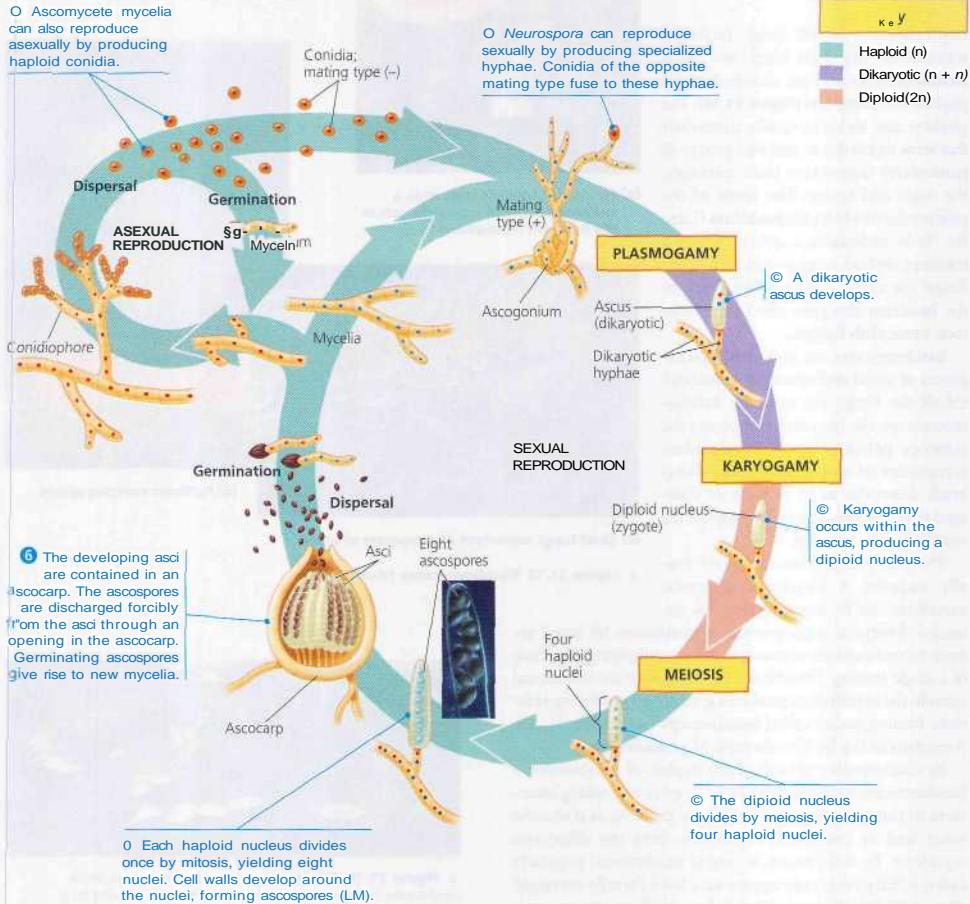

A Figure 31.16 Ascomycetes (sac fungi).

b'terokaryotic. The coenocytic ascogonium extends hyphae that are partitioned by septa, forming dikaryotic cells, each with two haploid nuclei representing the two parents. The cells at the tips of these dikaryotic hyphae develop into asci. Within an ascus, karyogamy combines the two parental genomes, and then meiosis forms four genetically different nuclei. This is followed by a mitotic division, forming eight ascospores. In many species, the eight ascospores are lined up in a row in the order in

which they formed from a single zygotic nucleus. The ascospores develop in and are eventually discharged from the ascocarp.

In contrast to the life cycle of zygomycetes, the extended dikaryotic stage of ascomycetes (and also basidiomycetes) provides increased opportunity for genetic recombination. For example, in some ascomycetes, certain dikaryotic cells fuse repeatedly, recombining genomes and resulting in a multitude of genetically different offspring from one mating event.

▲ Figure 31.17 The life cycle of *Neurospora crassa*, an ascomycete.

Basidiomycetes

Approximately 30,000 fungi, including mushrooms and shelf fungi, are called basidiomycetes and are classified in the phylum Basidiomycota (**Figure 31.18**). The phylum also includes molds, mutualists that form mycorrhizae, and two groups of particularly destructive plant parasites, the rusts and smuts. The name of the phylum derives from the basidium (Latin for "little pedestal"), a cell in which a transient diploid stage occurs during the fungal life cycle. The club-like shape of the basidium also gives rise to the common name club fungus.

Basidiomycetes are important decomposers of wood and other plant material. Of all the fungi, the saprobic basidiomycetes are the best at decomposing the complex polymer lignin, an abundant component of wood. Many shelf fungi break down the wood of weak or damaged trees and continue to decompose the wood after the tree dies.

The life cycle of a basidiomycete usually includes a long-lived dikaryotic mycelium. As in ascomycetes, this extended dikaryotic stage provides opportunities for many genetic recombinations to occur, in effect multiplying the result of a single mating. Periodically, in response to environmental stimuli, the mycelium reproduces sexually by producing elaborate fruiting bodies called basidiocarps (see **Figure 31.20**). A mushroom is a familiar example of a basidiocarp.

By concentrating growth in the hyphae of mushrooms, a basidiomycete mycelium can quickly erect its fruiting structures in just a few hours; a mushroom pops up as it absorbs water and as cytoplasm streams in from the dikaryotic mycelium. By this process, a ring of mushrooms, popularly called a "fairy ring," may appear on a lawn literally overnight (**Figure 31.19**). The mycelium below the fairy ring expands outward at a rate of about 30 cm per year, decomposing

(a) Fly agaric (*Amanita muscaria*), a common species in conifer forests in the northern hemisphere

(b) Maiden veil fungus (*Dictyophora*), a fungus with an odor like rotting meat

(c) Shelf fungi, important decomposers of wood

(d) Puffballs emitting spores?

A. Figure 31.18 Basidiomycetes (club fungi).

B. Figure 31.19 A fairy ring. According to legend, these mushrooms spring up where fairies have danced in a ring on a moonlit night. (The text provides a biological explanation of how rings form.)

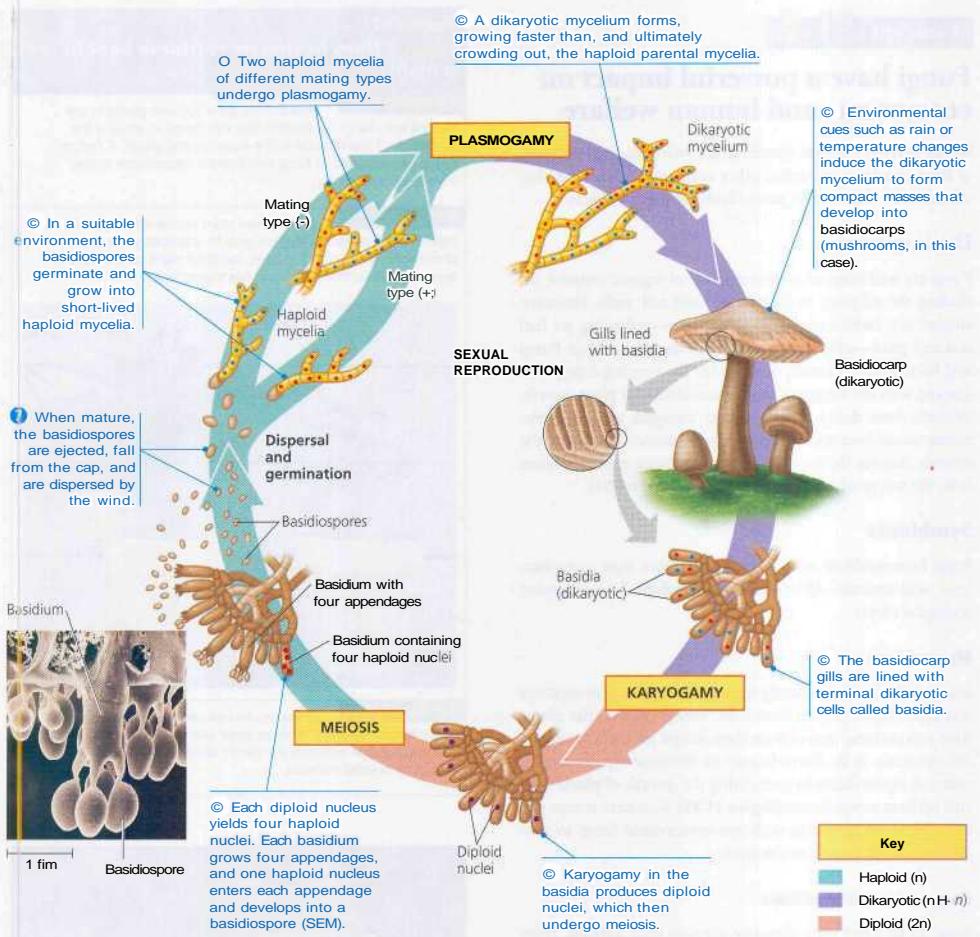

Figure 31.20 The life cycle of a mushroom-forming basidiomycete.

organic matter in the soil as it grows. Some giant fairy rings may be centuries old.

The numerous basidia in a basidiocarp are the sources of sexual spores called basidiospores (Figure 31.20). The mushroom's cap supports and protects a large surface area of basidia on gills. A common, store-bought white mushroom has a gill surface area of about 200 cm^2 and may release a billion basidiospores, which drop from the bottom of the cap and are blown away. Asexual reproduction is much less common in basidiomycetes than in ascomycetes.

Concept Check 31.4

- What feature of chytrids supports the hypothesis that they represent the most primitive fungal lineage?
- Why are glomeromycetes so ecologically significant?
- Give different examples of how form fits function in zygomycetes, ascomycetes, and basidiomycetes.

For suggested answers, see Appendix A.

Concept 31.5

Fungi have a powerful impact on ecosystems and human welfare

In our survey of fungal classification, we've touched on some of the ways fungi influence other organisms, including ourselves. We will now look more closely at these impacts.

Decomposers

Fungi are well adapted as decomposers of organic material, including the cellulose and lignin of plant cell walls. However, almost any carbon-containing substrate—including jet fuel and wall paint—can be consumed by at least some fungi. Fungi and bacteria are primarily responsible for keeping ecosystems stocked with the inorganic nutrients essential for plant growth. Without these decomposers, carbon, nitrogen, and other elements would become tied up in organic matter. Plants and the animals that eat them could not exist because elements taken from the soil would not be returned (see Chapter 54).

Symbionts

Fungi form symbiotic relationships with plants, algae, cyanobacteria, and animals. All of these relationships have profound ecological effects.

Mycorrhizae

Mycorrhizae are enormously important in natural ecosystems and agriculture. As you have read, almost all vascular plants have mycorrhizae and rely on their fungal partners for essential nutrients. It is relatively easy to demonstrate the significance of mycorrhizae by comparing the growth of plants with and without mycorrhizae (**Figure 31.21**). Foresters commonly inoculate pine seedlings with ectomycorrhizal fungi to promote vigorous growth in the trees.

Fungus-Animal Symbiosis

Some fungi share their digestive services with animals, helping break down plant material in the guts of cattle and other grazing mammals. Many species of ants and termites take advantage of the digestive power of fungi by raising them in "farms." The insects scour tropical forests in search of leaves, which they carry back to their nests and feed to the fungi (**Figure 31.22**). The fungi break down the leaves into a substance the insects can digest. In some tropical forests, the fungi have helped these insects become the major consumers of leaves.

The evolution of such farmer insects and that of their fungal "crops" have been tightly linked for well over 50 million years. The fungi have become so dependent on their caretakers that in many cases they can no longer survive without the insects.

Figure 31.21

Inquiry Does having mycorrhizae benefit a plant?

EXPERIMENT

Researchers grew soybean plants in soil treated with fungicide (poison that kills fungi) to prevent the formation of mycorrhizae in the experimental group. A control group was exposed to fungi that formed mycorrhizae in the soybean plants' roots.

RESULTS

The soybean plant on the left is typical of the experimental group. Its stunted growth is probably due to a phosphorus deficiency. The taller, healthier plant on the right is typical of the control group and has mycorrhizae.

CONCLUSION

These results indicate that the presence of mycorrhizae benefits a soybean plant and support the hypothesis that mycorrhizae enhance the plant's ability to take up phosphate and other needed minerals.

A Figure 31.22 Fungus-gardening insects. These leaf-cutting ants depend on fungi to convert plant material to a form the insects can digest. The fungi, in turn, depend on the nutrients from the leaves the ants feed them.

(a) A fruticose (shrub-like) lichen

(b) A foliose (leaf-like) lichen

(c) Crustose (crust-like) lichens

▲ Figure 31.23 Variation in lichen growth forms.

Lichens

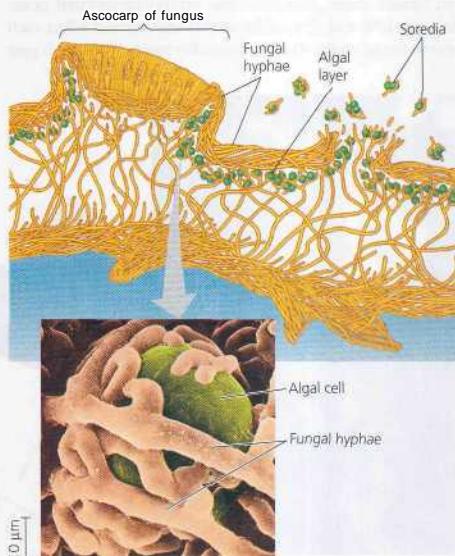

Lichens are a symbiotic association of millions of photosynthetic microorganisms held in a mass of fungal hyphae. They form a surface-hugging carpet that can be found growing on rocks, rotting logs, trees, and roofs in various shrub-like, leaf-like, or encrusting forms (Figure 31.23). The photosynthetic partners are typically unicellular or filamentous green algae or cyanobacteria. The fungal component is most often an ascomycete, but several basidiomycete lichens are known. The fungus usually gives a lichen its overall shape and structure, and tissues formed by hyphae account for most of the lichen's mass. The algae or cyanobacteria generally occupy an inner layer below the lichen surface (Figure 31.24). The merger of fungus and alga or cyanobacterium is so complete that lichens are actually given scientific names as though they were single organisms. More than 13,500 species have been described, accounting for a fifth of all known fungi.

In most lichens that have been studied, each partner provides something the other could not obtain on its own. The algae provide carbon compounds; the cyanobacteria also fix nitrogen (see Chapter 27) and provide organic nitrogen. The fungi provide their photosynthetic partners with a suitable environment for growth. The physical arrangement of hyphae allows for gas exchange, protects the photosynthetic partner, and retains water and minerals, most of which are absorbed either from airborne dust or from rain. The fungi also secrete acids, which aid in the

uptake of minerals. Fungal pigments help shade the algae or cyanobacteria from intense sunlight. Some fungal compounds are toxic and prevent lichens from being eaten by animals.

The fungi of many lichens reproduce sexually by forming ascocarps or basidioscapes. Lichen algae reproduce independently of the fungus by asexual cell division. As might be expected of "dual organisms," asexual reproduction as a symbiotic unit also occurs commonly, either by fragmentation of the parental lichen or by the formation of soredia, small clusters of hyphae with embedded algae (see Figure 31.24).

Phylogenetic studies of lichen DNA have helped illuminate the evolution of this symbiosis. Molecular studies published in 2001 support the hypothesis that all living lichens can be traced to three original associations involving a fungus and a photosynthetic symbiont. The same studies also indicate that numerous free-living fungi descended from lichen-forming ancestors. *Penicillium*, the

▲ Figure 31.24 Anatomy of an ascomycete lichen (colorized SEM).

free-living fungus that provides the antibiotic penicillin, for example, is thought to have descended from a lichen fungus.

Lichens are important pioneers on newly cleared rock and soil surfaces, such as burned forests and volcanic flows. They break down the surface by physically penetrating and chemically attacking it, and they trap windblown soil. Nitrogen-fixing lichens also add organic nitrogen to some ecosystems. These processes make it possible for a succession of plants to grow.

As tough as lichens are, many do not stand up very well to air pollution. Their passive mode of mineral uptake from rain and moist air makes them particularly sensitive to sulfur dioxide and other aerial poisons. The death of sensitive lichens and an increase in the number of hardier species in an area can be an early warning that air quality is deteriorating.

Pathogens

Of the 100,000 known species of fungi, about 30% make their living as parasites, mostly on or in plants (Figure 31.25). For example, *Ophiostoma ulmi*, the ascomycete that causes Dutch elm disease, has drastically changed the landscape of the northeastern United States. Accidentally introduced to the United States on logs that were sent from Europe to help pay World War I debts, the fungus is carried from tree to tree by bark beetles. Another ascomycete, *Cryphonectria parasitica*, has killed 4 billion native American chestnut trees in the eastern United States. Fungi are also serious agricultural pests. Between 10% and 50% of the world's fruit harvest is lost each year to fungal attack. Grain crops suffer major losses each year

from fungi such as the basidiomycete *Puccinia graminis*, which causes black stem rust on wheat.

Some of the fungi that attack food crops are toxic to humans. For example, certain species of the ascomycete mold *Aspergillus* contaminate improperly stored grain and peanut by secreting carcinogenic compounds called aflatoxins. In another example, the ascomycete *Claviceps purpurea* form purple structures called ergots on rye. If diseased rye is inadvertently milled into flour and then consumed, poisons from the ergots can cause ergotism, a condition characterized by gangrene, nervous spasms, burning sensations, hallucinations and temporary insanity. An epidemic of ergotism around AD. 944 killed more than 40,000 people in France. One of the compounds that has been isolated from ergots is lysergic acid, the raw material from which the hallucinogen LSD is made.

Animals are much less susceptible to parasitic fungi than are plants. Only about 50 species of fungi are known to parasitize humans and other animals, but these relatively few species do considerable damage. The general term for such a fungal infection is mycosis.

Skin mycoses include the disease ringworm, so named because it appears as circular red areas on the skin. The ascomycetes that cause ringworm can infect almost any skin surface. Most commonly, they grow on the feet, causing the intense itching and blisters known as athlete's foot. Though highly contagious, athlete's foot and other ringworm infections can be treated with fungicidal lotions and powders.

Systemic mycoses, by contrast, spread through the body and usually cause very serious illnesses. They are typically caused

(a) Corn smut on corn

(b) Tar spot fungus on maple leaves

(c) Ergots on rye

A Figure 31.25 Examples of fungal diseases of plants.

by inhaled spores. Coccidioidomycosis is a systemic mycosis that produces tuberculosis-like symptoms in the lungs. It is so deadly that it is now considered a potential biological weapon.

Some mycoses are opportunistic, occurring only when a large part of the body's microbiology, chemistry, or immunology allows fungi to grow unchecked. *Candida albicans*, for example, is one of the normal inhabitants of moist epithelia, such as the vaginal lining. Under certain circumstances, *Candida* can grow too rapidly and become pathogenic, leading to so-called "yeast infections." Many other opportunistic mycoses in humans have become more common in recent decades, due in part to AIDS, which compromises the immune system.

Over the past few years, the alleged dangers of black mold (*Tachybotrys chartarum*, an ascomycete) have been the subject of sensationalistic news reports. Black mold thrives in damp buildings and has been implicated in some studies as the cause of a wide variety of diseases. As a result, entire "sick buildings" have been abandoned. Yet there is no well-substantiated evidence linking the presence of *T. chartarum* to these diseases. Any other factors—including bacteria, human-made chemicals, and other fungi—may cause some of the symptoms attributed to black mold.

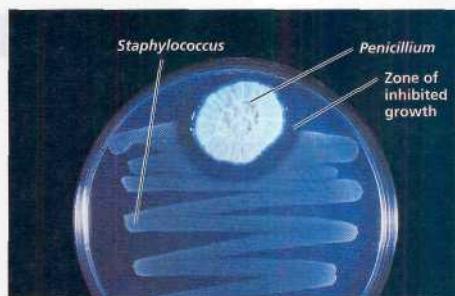

Practical Uses of Fungi

The dangers posed by fungi should not overshadow the immense benefits we derive from these remarkable eukaryotes. We depend on their ecological services as decomposers and recyclers of organic matter. Without mycorrhizae, our agriculture would be far less productive.

Mushrooms are a popular food, but they are not the only fungi we eat. The distinctive flavors of certain kinds of cheeses, including Roquefort and blue cheese, come from the fungi used to ripen them. The soft drink industry uses a species of *Saccharomyces* to produce citric acid for colas. Morels and truffles, the edible fruiting bodies of various ascomycetes, are highly prized for their complex flavors (see Figure 31.16b and c). These fungi can fetch several hundred dollars a pound. Truffles release strong odors that attract mammals and insects, which feed on them and disperse their spores. In some cases, these odors mimic the sex attractants of certain mammals.

Humans have used yeasts to produce alcoholic beverages and raise bread for thousands of years. Under anaerobic conditions, yeasts ferment sugars to alcohol and CO₂, which leavens dough. Only relatively recently have the yeasts involved been separated into pure cultures for more controlled use. The yeast *Saccharomyces cerevisiae* is the most important of all cultured fungi (see Figure 31.7). It is available as many strains of baker's yeast and brewer's yeast.

Many fungi have great medical value as well. For example, a compound extracted from ergots is used to reduce high blood pressure and to stop maternal bleeding after childbirth. Some fungi produce antibiotics that are essential in treating bacterial infections. In fact, the first antibiotic discovered

A Figure 31.26 Fungal production of an antibiotic. The mold *Penicillium* produces an antibiotic that inhibits the growth of *Staphylococcus* bacteria, resulting in the clear area between the mold and the bacteria.

was penicillin, made by the ascomycete mold *Penicillium* (Figure 31.26).

Fungi also figure prominently in research in molecular biology and biotechnology. Researchers use *Saccharomyces* to study the molecular genetics of eukaryotes because its cells are easy to culture and manipulate (see Chapter 19). Scientists are gaining insight into the genes involved in human diseases such as Parkinson's disease and Huntington's disease by examining the interactions of homologous genes in *Saccharomyces*.

Genetically modified fungi hold much promise. Although bacteria such as *Escherichia coli* can produce some useful proteins, they cannot synthesize glycoproteins because they lack enzymes that can attach carbohydrates to proteins. Fungi, on the other hand, contain such enzymes. In 2003, scientists succeeded in engineering a strain of *S. cerevisiae* that produces human glycoproteins, such as insulin. Such fungus-produced glycoproteins could treat people with medical conditions that make them unable to produce these compounds. Meanwhile, other researchers are sequencing the genome of the wood-digesting basidiomycete *Phanerochaete chrysosporium*, also known as white rot. They hope to decipher the metabolic pathways by which white rot breaks down wood, with the goal of harnessing these pathways to produce paper pulp.

Having now completed our survey of the kingdom Fungi, we will turn in the remaining chapters of this unit to its sister kingdom, Animalia, to which we humans belong.

Concept Check 31.5

- What are some of the benefits that algae in lichens can derive from their relationship with fungi?
- What characteristics of pathogenic fungi result in their being efficiently transmitted?

For suggested answers, see Appendix A.

Chapter 31 Review

SUMMARY OF KEY CONCEPTS

Concept 31.1

Fungi are heterotrophs that feed by absorption

- **Nutrition and Fungal Lifestyles** (pp. 608–609) All fungi are heterotrophs (including decomposers and symbionts) that acquire nutrients by absorption. They secrete enzymes that break down complex molecules in food to smaller molecules that can be absorbed.
Activity Fungal Reproduction and Nutrition
- **Body Structure** (pp. 609–610) Fungi consist of mycelia, networks of branched hyphae adapted for absorption. Most fungi have cell walls made of chitin. Some fungi have hyphae partitioned into cells by septa, with pores allowing cell-to-cell movement of materials. Coenocytic fungi lack septa. Mycorrhizal fungi have a symbiotic relationship with plants.

Concept 31.2

Fungi produce spores through sexual or asexual life cycles

- **Sexual Reproduction** (pp. 610–611) The sexual cycle involves cytoplasmic fusion (plasmogamy) and nuclear fusion (karyogamy), with an intervening heterokaryotic stage in which cells have haploid nuclei from two parents. The diploid phase resulting from karyogamy is short-lived and undergoes meiosis, producing haploid spores.
- **Asexual Reproduction** (pp. 611–612) Molds are rapidly growing, asexually reproducing fungi. Yeasts are unicellular fungi adapted to life in liquids such as plant saps. Fungi with no known sexual stage have traditionally been called deuteromycetes, but mycologists are using genetic techniques to assign many of these fungi to particular phyla.

Concept 31.3

Fungi descended from an aquatic, single-celled, flagellated protist

- **The Origin of Fungi** (p. 612) Molecular evidence supports the hypothesis that fungi and animals diverged from a common ancestor that was unicellular and bore flagella.
- **The Move to Land** (p. 612) Fungi were among the earliest colonizers of land, probably as symbionts with early land plants.

Concept 31.4

Fungi have radiated into a diverse set of lineages

- **Table 31.1**, in the next column, summarizes the fungal phyla and some of their distinguishing characteristics.
- **Chytrids** (p. 613) Chytrids are saprobic or parasitic fungi found in freshwater and terrestrial habitats. They are the only fungi that produce flagellated spores.
- **Zygomycetes** (pp. 613–615) Zygomycetes, such as black bread mold, are named for their sexually produced zygosporangia, which are heterokaryotic structures capable of persisting through unfavorable conditions. Unicellular parasites called microsporidia are now thought to be zygomycetes.

Table 31.1 Review of Fungal Phyla

| Phylum | Distinguishing Feature |
|----------------------------|--|
| Chytridiomycota (chytrids) | Motile spores with flagella |
| Zygomycota | Resistant zygosporangium as sexual stage |
| Glomeromycota | Arbuscular mycorrhizae |
| Ascomycota (sac fungi) | Sexual spores borne internally in sacs called asci |
| Basidiomycota (club fungi) | Elaborate fruiting body called basidiocarp |

- **Glomeromycetes** (p. 615) The vast majority of plants have symbiotic relationships with glomeromycetes in the form of arbuscular mycorrhizae.
- **Ascomycetes** (pp. 616–617) Ascomycetes (sac fungi) reproduce asexually by producing vast numbers of asexual spores called conidia. Sexual reproduction involves the formation of spores in sacs, or asci, at the ends of dikaryotic hyphae, which are usually contained in fruiting bodies called ascocarps.
- **Basidiomycetes** (pp. 618–619) Important decomposers of wood, the mycelia of basidiomycetes (club fungi) can grow for years in the heterokaryotic stage. Sexual reproduction involves the formation of fruiting bodies called basidiocarps, which produce spores on club-shaped basidia at the ends of dikaryotic hyphae.

Activity Fungal Life Cycles

Investigation How Does the Fungus Pilobolus Succeed as a Decomposer?

Concept 31.5

Fungi have a powerful impact on ecosystems and human welfare

- **Decomposers** (p. 620) Fungi perform essential recycling of chemical elements between the living and nonliving world.
- **Symbionts** (pp. 620–622) Mycorrhizae increase plant productivity. Fungi enable animals such as cattle, ants, and termites to digest plant tissue. Lichens are highly integrated symbiotic associations of fungi and algae or cyanobacteria.

- **Pathogens** (pp. 622–623) About 30% of all known fungal species are parasites, mostly of plants. Some fungi also cause human diseases.
- **Practical Uses of Fungi** (p. 623) Humans eat many fungi and use others to make cheeses, alcoholic beverages, and bread. Antibiotics produced by fungi treat bacterial infections. Genetic research on fungi is leading to applications in biotechnology

TESTING YOUR KNOWLEDGE

Evolution Connection

The fungus-alga symbiosis that makes up a lichen is thought to have evolved several times independently in different fungal groups. However, lichens fall into three well-defined growth forms (see Figure 31.23). What research could you perform LO test the following hypotheses? Hypothesis 1: Crustose, foliose, and fruticose lichens each represent a monophyletic group. Hypothesis 2: Each lichen growth form represents convergent evolution by taxonomically diverse fungi.

Scientific Inquiry

Lichens colonize gravestones, such as the one in this photo, almost as soon as the stones are placed and then continue to grow for decades or even centuries. Explain how you could calculate the growth rate of a particular lichen species by collecting data at an old cemetery.

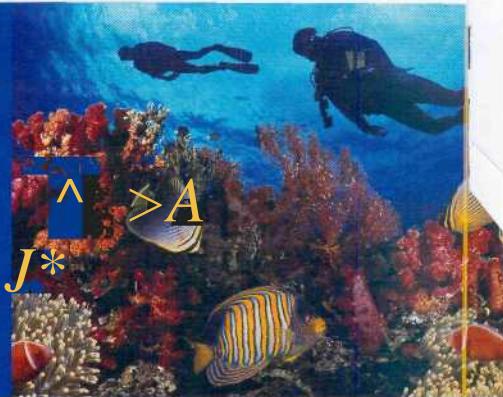

Investigation *How Does the Fungus *F. lobolus* Succeed as a Decomposer?*

Science, Technology, and Society

American chestnut trees once made up more than 25% of the hardwood forests of the eastern United States. These trees were wiped out by a fungus accidentally introduced on imported Asian chestnuts, which are not affected. More recently, a fungus has killed many eastern dogwood trees; some experts suspect that the parasite was accidentally introduced from somewhere else. Why are plants particularly vulnerable to fungi imported from other regions? What kinds of human activities might contribute to the spread of plant diseases? Do you think introductions of plant pathogens such as chestnut blight are more or less likely to occur in the future? Why?

An Introduction to Animal Diversity

A Figure 32.1 An underwater glimpse of animal diversity on and around a coral reef.

Key Concepts

- 32.1 Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers
- 32.2 The history of animals may span more than a billion years
- 32.3 Animals can be characterized by "body plans"
- 32.4 Leading hypotheses agree on major features of the animal phylogenetic tree

Overview

Welcome to Your Kingdom

Reading the last few chapters, you may have felt a little like a tourist among some rather unfamiliar organisms, such as slime molds, whisk ferns, and sac fungi. You probably are more at home with the topic introduced in this chapter—the animal kingdom, which of course includes yourself. But as **Figure 32.1** suggests, animal diversity extends far beyond humans or even the dogs, cats, birds, and other animals we humans regularly encounter. Biologists have identified 1.3 million living species of animals, and estimates of the total number of animal species run far higher, from 10 to 20 million to as many as 100 to 200 million. This vast diversity encompasses a spectacular range of morphological variation, from corals to cockroaches to crocodiles.

In this chapter, we embark on a tour of the animal kingdom, which will continue in the next two chapters. We will consider the characteristics that all animals share as well as those that distinguish various taxonomic groups. This information is central to understanding why animal phylogeny is currently one of the liveliest arenas of biological research and debate, as you will read later in the chapter.

Concept 32.1

Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers

Constructing a good definition of an animal is not straightforward, as there are exceptions to nearly every criterion for distinguishing animals from other life-forms. However, several characteristics of animals, when taken together, sufficiently define the group for our discussion.

Nutritional Mode

Animals differ from both plants and fungi in their mode of nutrition. Recall that plants are autotrophic eukaryotes capable of generating organic molecules through photosynthesis¹; fungi are heterotrophs that grow on or near their food, releasing exoenzymes that digest the food outside their bodies. Unlike plants, animals cannot construct all of their own organic molecules and so, in most cases, they ingest them—either by eating other living organisms or by eating nonliving organic material. But unlike fungi, most animals use enzymes to digest their food only after they have ingested it.

Cell Structure and Specialization

Animals are eukaryotes, and like plants and fungi (but unlike most protists), animals are multicellular. In contrast to plants and fungi, however, animals lack the structural support of cell walls. Instead, animal bodies are held together by structural proteins, the most abundant being collagen (see Figure 6.29).

in addition to collagen, which is found mainly in extracellular matrices, animals have three unique types of intercellular junctions—tight junctions, desmosomes, and gap junctions—that consist of other structural proteins (see Figure 6.31).

Among animal cells are two specialized forms not seen in other multicellular organisms: muscle cells and nerve cells. In most animals, these specialized cells are organized into muscle tissue and nervous tissue, respectively, and are responsible for movement and impulse conduction.

Reproduction and Development

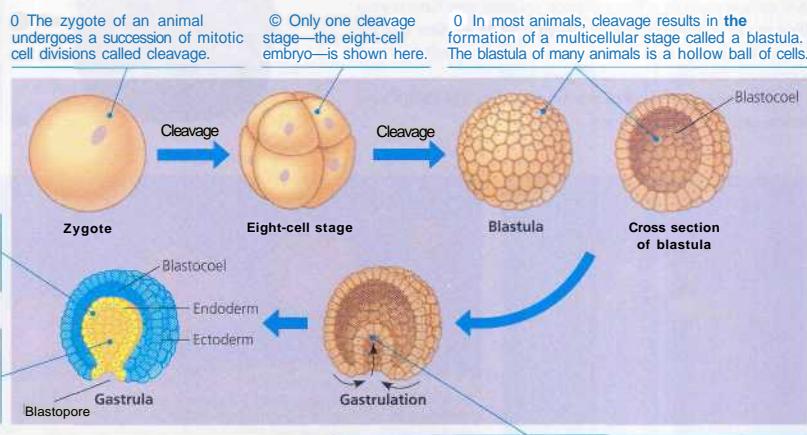

Most animals reproduce sexually, and the diploid stage usually dominates the life cycle. In most species, a small, flagellated sperm fertilizes a larger, nonmotile egg, forming a diploid zygote. The zygote then undergoes **cleavage**, a succession of mitotic cell divisions without cell growth between division cycles. During the development of most animals, cleavage leads to the formation of a multicellular stage called a **blastula**, which in many animals takes the form of a hollow ball (Figure 32.2). Following the blastula stage is the process of gastrulation, during which layers of embryonic tissues that will develop into adult body parts are produced. The resulting developmental stage is called a **gastrula**.

Some animals develop directly through transient stages of maturation into adults, but the life cycles of many animals also include at least one larval stage. A **larva** is a sexually immature form of an animal that is morphologically distinct from the adult stage, usually eats different food, and may even

have a different habitat than the adult, as in the case of the aquatic tadpole (larva) of a terrestrial frog. Animal larvae eventually undergo **metamorphosis**, a resurgence of development that transforms the animal into an adult.

Despite the extraordinary diversity of morphology exhibited by adult animals, the underlying genetic network that controls animal development has been relatively conserved. All eukaryotes have genes that regulate the expression of other genes, and many of these regulatory genes contain common "modules" of DNA sequences called homeoboxes (see Chapter 21). Animals share a unique homeobox-containing family of genes, known as *Hox* genes, suggesting that this gene family evolved in the eukaryote lineage that gave rise to animals. *Hox* genes play important roles in the development of animal embryos, controlling the expression of dozens or even hundreds of other genes. *Hox* genes can thus control cell division and differentiation, producing different morphological features of animals.

The sponges, which represent the lineage of simplest extant (living) animals, have *Hox* genes that regulate the formation of water channels in the body wall, the primary feature of sponge morphology (see Chapter 33). In more complex animals, the *Hox* gene family underwent further duplications, yielding a more versatile "toolkit" for regulating development. In bilaterians (a grouping that includes vertebrates, insects, and most other animals), *Hox* genes regulate patterning of the anterior-posterior axis, as well as other aspects of development. The same conserved genetic network governs the development of both a fly and a human, despite their obvious differences and hundreds of millions of years of divergent evolution.

i* Figure 32.2 Early embryonic development in animals.

Concept Check 32.1

- Both plants and animals are multicellular eukaryotes. Identify four ways in which plants and animals differ.
- Complex early developmental patterns such as the formation of a blastula and a gastrula are shared by diverse animals ranging from grasshoppers to clams to humans. What does this observation imply about the timing of the origins of these processes in animal evolution?

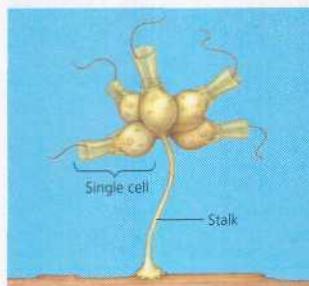

For suggested answers, see Appendix A.

Concept 32.2

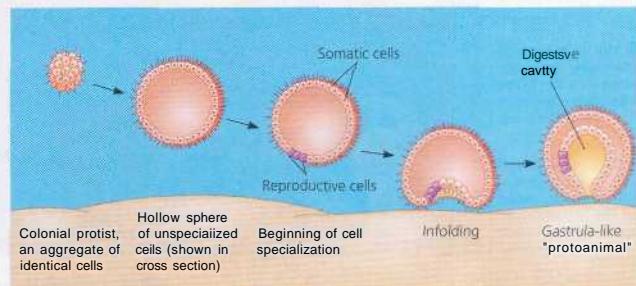

The history of animals may span more than a billion years

The animal kingdom includes not only the great diversity of living species, but the even greater diversity of extinct ones as well. (Some paleontologists have estimated that 99% of all animal species are extinct.) Various studies suggest that animal diversification began more than a billion years ago. For example, some calculations based on molecular clocks estimate that the ancestors of animals diverged from the ancestors of fungi as far back as 1.5 billion years ago. Similar studies on the common ancestor of living animals suggest that it lived 1.2 billion—800 million years ago. This common ancestor may have resembled modern choanoflagellates (Figure 32.3), protists that are the closest living relatives of animals, and was probably itself a colonial, flagellated protist (Figure 32.4).

In this section, we will survey fossil evidence of animal evolution over four geologic eras.

A. **Figure 32.3 A choanoflagellate colony.** Such a colony is about 0.02 mm high.

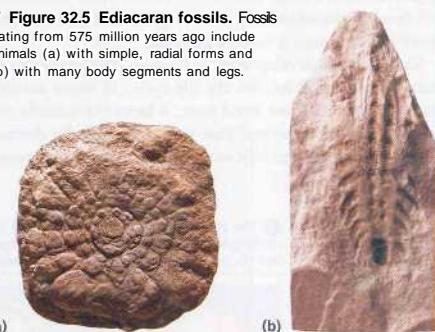

A. **Figure 32.4 One hypothesis for the origin of animals from a flagellated protist.** (The arrows symbolize evolutionary time.)

Neoproterozoic Era (1 Billion–542 Million Years Ago)

Despite the molecular data indicating a much earlier origin of animals, the first generally accepted fossils of animals are only 575 million years old. These fossils are known collectively as the Ediacaran fauna, named for the Ediacara Hills of Australia where they were first discovered (Figure 32.5). Similar fossils have since been found on other continents. Some appear to be related to living cnidarians such as corals (see Chapter 33). Other fossils may represent soft-bodied molluscs, and numerous fossilized tunnels and tracks indicate the presence of several forms of worms.

In addition to these macroscopic fossils, Neoproterozoic rocks have also yielded microscopic signs of early animals. As we discussed in Chapter 26, 570-million-year-old embryos discovered in China clearly exhibit the basic structural organization of present-day animal embryos, though paleontologists are still uncertain which animal clade the embryos represent. Though older fossils of animals will likely be discovered in the future, the fossil record as it is known today strongly suggests

T **Figure 32.5 Ediacaran fossils.** Fossils dating from 575 million years ago include animals (a) with simple, radial forms and (b) with many body segments and legs.

At the end of the Neoproterozoic Era was a time of rising levels of animal diversity.

Paleozoic Era (542–251 Million Years Ago)

Animal diversification appears to have accelerated dramatically between 542 and 525 million years ago, early in the Cambrian period of the Paleozoic Era—a phenomenon often referred to as the Cambrian explosion. In strata formed before the Cambrian explosion, only a handful of animal phyla can be recognized. But in strata that are between 542 and 525 million years old, paleontologists have found the oldest fossils of about half of all extant phyla. Many of these distinctive fossils—which include the first animals with hard mineralized skeletons—look quite different from most living animals (Figure 32.6). But for the most part, paleontologists have established that these various Cambrian fossils are members of extant animal phyla—or at least are close relatives.

There are several current hypotheses regarding the cause of the Cambrian explosion. Some evidence suggests that new predator-prey relationships that emerged in the Cambrian period generated diversity through natural selection. Predators acquired adaptations, such as new forms of locomotion that helped them catch prey, while prey species acquired new defenses, such as protective shells. Another hypothesis focuses on the rise in atmospheric oxygen that preceded the Cambrian explosion. With more oxygen available, the opportunity arose for the success of animals with higher metabolic rates and larger body size. A third hypothesis holds that the evolution of the *Hox* gene complex provided the developmental flexibility that resulted in variations in morphology. These hypotheses are not mutually exclusive, however; predator-prey relationships, atmospheric changes, and developmental flexibility may each have played a role.

The Cambrian period was followed by the Ordovician, Silurian, and Devonian periods, when animal diversity continued to increase, although punctuated by episodes of mass extinctions. Vertebrates (fishes) emerged as the top predators of the marine food web. By 460 million years ago, the "innovations" that emerged during the Cambrian period were making an impact on land. Arthropods began to adapt to terrestrial habitats, as indicated by the appearance of millipedes and centipedes. Fern galls—enlarged cavities that resident insects stimulate fern plants to form, providing protection for the insects—date back to at least 302 million years ago, suggesting that insects and plants were influencing each other's evolution by that time.

Vertebrates made the transition to land around 360 million years ago and diversified into numerous terrestrial lineages. Two of these survive today: amphibians (such as frogs and salamanders) and amniotes (such as reptiles and mammals). We will explore these groups, known collectively as tetrapods, in more detail in Chapter 34.

A Figure 32.6 A Cambrian seascape. This artist's reconstruction depicts a diverse array of organisms represented in fossils from the Burgess Shale site in British Columbia, Canada. The animals include *Pikaia* (swimming eel-like chordate), *Hallucigenia* (animal with toothpick-like spikes on seafloor), *Arenalocaris* (large animal with hooked claws), and *Marella* (arthropod swimming at left).

Mesozoic Era (251–65.5 Million Years Ago)

Few fundamentally new body plans emerged among animals during the Mesozoic era. But the animal phyla that had evolved during the Paleozoic now began to spread into new ecological niches. In the oceans, the first coral reefs formed, providing other animals with new marine habitats. Some reptiles returned to the water and succeeded as large aquatic predators. On land, modification of the tetrapod body plan included wings and other flight equipment in pterosaurs and birds. Large dinosaurs emerged, both as predators and herbivores. At the same time, the first mammals—tiny nocturnal insect-eaters—appeared on the scene.

Cenozoic Era (65.5 Million Years Ago to the Present)

As you read in Chapter 30, insects and flowering plants both underwent a dramatic diversification during the Cenozoic era. The beginning of this era followed mass extinctions of both terrestrial and marine animals. Among the groups of species that disappeared were the large, nonflying dinosaurs and the marine reptiles. The fossil record of the early Cenozoic documents the rise of large mammalian herbivores and carnivores as mammals began to exploit the vacated ecological niches. The global climate gradually cooled throughout the Cenozoic, triggering significant shifts in many animal lineages. Among primates, for example, some species in Africa adapted to the

open woodlands and savannas that replaced the former dense forests. The ancestors of our own species were among those grassland apes.

Concept Check 32.2

- Put the following milestones in animal evolution in chronological order from least recent to most recent:
(a) origin of mammals, (b) earliest evidence of terrestrial arthropods, (c) Ediacaran fauna, (d) extinction of large, nonflying dinosaurs.
- Explain how the relatively rapid Cambrian radiation of animal phyla could have been the product of causes both external and internal to organisms.

For suggested answers, see Appendix A.

Concept 32.3

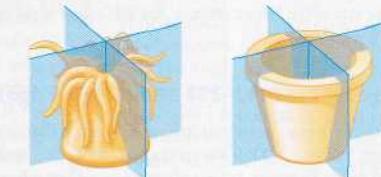

Animals can be characterized by "body plans"

One way in which zoologists categorize the diversity of animals is according to general features of morphology and development. A group of animal species that share the same level of organizational complexity is known as a grade. Grades, it's important to remember, are not necessarily equivalent to clades. Consider the case of slugs: A class of animals called gastropods includes many species that lack shells and are referred to as slugs, along with many shelled species such as snails. You may have encountered terrestrial slugs in a garden; many other slug species live in aquatic habitats. But these species do not all descend from a common ancestor and thus do not form a monophyletic clade (see Figure 25.10). Rather, phylogenetic studies show that several gastropod lineages independently lost their shells and became "slugs." The slug grade, in other words, is polyphyletic.

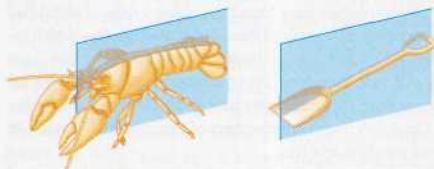

The set of morphological and developmental traits that define a grade are generally integrated into a functional whole referred to as a body plan. Let's now explore some of the major features of animal body plans.

Symmetry

Animals can be categorized according to the symmetry of their bodies (or its absence). Most sponges, for example, lack symmetry altogether. Among the animals that do have symmetrical bodies, symmetry can take different forms. Some animals exhibit radial symmetry, the form found in a flowerpot (**Figure 32.7a**). Sea anemones, for example, have a top (oral),

(a) Radial symmetry. The parts of a radial animal, such as a sea anemone (phylum Cnidaria), radiate from the center. Any imaginary slice through the central axis divides the animal into mirror images.

(b) Bilateral symmetry. A bilateral animal, such as a lobster (phylum Arthropoda), has a left side and a right side. Only one imaginary cut divides the animal into mirror-image halves.

A Figure 32.7 Body symmetry. The flowerpot and shovel are included to help you remember the radial-bilateral distinction.

or mouth) side and a bottom (aboral) side. But they have no head and rear end, and no left and right side.

The two-sided symmetry seen in a shovel is an example of bilateral symmetry (**Figure 32.7b**). A bilateral animal has a dorsal (top) side and a ventral (bottom) side, as well as a left and right side and an anterior (head) end with a mouth and a posterior (tail) end. Many animals with a bilaterally symmetrical body plan (such as arthropods and mammals) have sensory equipment concentrated at the anterior end, along with a central nervous system ("brain") in the head—an evolutionary trend known as cephalization (from the Greek *kephala*, head).

The symmetry of an animal generally fits its lifestyle. Many radial animals are sessile (living attached to a substrate) or planktonic (drifting or weakly swimming, such as jellies, or jellyfishes). Their symmetry equips them to meet the environment equally well from all sides. In contrast, bilateral animals generally move actively from place to place. Their central nervous system enables them to coordinate complex movements involved in crawling, burrowing, hunting, or swimming. These two fundamentally different kinds of symmetry probably arose very early in the history of animal life (see Figure 32.5).

Tissues

Animal body plans also vary according to the organization of the animal's tissues. True tissues are collections of specialized cells isolated from other tissues by membranous layers. Sponges lack true tissues. In all other animals, the embryo

becomes Layered through the process of gastrulation, as you read earlier in this chapter (see Figure 32.2). As development progresses, these concentric layers, called **germ layers**, form the various tissues and organs of the body. **Ectoderm**, the germ layer covering the surface of the embryo, gives rise to the outer covering of the animal and, in some phyla, to the central nervous system. **Endoderm**, the innermost germ layer, lines the developing digestive tube, or **archenteron**, and gives rise to the lining of the digestive tract and organs derived from it, such as the liver and lungs of vertebrates.

Animals that have only these two germ layers are said to be **diploblastic**. Diploblasts include the animals called cnidarians (jellies and corals, for example) as well as comb jellies (see Chapter 33). Other animals have a third germ layer, called the **mesoderm**, between the ectoderm and endoderm. These animals are said to be **triploblastic** (having three germ layers). In triploblasts, the mesoderm forms the muscles and most other organs between the digestive tube and the outer covering of the animal. Triploblasts include all bilaterally symmetrical animals, which range from flatworms to arthropods to vertebrates. (Although some diploblasts actually do have a third germ layer, it is not nearly as well developed as the mesoderm of animals considered to be triploblastic.)

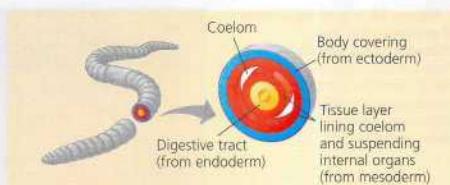

Body Cavities

Some triploblastic animals possess a **body cavity**, a fluid-filled space separating the digestive tract from the outer body wall. This body cavity is also known as a **coelom** (from the Greek *knilos*, hollow). A so-called "true" coelom forms from tissue derived from mesoderm. The inner and outer layers of tissue that surround the cavity connect dorsally and ventrally and form structures called mesenteries that suspend the internal organs. Animals that possess a true coelom are known as **coelomates** (Figure 32.8a).

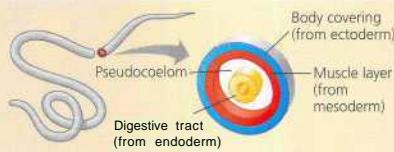

Some triploblastic animals have a cavity formed from the blastocoel, rather than from mesoderm (Figure 32.8b). Such a cavity is called a "pseudocoelom" (from the Greek *pseudo*, false), and animals that have one are **pseudocoelomates**. Despite its name, a pseudocoelom is not false; it is a fully functional cavity.

Finally, some triploblastic animals lack a coelom altogether (Figure 32.8c). They are known collectively as **acoelomates** (from the Greek *a*, without).

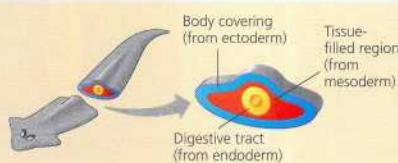

A body cavity has many functions. Its fluid cushions the suspended organs, helping to prevent internal injury. In soft-bodied coelomates, such as earthworms, the coelom contains noncompressible fluid that acts like a skeleton against which muscles can work. The cavity also enables the internal organs to grow and move independently of the outer body wall. If it were not for your coelom, for example, every beat of your heart or ripple of your intestine could warp your body's surface.

(a) **Coelomate.** Coelomates such as annelids have a true coelom, a body cavity completely lined by tissue derived from mesoderm.

(b) **Pseudocoelomate.** Pseudocoelomates such as nematodes have a body cavity only partially lined by tissue derived from mesoderm.

(c) **Acoelomate.** Acoelomates such as flatworms lack a body cavity between the digestive tract and outer body wall.

A Figure 32.8 Body plans of triploblastic animals. The various organ systems of an animal develop from the three germ layers that form in the embryo. Blue represents tissue derived from ectoderm, red from mesoderm, and yellow from endoderm.

Current phylogenetic research suggests that true coeloms and pseudocoeloms have been gained or lost multiple times in the course of animal evolution. Thus, the terms **coelomates** and **pseudocoelomates** refer to grades, not clades.

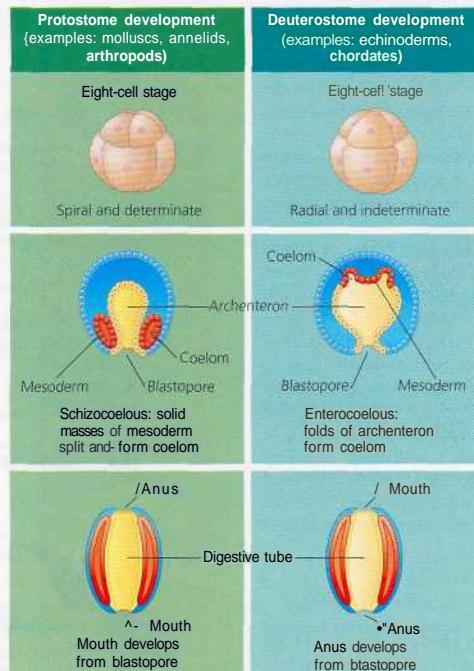

Protostome and Deuterostome Development

Based on certain features of early development, many animals can be categorized as having one of two developmental modes: **protostome development** or **deuterostome development**. Three features often distinguish these modes.

Cleavage

A pattern in many animals with protostome development is **spiral cleavage**, in which the planes of cell division are diagonal to the vertical axis of the embryo. As seen in the

- Figure 32.9 A comparison of protostome and deuterostome development.** These are useful general distinctions, though there are many variations and exceptions to these patterns. (Blue = ectoderm; red = mesoderm; yellow = endoderm.)

(a) Cleavage. In general, protostome development begins with spiral, determinate cleavage. Deuterostome development is characterized by radial, indeterminate cleavage.

(b) Coelom formation. Coelom formation begins in the gastrula stage. In protostome development, the coelom forms from splits in the mesoderm (schizocoelous development). In deuterostome development, the coelom forms from mesodermal outpocketings of the archenteron (enterocoelous development).

(c) Fate of the blastopore. In protostome development, the mouth forms from the blastopore. In deuterostome development, the mouth forms from a secondary opening.

eight-cell stage resulting from spiral cleavage, smaller cells lie in the grooves between larger, underlying cells (**Figure 32.9a**). Furthermore, the so-called determinate cleavage of some animals with this development pattern rigidly casts ("determines") the developmental fate of each embryonic cell very early. A cell isolated at the four-cell stage from a snail, for example, forms an inviable embryo that lacks many parts.

In contrast to the spiral cleavage pattern, deuterostome development is predominantly characterized by radial cleavage. The cleavage planes are either parallel or perpendicular to the vertical axis of the egg; as seen in the eight-cell stage, the tiers of cells are aligned, one directly above the other. Most animals with deuterostome development are further characterized by indeterminate cleavage, meaning that each cell produced by early cleavage divisions retains the capacity to develop into a complete embryo. For example, if the cells of a sea star embryo are isolated at the four-cell stage, each will form a larva. It is the indeterminate cleavage of the human zygote that makes identical twins possible. This characteristic also explains the developmental versatility of the embryonic "stem cells" that may provide new ways to overcome a variety of dis-

eases, including juvenile diabetes, Parkinson's disease, and Alzheimer's disease (see Chapter 21).

Coelom Formation

Another difference between protostome and deuterostome development is apparent later in the process, in gastrulation, the developing digestive tube of an embryo initially forms as a blind pouch, the archenteron (**Figure 32.9b**). As the archenteron forms in protostome development, initially solid masses of mesoderm split and form the coelomic cavity; this pattern is called schizocoelous development (from the Greek *schizein*, to split). In contrast, formation of the body cavity in deuterostome development is described as enterocoelous: The mesoderm buds from the wall of the archenteron, and its cavity becomes the coelom (see Figure 32.9b).

Fate of the Blastopore

The fundamental character that distinguishes the two developmental modes is the fate of the blastopore, the indentation that during gastrulation leads to the formation of the archenteron (**Figure 32.9c**). After the archenteron develops, a secod

opening forms at the opposite end of the gastrula. Ultimately, the blastopore and this second opening become the two openings of the digestive tube (the mouth and the anus), in protostome development, the mouth generally develops from the first opening, the blastopore, and it is for this characteristic that the term *protostome* derives (from the Greek *protos*, first, and *stoma*, mouth). In deuterostome (from the Greek *deuteros*, second) development, the mouth is derived from the second-opening, and the blastopore usually forms the anus.

Concept 32.3

1. Why is it important to distinguish *grade*-level characteristics from characteristics that unite clades?
1. Compare three features of the early development of a snail (a mollusc) and a human (a chordate).

For suggested answers, see Appendix A.

Concept 32.4

Leading hypotheses agree on major features of the animal phylogenetic tree

Zoologists currently recognize about 35 animal phyla. But the relationships between these phyla continue to be debated. Although many biology students must find it frustrating that the phylogenetic trees depicted in textbooks cannot be memorized as set-in-stone truths, the uncertainty inherent in these diagrams is a healthy reminder that science is a process of inquiry and as such is dynamic.

Researchers have long tested their hypotheses about animal phylogeny through morphological studies. In the mid-1990s, zoologists also began to study the molecular systematics of animals. Additional clues to animal phylogeny have come from new studies of lesser-known phyla, along with fossil analyses that can help clarify which traits are primitive in various animal groups and which are derived. Recall that science is partly distinguished from other ways of knowing because its ideas can be falsified through testing with experiments, observations, and new analytical methods.

Modern phylogenetic systematics is based on the identification of clades, which are monophyletic sets of taxa as defined by shared derived characters unique to those taxa and their common ancestor. (See Chapter 25 to review cladistic analysis and phylogenetic systematics.) Based on cladistic methods, a phylogenetic tree takes shape as a hierarchy of clades nested within larger clades—the finer branches and thicker branches of the tree, respectively. Defining the shared derived characters

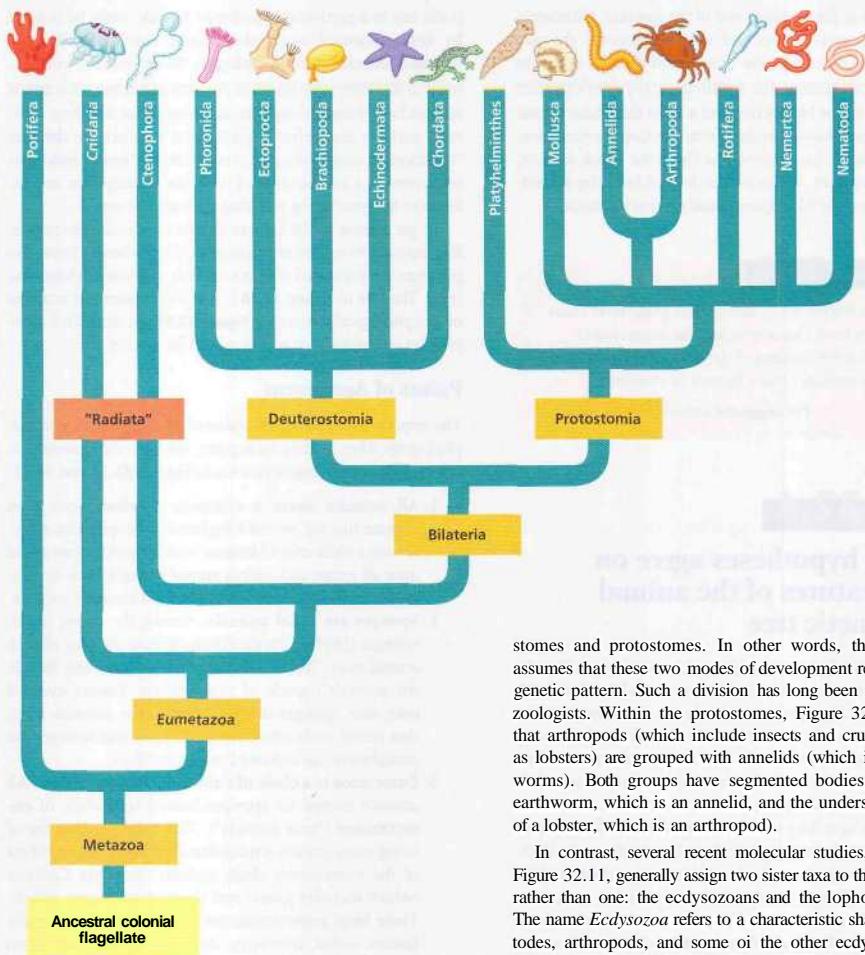

is the key to a particular hypothesis. A clade might be defined by key anatomical and embryological similarities that researchers conclude are homologous. More recently, comparisons of monomer sequences in proteins or nucleic acids across species have provided another data source for inferring common ancestry and defining clades. But whether the data are “traditional” morphological characters or “new” molecular sequences or a combination of both, the assumptions and inferences inherent in the resulting trees are the same.

To get a sense of the current debate in animal systematics, let's examine two current phylogenetic hypotheses. These hypotheses are presented on the next two pages as phylogenetic trees. The tree in Figure 32.10 is based on systematic analyses of morphological characters. Figure 32.11 is a simplified compilation of results from recent molecular studies.

Points of Agreement

The hypotheses agree on a number of major features of animal phylogeny. After reading each point, see how the statement is reflected by the phylogenetic trees in Figures 32.10 and 32.11.

1. All animals share a common ancestor. Both trees indicate that the animal kingdom is monophyletic, representing a clade called Metazoa. In other words, if we could trace all extant and extinct animal lineages back to their origin, the lineages would converge on a common ancestor.
2. Sponges are basal animals. Among the extant phyla, sponges (phylum Porifera) branch from the base of both animal trees. They exhibit a parazoan (meaning “beside the animals”) grade of organization. Tissues evolved only after sponges diverged from other animals. Note that recent molecular analyses suggest that sponges are paraphyletic, as indicated in Figure 32.11.
3. Eumetazoa is a clade of animals with true tissues. All animals except for sponges belong to a clade of eumetazoans (“true animals”). The common ancestor of living eumetazoans acquired true tissues. Basal members of the eumetazoan clade include the phyla Cnidaria (which includes jellies) and Ctenophora (comb jellies). These basal eumetazoans are diploblastic and generally feature radial symmetry. As a result, they are often placed in the informal grade called Radiata.
4. Most animal phyla belong to the clade Bilateria. Bilateral symmetry is a shared derived character that helps to define a clade (and grade) containing the majority of animal phyla, called the bilaterians. The Cambrian explosion was primarily a rapid diversification of the bilaterians.
5. Vertebrates and some other phyla belong to the clade Deuterostomia. The name deuterostome refers not only to an animal development grade, but also to a clade that includes vertebrates. (Note, however, that the two hypotheses depicted disagree as to which other phyla are also deuterostomes.)

• **Figure 32.10 One hypothesis of animal phylogeny based mainly on morphological and developmental comparisons.** The bilaterians are divided into protostomes and deuterostomes.

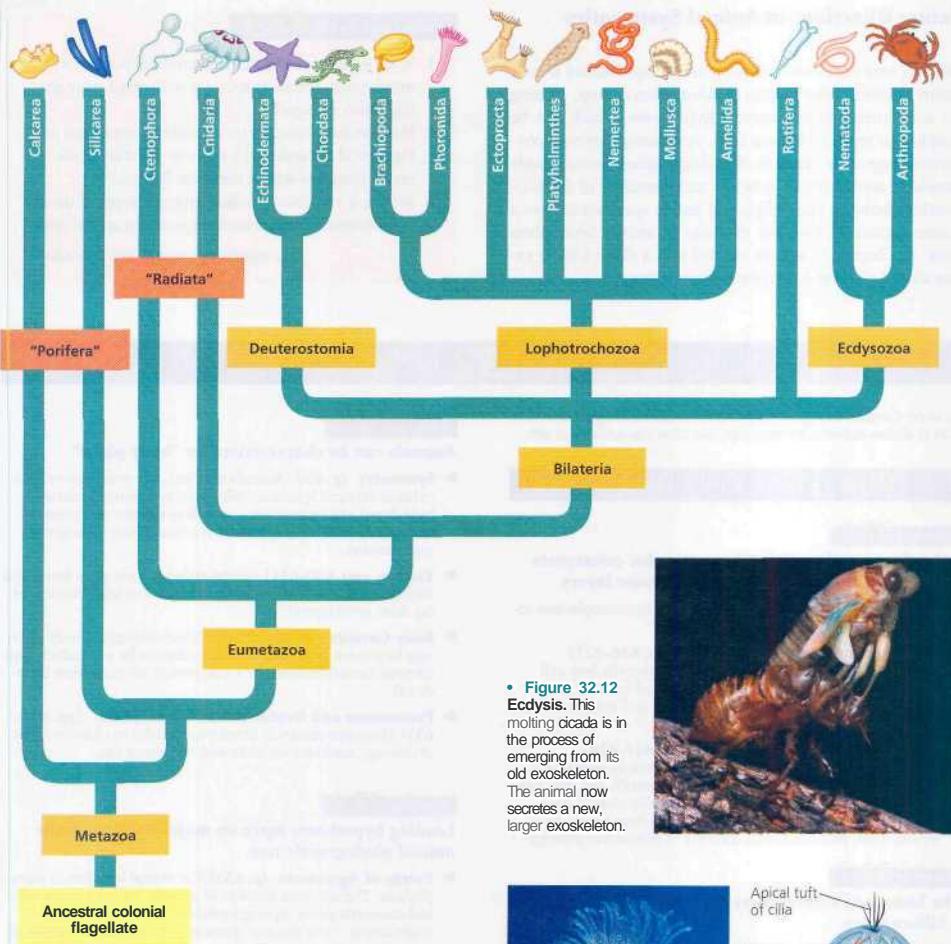

Disagreement over the Bilaterians

While these two phylogenetic hypotheses agree on the overall structure of the animal tree, they also disagree on some significant points. The most important of these is the relationships among the bilaterians. The morphology-based tree in Figure 32.10 divides the bilaterians into two clades: deuto-

stomes and protostomes. In other words, this hypothesis assumes that these two modes of development reflect a phylogenetic pattern. Such a division has long been recognized by zoologists. Within the protostomes, Figure 32.10 indicates that arthropods (which include insects and crustaceans such as lobsters) are grouped with annelids (which include earthworms). Both groups have segmented bodies (think of an earthworm, which is an annelid, and the underside of the tail of a lobster, which is an arthropod).

In contrast, several recent molecular studies, as shown in Figure 32.11, generally assign two sister taxa to the protostomes rather than one: the ecdysozoans and the lophotrochozoans. The name *Ecdysozoa* refers to a characteristic shared by nematodes, arthropods, and some of the other ecdysozoan phyla (which are not included in our survey). These animals secrete external skeletons (exoskeletons); the stiff covering of a cricket is an example. As the animal grows, it molts, squirming out of its old exoskeleton and secreting a new, larger one. The shedding of the old exoskeleton is called *ecdysis*, the process for which the ecdysozoans are named (**Figure 32.12**). Though named for this characteristic, the clade is actually defined mainly by molecular evidence supporting the common ancestry of its members. Furthermore, some taxa excluded from this clade by their molecular data do in fact molt, such as certain leeches.

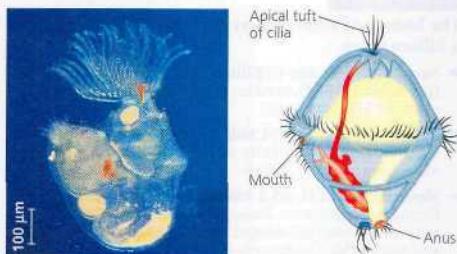

The name *Lophotrochozoci* refers to two different structures observed in animals belonging to this clade. Some animals, such

A Figure 32.11 One hypothesis of animal phylogeny based mainly on molecular data. The bilaterians are divided into deuterostomes, lophotrochozoans, and ecdysozoans, plus rotifers.

as ectoprocts, develop a structure called a lophophore (from the Greek *lophos*, crest, and *pheirein*, to carry), a crown of ciliated tentacles that function in feeding (Figure 32.13a). Other phyla, including annelids and molluscs, go through a distinctive larval stage called the trophophore larva (Figure 32.13b)—hence the name lophotrochozoan.

- **Figure 32.12**
Ecdysis. This molting cicada is in the process of emerging from its old exoskeleton. The animal now secretes a new, larger exoskeleton.

A Figure 32.13 Characteristics of lophotrochozoans.

Future Directions in Animal Systematics

like any area of scientific inquiry, animal systematics is constantly evolving. New sources of information emerge, offering the opportunity to test current hypotheses, which can be modified or replaced by new ones. Systematists are now conducting large-scale analyses of multiple genes across a wide sample of animal phyla. A better understanding of the relationships between these phyla will enable scientists to have a clearer picture of how the diversity of animal body plans arose. In Chapter 33 and 34, we will take a closer look at extant animal phyla and their evolutionary history.

Concept Check 32.4

- What evidence indicates that cnidarians share a more recent common ancestor with other¹ animals than with sponges?
- How do the phylogenetic hypotheses presented in Figures 32.10 and 32.11 differ in structuring the major branches within the clade Bilateria?
- Why is it valuable to collect multiple types of data to evaluate evolutionary relationships among animal phyla?

For suggested answers, see Appendix A.

Chapter 32 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 32.1

Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers

- Nutritional Mode** (p. 626) Animals are heterotrophs that ingest their food.
- Cell Structure and Specialization** (pp. 626–627) Animals are multicellular eukaryotes. Their cells lack cell walls; their bodies are held together instead by structural proteins such as collagen. Nervous tissue and muscle tissue are unique to animals.
- Reproduction and Development** (pp. 627–628) Gastrulation follows the formation of the blastula, resulting in formation of embryonic tissue layers. All animals, and only animals, have *Hox* genes that regulate the development of body form. Although the *Hox* family of genes has been highly conserved, it can produce a wide diversity of animal morphology.

Concept 32.2

The history of animals may span more than a billion years

- Neoproterozoic Era (1 Billion–542 Million Years Ago)** (pp. 628–629) Early members of the animal fossil record include the Ediacaran fauna.
- Paleozoic Era (542–251 Million Years Ago)** (p. 629) The Cambrian explosion marks the earliest fossil appearance of many major groups of living animals.
- Mesozoic Era (251–65.5 Million Years Ago)** (p. 629) During the Mesozoic era, dinosaurs were dominant terrestrial vertebrates. Coral reefs emerged, becoming important marine ecological niches for other organisms.
- Cenozoic Era (65.5 Million Years Ago to the Present)** (pp. 629–630) The present-day mammal orders diversified during the Cenozoic. Insects diversified.

Concept 32.3

Animals can be characterized by "body plans"

- Symmetry** (p. 630) Animals may lack any symmetry or have radial or bilateral symmetry. Bilaterally symmetrical animals have dorsal and ventral sides, as well as anterior and posterior ends. Many bilaterally symmetrical animals have undergone cephalization.
- Tissues** (pp. 630–631) Animal embryos form germ layers and may be diploblastic (having two germ layers) or triploblastic (having three germ layers).
- Body Cavities** (p. 631) In triploblastic animals, a body cavity may be present or absent. A body cavity can be a pseudocoelom (derived from blastocoel) or a true coelom (derived from mesoderm).
- Protostome and Deuterostome Development** (pp. 631–633) These two modes of development differ in characteristics of cleavage, coelom formation, and blastopore fate.

Concept 32.4

Leading hypotheses agree on major features of the animal phylogenetic tree

- Points of Agreement** (p. 633) The animal kingdom is monophyletic. The common ancestor of animals was probably a colonial choanoflagellate. Sponges exhibit a parazoan grade of organization. "True animals" possess true tissues and include all animals except sponges. Cnidaria and Ctenophora are sometimes placed in the grade Radiata. Bilateral symmetry is a trait shared by a clade containing the other phyla of animals.
- Disagreement over the Bilaterians** (pp. 634–635) Different analyses of animal systematics support different bilaterian clades.
- Future Directions in Animal Systematics** (p. 636) Phylogenetic studies based on larger databases will likely provide further insights into animal evolutionary history.

Activity Animal Phylogenetic Tree

Investigation How Do Molecular Data Fit Traditional Phylogenies?

TESTING YOUR KNOWLEDGE

Evolution Connection

Some scientists suggest that the phrase "Cambrian fizz" might be more appropriate than "Cambrian explosion" to describe the diversification of animals during that geologic period. In a similar vein, Lynn Margulis, of the University of Massachusetts, has compared observing an explosion of animal diversity in Cambrian strata to monitoring Earth from a satellite and noticing the emergence of cities only when they are large enough to be visible from that distance. What do these statements imply about the evolutionary history of animals during that time?

Scientific Inquiry

If you were constructing a phylogenetic analysis of the animal kingdom, based on comparing morphological characteristics, why would the presence of flagella be a poor choice of a characteristic to use as a basis for grouping phyla into clades?

Investigation *How Do Molecular Data Fit Traditional Phylogenies?*

Science, Technology, and Society

The study of animal phylogeny is viewed by some people as "science for science's sake," and some organizations that fund scientific research tend to favor projects that have more apparent applications to human needs. On the other hand, general interest in the history of life seems to remain high, with articles on new discoveries frequently featured in popular magazines. Suppose you had the opportunity to join a research team studying animal phylogeny. Write a short letter to a nonbiologist explaining why this research might be worth funding.

33

Invertebrates

A Figure 33.1 A Christmas tree worm, a marine invertebrate.

Key Concepts

- 33.1 Sponges are sessile and have a porous body and choanocytes
- 33.2 Cnidarians have radial symmetry, a gastrovascular cavity, and cnidocytes
- 33.3 Most animals have bilateral symmetry
- 33.4 Molluscs have a muscular foot, a visceral mass, and a mantle
- 33.5 Annelids are segmented worms
- 33.6 Nematodes are nonsegmented pseudocoelomates covered by a tough cuticle
- 33.7 Arthropods are segmented coelomates that have an exoskeleton and jointed appendages
- 33.8 Echinoderms and chordates are deuterostomes

Overview

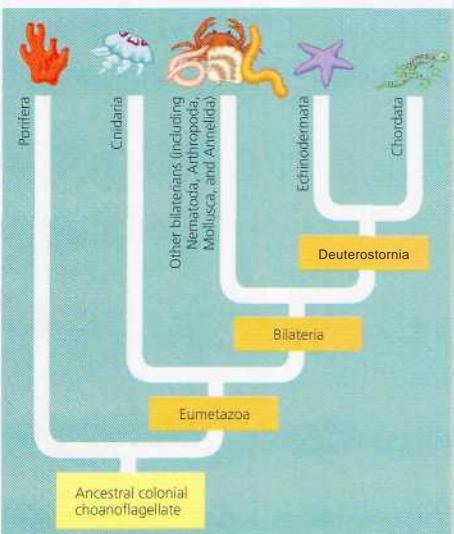

Life Without a Backbone

At first glance, you might mistake the organism shown in Figure 33.1 for some type of seaweed. But this colorful inhabitant of coral reefs is actually an animal, not an alga. Specifically, it is a kind of segmented worm commonly called a Christmas tree worm. The two whorls are tentacles, which the worm uses for gas exchange and for filtering small organisms from the water. The tentacles emerge from a tube of calcium carbonate secreted by the worm that protects and supports its soft body. Light-sensitive structures on the tentacles can detect the shadow cast by a predator, triggering muscular contractions that rapidly withdraw the tentacles into the tube.

Christmas tree worms are invertebrates—animals that lack a backbone. Invertebrates account for 95% of known animal species and all but one of the roughly 35 animal phyla

that have been described. Invertebrates occupy almost every habitat on Earth, from the scalding water released by deep-sea hydrothermal vents to the rocky, frozen ground of Antarctica.

In this chapter, we'll take a brief tour of the invertebrate world, using the phylogenetic tree in Figure 33.2 as a guide. Figure 33.3, on the next three pages, explores two dozen invertebrate phyla. We'll examine 14 of those phyla in more detail in this chapter.

A Figure 33.2 Review of animal phylogeny.

The animal kingdom is divided into about 3⁸ phyla encompassing 1.3 million known species, but estimates of the total number of species range from 10 million to 200 million. Here we explore 24

animal phyla, all of which include invertebrates. Of the phyla surveyed in this figure, those that are illustrated with smaller-sized "preview" photographs are discussed more fully later in this chapter.

PORIFERA (5,500 species)

A sponge

Sponges are simple, sessile animals that lack true tissues. They live as suspension feeders, trapping particles that pass through the internal channels of their bodies (see Concept 33.1).

PLACOZOA (1 species)

On first inspection, the single known species in this phylum, *Trichoplax adhaerens*, does not even look like an animal. It consists of a few thousand cells arranged in a double-layered plate 2 mm across. Feeding on organic detritus, *Trichoplax* can reproduce by dividing into two individuals or by budding off many multicellular individuals.

A placozoan (LM)

PLATYHELMINTHES (20,000 species)

A marine flatworm

Flatworms (including tapeworms, planarians, and flukes) have bilateral symmetry and a central nervous system that processes information from eyes and other sensory structures. They have no body cavity or organs for circulation (see Concept 33.3).

ECTOPROCTA (4,500 species)

"Ectoprocts (also known as bryozoans) live as sessile colonies and are covered by a tough exoskeleton (see Concept 33.3).

Ectoprocts

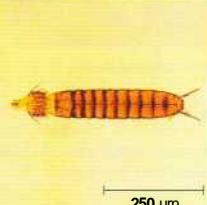

CNIDARIA (10,000 species)

A jelly

Cnidarians include corals, jellies, and hydroids. These animals share a distinctive body plan that includes a gastrovascular cavity with a single opening that serves as both mouth and anus (see Concept 33.2).

KINORHYNCHA (150 species)

A kinorhynch (LM)

Almost all kinorhynchs are less than 1 mm long. They live in sand and mud in oceans around the world, from the intertidal zone to depths of 8,000 m. A kinorhynch's body consists of 13 segments covered in plates. The mouth is tipped with a ring of spines and can be retracted into the body.

ROTIFERA (1,800 species)

A rotifer (LM)

Despite their microscopic size, rotifers have specialized organ systems, including an alimentary canal (digestive tract). They feed on microorganisms suspended in water (see Concept 33.3).

PHORONIDA (20 species)

Phoronids

Phoronids are marine worms. They live in tunnels in the seafloor, extending tentacles out of the tunnel opening to trap food particles (see Concept 33.3).

continued on the next page

Figure 33.3 (continued)

Exploring Invertebrate Diversity

BRACHIOPODA (335 species)

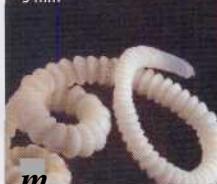

A brachiopod

Brachiopods, or lamp shells, may be easily mistaken for clams or other molluscs. However, most brachiopods have a unique stalk that anchors them to their substrate (see Concept 33.3).

ACANTHOCEPHALA (1,100 species)

5 mm

An acanthocephalan

Acanthocephalans (from the Greek *acanthias*, prickly and *cephalo*, head) are commonly known as thorny-headed worms because of the curved hooks located on the proboscis at the anterior end of their body. All species are parasites. The larvae develop in arthropods, and the adults live in vertebrates. Some acanthocephalans manipulate their intermediate hosts in ways that increase their chances of reaching their final hosts. For example, acanthocephalans that infect New Zealand mud crabs force their hosts to move to more visible locations on the beach, where the crabs are more likely to be eaten by birds, the worms' final hosts.

MOLLUSCA (93,000 species)

Molluscs (including snails, clams, squids, and octopuses) have a soft body that in many species is protected by a hard shell (see Concept 33.4).

An octopus

LORICIFERA (10 species)

Loriciferans (from the Latin *lorica*, corset, and *ferre*, to bear) are animals measuring only 0.1–0.4 mm in length that inhabit the deep-sea bottom. A loriciferan can telescope its head, neck, and thorax in and out of the lorica, a pocket formed by six plates surrounding the abdomen. Though the natural history of loriciferans is mostly a mystery, at least some species likely eat bacteria.

50 µm

A loriciferan (LM)

NEMERTEA (900 species)

A ribbon worm

CTENOPHORA (100 species)

Actenophore, or comb jelly

Ctenophores (comb jellies) are diploblastic like cnidarians, suggesting that both phyla diverged from other animals very early in evolution. Although they superficially resemble some cnidarians, comb jellies possess a number of distinctive traits, including a set of eight "combs" of cilia that propel the animals through the water. They also have a unique method for catching prey: When

a small animal contacts one of their two tentacles, specialized cells burst open, covering the prey with sticky threads. Comb jellies make up a major portion of the ocean's planktonic biomass.

ANNELIDA (16,500 species)

Annelids, or segmented worms, are distinguished from other worms by their body segmentation. Earthworms are the most familiar annelids, but the phylum also includes marine and freshwater species (see Concept 33.5).

A marine annelid

PRIAPULA (16 species)

A priapulan

Priapulans are worms with a large, rounded proboscis at the anterior end. (They are named after Priapus, the Greek god of fertility, who was symbolized by a giant penis.) Ranging from 0.5 mm to 20 cm in length, most species burrow through sea-floor sediments. Fossil evidence suggests that priapulans were among the major predators during the Cambrian period.

NEMATODA (25,000 species)

A roundworm

Roundworms are enormously abundant and diverse in the soil and in aquatic habitats; many species parasitize plants and animals. The most distinctive feature of roundworms is a tough, cuticle that coats the body (see Concept 33.6).

ARTHROPODA (1,000,000+ species)

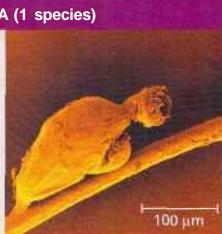

The vast majority of known animal species, including insects, crustaceans, and arachnids, are arthropods. All arthropods have a segmented exoskeleton and jointed appendages (see Concept 33.7).

A scorpion
(an arachnid)

CYCLOPHORA (1 species)

The only known species of cyclophoran, *Symphum pandora*, was discovered in 1995 on the mouthparts of a lobster. This tiny vase-shaped creature has a unique body plan and a particularly bizarre life cycle. Males impregnate females that are still developing in their mothers' bodies. The fertilized females then escape, settle elsewhere on the lobster, and release their offspring. The offspring apparently leave that lobster and search for another one to which they attach.

A cyclophoran (colorized SEM)

100 μm

ONYCHOPHORA (110 species)

Onychophorans, also called velvet worms, originated during the Cambrian explosion (see Chapter 32). Originally, they thrived in the ocean, but at some point they succeeded in colonizing land. Today they live only in humid forests. Onychophorans have fleshy antennae and several dozen pairs of saclike legs.

An onychophoran

TARDIGRADA (800 species)

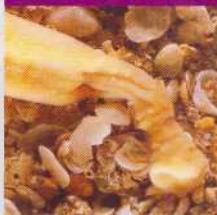

Tardigrades (colorized SEM)

Tardigrades (from the Latin *tardus*, slow, and *gradus*, step) are sometimes called water bears for their rounded shape, stubby appendages, and lumbering, beatlike gait. Most tardigrades are less than 0.5 mm in length. Some live in oceans or fresh water, while others live on plants or animals. As many as 2 million tardigrades can be found on a square meter of moss.

Harsh conditions may cause tardigrades to enter a state of dormancy; while dormant, they can survive temperatures as low as -272°C , close to absolute zero!

HEMICORDATA (85 species)

An acorn worm

Like echinoderms and chordates, hemichordates are deuterostomes (see Chapter 32). Hemichordates also share other traits with chordates, such as gill slits and a dorsal nerve cord. Most hemichordates are known as enteropneusts, or acorn worms. Acorn worms are marine and generally live buried in mud or under rocks; they may reach a length greater than 2 m.

ECHINODERMATA (7,000 species)

A sea urchin

Echinoderms, such as sand dollars, sea stars, and sea urchins, are aquatic animals that display radial symmetry as adults. They move and feed by using a network of internal canals to pump water to different parts of the body (see Concept 33.8).

CHORDATA (52,000 species)

More than 90% of all chordate species are animals with backbones (vertebrates). However, the phylum Chordata also includes three groups of invertebrates: tunicates, lancelets, and hagfishes. See Chapter 34 for a full discussion of this phylum.

A tunicate

Concept 33.1

Sponges are sessile and have a porous body and choanocytes

Sponges (phylum Porifera) are so sedentary that they were mistaken for plants by the ancient Greeks. Living in both fresh and marine waters, sponges are **suspension feeders**: They capture food particles suspended in the water that passes through their body, which typically resembles a sac perforated with pores (the name *Porifera* means "pore bearer"). Water is drawn through the pores into a central cavity the **spongocoel**, and then flows out of the sponge through a larger opening called the **osculum** (Figure 33.4). More complex sponges have folded body walls, and many contain branched water canals and several oscula. Under certain conditions, the cells around the pores and osculum contract, closing the openings. Sponges range in size from a few millimeters to a few meters.

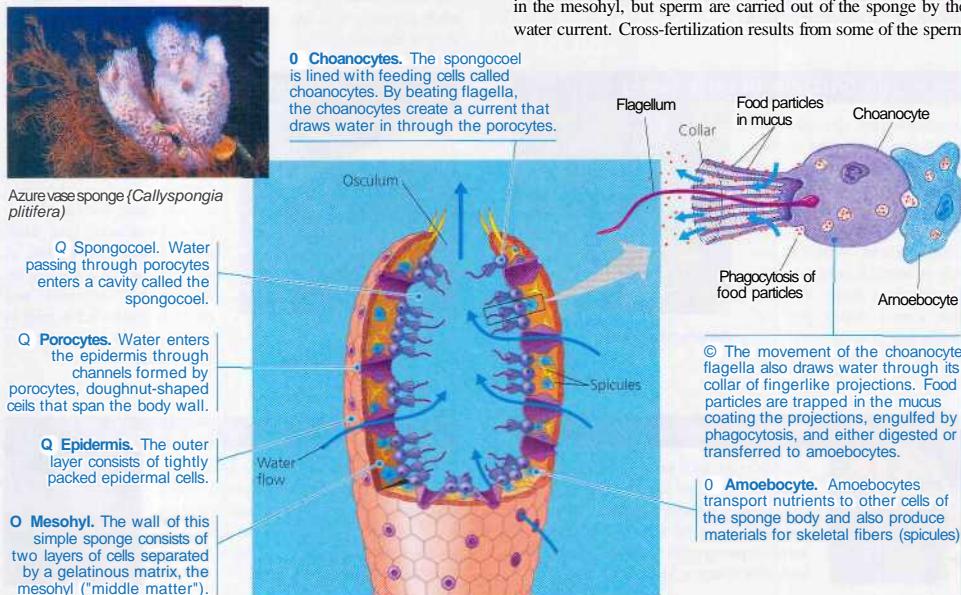

Unlike eumetazoans, sponges lack true tissues, groups of similar cells that act as a functional unit and are isolated from other tissues by membranous layers. However, the sponge body does contain several different cell types. Lining the interior of the spongocoel or internal water chambers are flagellated

choanocytes, or collar cells (named for the membranous collar around the base of the flagellum). The flagella generate a water current, and the collars trap food particles that the choanocytes then ingest by phagocytosis. The similarity between choanocytes and the cells of choanoflagellates supports the molecular evidence suggesting that animals evolved from a choanoflagellate-like ancestor (see Chapter 32).

The body of a sponge consists of two layers of cells separated by a gelatinous region, the **mesohyl**. Wandering through the mesohyl are cells called **amoebocytes**, named for their use of pseudopodia. Amoebocytes have many functions. They take up food from the water and from choanocytes, digest it, and carry nutrients to other cells. They also manufacture tough skeletal fibers within the mesohyl. In some groups of sponges, these fibers are sharp spicules made from calcium carbonate or silica; other sponges produce more flexible fibers composed of a collagen protein called spongin. (These pliant skeletons are used as bath sponges.)

Most sponges are **hermaphrodites** (named for the Greek god Hermes and goddess Aphrodite), meaning that each individual functions as both male and female in sexual reproduction by producing sperm and eggs. Almost all sponges exhibit sequential hermaphroditism, functioning first as one sex and then as the other.

Gametes arise from choanocytes or amoebocytes. Eggs reside in the mesohyl, but sperm are carried out of the sponge by the water current. Cross-fertilization results from some of the sperm

A Figure 33.4 Anatomy of a sponge.

being drawn into neighboring individuals. Fertilization occurs in the mesohyl, where the zygotes develop into flagellated, swimming larvae that disperse from the parent sponge. Upon settling on a suitable substrate, a larva develops into the sessile adult.

Sponges produce a variety of antibiotics and other defensive compounds. Researchers are now isolating these compounds, which hold promise for fighting human diseases. For example, Robert Pettit and his colleagues at Arizona State University have found a compound called cibrostatin in marine sponges that can kill penicillin-resistant strains of the bacterium *Streptococcus*. The team is studying other sponge-derived compounds as anti-cancer agents.

Concept Check 33.1

1. Describe how sponges feed.
2. Explain how changes in water currents can affect sponge reproduction.

For suggested answers, see Appendix A.

Concept 33.2

Cnidarians have radial symmetry, a gastrovascular cavity, and cnidocytes

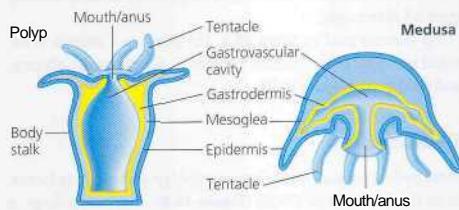

All animals except sponges belong to the clade Eumetazoa, the animals with true tissues (see Chapter 32). One of the oldest animal groups in this clade is the phylum Cnidaria. Cnidarians have diversified into a wide range of both sessile and floating forms, including jellies (commonly called "jellyfish"), corals, and hydras. Yet cnidarians continue to exhibit a relatively simple, diploblastic, radial body plan that existed some 570 million years ago.

The basic body plan of a cnidarian is a sac with a central digestive compartment, the gastrovascular cavity. A single opening to this cavity functions as both mouth and anus. There are two variations on this body plan: the sessile polyp and the floating medusa (Figure 33.5). Polyps are cylindrical forms that adhere to the substrate by the aboral end of the body (the end opposite the mouth) and extend their

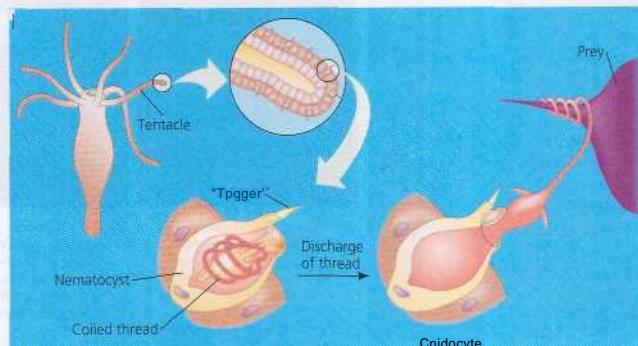

tentacles, waiting for prey. Examples of the polyp form include hydras and sea

anemones. A medusa is a flattened, mouth-down version of the polyp. It moves freely in the water by a combination of passive drifting and contractions of its bell-shaped body. Medusae include free-swimming jellies. The tentacles of a jelly dangle from the oral surface, which points downward. Some cnidarians exist only as polyps or only as medusae; others have both a medusa stage and a polyp stage in their life cycle.

Cnidarians are carnivores that use tentacles arranged in a ring around their mouth to capture prey and to push the food into their gastrovascular cavity, where digestion begins. The undigested remains are egested through the mouth/anus. The tentacles are armed with batteries of cnidocytes, unique cells that function in defense and the capture of prey (Figure 33.6).

A. Figure 33.5 Polyp and medusa forms of cnidarians. The body wall of a cnidarian has two layers of cells: an outer layer of epidermis (from ectoderm) and an inner layer of gastrodermis (from endoderm). Digestion begins in the gastrovascular cavity and is completed inside food vacuoles in the gastrodermal cells. Flagella on the gastrodermal cells keep the contents of the gastrovascular cavity agitated and help distribute nutrients. Sandwiched between the epidermis and gastrodermis is a gelatinous layer, the mesoglea.

& Figure 33.6 A cnidocyte of a hydra. This type of cnidocyte contains a stinging capsule, the nematocyst, which itself contains an inverted thread. When a "trigger" is stimulated by touch or by certain chemicals, the thread shoots out, puncturing and injecting poison into prey.

Cnidocytes contain cnidae (from the Greek *cnide*, nettle), capsule-like organelles that are capable of evertting and that give phylum Cnidaria its name. Cnidae called nematocysts are stinging capsules. Other cnidae have very long threads that stick to or entangle small prey that bump into the tentacles.

Contractile tissues and nerves occur in their simplest forms in cnidarians. Cells of the epidermis (outer layer) and gastrodennins (inner layer) have bundles of microfilamenis arranged into contractile fibers (see Chapter 6). The gastrovascular cavity acts as a hydrostatic skeleton against which the contractile cells can work. When a cnidian closes its mouth, the volume of the cavity is fixed, and contraction of selected cells causes the animal to change shape. Movements are coordinated by a nerve net. Cnidarians have no brain, and the noncentralized nerve net is associated with simple sensory structures that are distributed radially around the body. Thus, the animal can detect and respond to stimuli equally from all directions.

As summarized in **Table 33.1**, the phylum Cnidaria is divided into four major classes: Hydrozoa, Scyphozoa, Cubozoa, and Anthozoa (**Figure 33.7**).

Hydrozoans

Most hydrozoans alternate between polyp and medusa forms, as in the life cycle of *Obelia* (**Figure 33.8**). The polyp stage, a colony of interconnected polyps in the case of *Obelia*, is more conspicuous than the medusae. Hydras, among the few cnidarians found in fresh water, are unusual hydrozoans in that they exist only in the polyp form. When environmental conditions are favorable, a hydra reproduces asexually by

budding, the formation of outgrowths that pinch off from the parent and live independently (see Figure 13.2). When environmental conditions deteriorate, hydras can reproduce sexually, forming resistant zygotes that remain dormant until the conditions improve.

Scyphozoa

The medusa generally is the predominant stage in the life cycle of the class Scyphozoa. The medusae of most species live among the plankton as jellies. Most coastal scyphozoans go through a small polyp stage during their life cycle, whereas those that live in the open ocean generally lack the polyp stage completely.

Table 33.1 Classes of Phylum Cnidaria

| Class and Examples | Main Characteristics |
|---|---|
| Hydrozoa (Portuguese man-of-war, hydras, <i>Obelia</i> , some corals; see Figures 33.7a and 33.8) | Most marine, a few freshwater; both polyp and medusa stages in most species; polyp stage often colonial |
| Scyphozoa (jellies, sea nettles; see Figure 33.7b) | All marine; polyp stage reduced; free-swimming; medusae up to 2 m in diameter |
| Cubozoa (box jellies, sea wasps; see Figure 33.7c) | All marine; box-shaped medusae; complex eyes |
| Anthozoa (sea anemones, most corals, sea fans; see Figure 33.7d) | All marine; medusa stage completely absent; most sessile; many colonial |

(a) These colonial polyps are members of class Hydrozoa.

(b) Many species of jellies (class Scyphozoa), including the species pictured here, are bioluminescent. The largest scyphozoans have tentacles more than 100 m long dangling from a bell-shaped body up to 2 m in diameter.

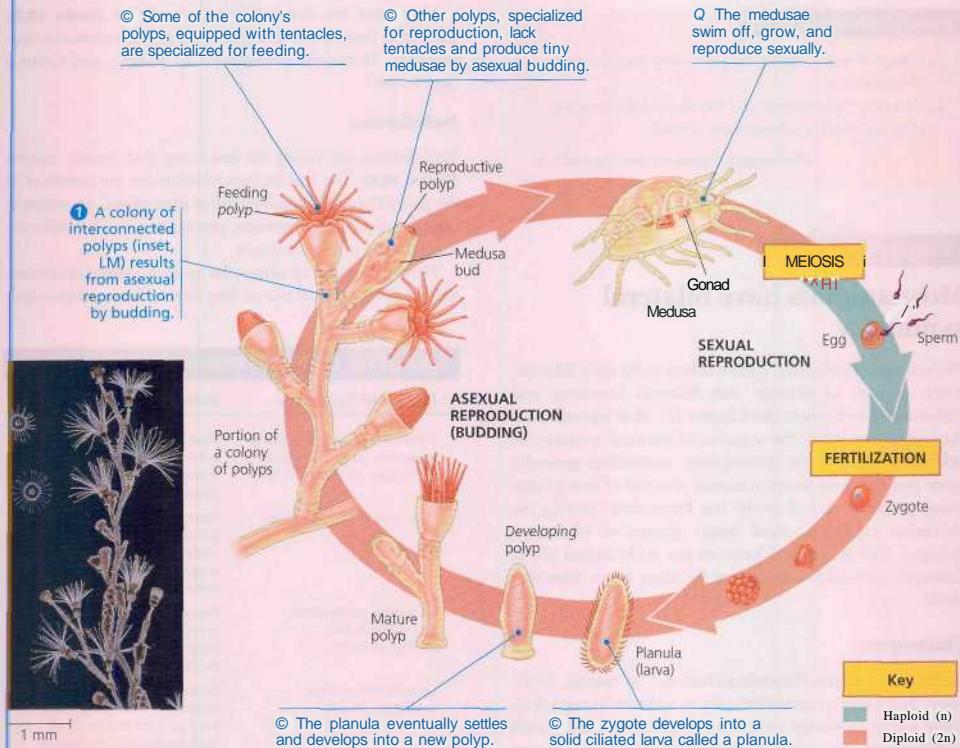

(c) The sea wasp (*Chironex fleckeri*) is a member of class Cubozoa. Its poison, which can subdue fish and other large prey, is more potent than cobra venom.

(d) Sea anemones and other members of class Anthozoa exist only as polyps.

A Figure 33.7 Cnidarians.

▲ **Figure 33.8** The life cycle of the hydrozoan *Obelia*. The polyp stage is asexual, and the medusa stage is sexual; these two stages alternate, one producing the other. Do not confuse this with the alternation of generations that occurs in plants and some algae. Both the polyp and the medusa are diploid organisms. (Typical of animals, only the gametes of *Obelia* are haploid.) By contrast, one plant generation is haploid, and the other is diploid.

Cubozoans

As their name (which means "cube animals") suggests, cubozoans have a box-shaped medusa stage. They can be distinguished from scyphozoans in other significant ways, such as having complex eyes embedded in the fringe of their medusae. Cubozoans, which generally live in tropical oceans, are often equipped with highly toxic cnidocytes. The sea wasp (*Chironex fleckeri*), a cubozoan that lives off the coast of northern Australia, is one of the deadliest organisms on Earth: Its sting causes intense pain and can lead to respiratory failure, cardiac arrest, and death within minutes. The amount of poison in one sea wasp is enough to kill 60 people. The poison of sea wasps isn't universally fatal however; sea turtles have defenses against it, allowing them to eat the cubozoan in great quantities.

Anthozoans

Sea anemones and corals belong to the class Anthozoa ("flower animals"). They occur only as polyps. Corals live as solitary or colonial forms and secrete a hard external skeleton of calcium carbonate. Each polyp generation builds on the skeletal remains of earlier generations, constructing "rocks" with shapes characteristic of their species. It is these skeletons that we call coral.

Coral reefs are to tropical seas what rain forests are to tropical land: They provide habitat for a wealth of other species. Unfortunately, like rain forests, coral reefs are being destroyed at an alarming rate by human activity. Pollution and overfishing are major threats, and global warming may also be contributing to their demise. We'll examine this problem in more detail in Chapter 54.

Concept Check 33.2

1. Compare and contrast the polyp and medusa forms of cnidarians.
2. Describe the structure and function of the stinging cells for which cnidarians are named.

For suggested answers, see Appendix A.

Concept 33.3

Most animals have bilateral symmetry

The vast majority of animal species belong to the clade Bilateria, which consists of animals with bilateral symmetry and triploblastic development (see Chapter 32). Most bilaterians are also coelomates. While the sequence of bilaterian evolution is still a subject of active investigation, researchers generally agree that the most recent common ancestor of living bilaterians probably existed in the late Proterozoic. During the Cambrian explosion, most major groups of bilaterians emerged. This section will focus on just six bilaterian phyla; Concepts 33.4–33.8 will explore six other major bilaterian phyla.

Flatworms

Flatworms (phylum Platyhelminthes) live in marine, freshwater, and damp terrestrial habitats. In addition to many free-living forms, flatworms include many parasitic species, such as flukes and tapeworms. Flatworms are so named because their bodies are thin between the dorsal and ventral surfaces (flattened dorsoventrally; *platyhelminth* means "flat worm"). The smallest are nearly microscopic free-living species, while some tapeworms can be over 20 m long. (Note that *worm* is not a formal taxonomic name but a general term for animals with long, thin bodies.)

Although flatworms undergo triploblastic development, they are acelomates (animals that lack a body cavity). Their flat shape places all cells close to the surrounding water, enabling gas exchange and the elimination of nitrogenous waste (ammonia) to occur by diffusion across the body surface. Flatworms have no organs specialized for gas exchange or circulation, and their relatively simple excretory apparatus functions mainly to maintain osmotic balance with their surroundings. This apparatus consists of ciliated cells called flame bulbs that waft fluid through branched ducts opening to the outside (see Figure 44.10). Most flatworms have a gastrovascular cavity with only one opening. The fine branches of the gastrovascular cavity distribute food throughout the animal.

Flatworms are divided into four classes (Table 33.2): Turbellaria (mostly free-living flatworms), Monogenea (monogeneans), Trematoda (trematodes, or flukes), and Cestoda (tapeworms).

Turbellarians

Turbellarians are nearly all free-living and mostly marine (Figure 33.9). The best-known turbellarians are members of the genus *Dugesia*, commonly called planarians. Abundant in unpolluted ponds and streams, planarians prey on smaller animals or feed on dead animals.

Planarians move by using cilia on their ventral epidermis gliding along a film of mucus they secrete. Some other turbel-

Table 33.2 Classes of Phylum Platyhelminthes

| Class and Examples | Main Characteristics |
|---|--|
| Turbellaria (mostly free-living flatworms, such as <i>Dugesia</i> ; see Figures 33.9 and 33.10) | Most marine, some freshwater, a few terrestrial; predators and scavengers; body surface ciliated |
| Monogenea (monogeneans) | Marine and freshwater parasites; most infect external surfaces of fishes; life history simple; ciliated larva starts infection on host |
| Trematoda (trematodes; also called flukes; see Figure 33.11) | Parasites, almost always of vertebrates; two suckers attach to host; most life cycles include intermediate hosts |
| Cestoda (tapeworms; see Figure 33.12) | Parasites of vertebrates; scolex attaches to host; proglottids produce eggs and break off after fertilization; no head or digestive system; life cycle with one or more intermediate hosts |

A Figure 33.9 A marine flatworm (class Turbellaria).

Planarians also use their muscles to swim through water with an undulating motion.

A planarian's head is equipped with a pair of light-sensitive eyespots and lateral flaps that function mainly to detect specific chemicals. The planarian nervous system is more complex and centralized than the nerve nets of cnidarians (Figure 33.10). Planarians can learn to modify their responses to stimuli.

Planarians can reproduce asexually through regeneration, the parent constricts in the middle, and each half regenerates its missing end. Sexual reproduction also occurs. Although planarians are hermaphrodites, copulating mates cross-fertilize.

Monogeneans and Trematodes

Monogeneans and trematodes live as parasites in or on other animals. Many have suckers for attaching to internal organs or to the outer surfaces of the host. A tough covering helps protect the parasites within their hosts. Reproductive organs occupy nearly the entire interior of these worms.

As a group, trematodes parasitize a wide range of hosts, and most species have complex life cycles with alternating sexual and asexual stages. Many trematodes require an intermediate host in which larvae develop before infecting the final host (usually a vertebrate), where the adult worms live. For example, trematodes that parasitize humans spend part of their lives in snail hosts (Figure 33.11).

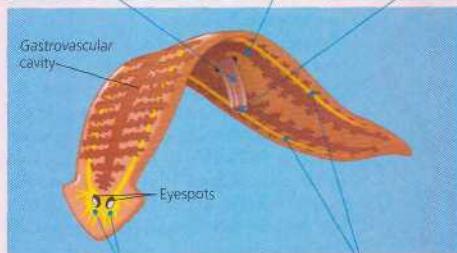

The 200 million people around the world who are infected with blood flukes (*Schistosoma*) suffer from schistosomiasis, a disease whose symptoms include pain, anemia, and dysentery.

Living within different hosts puts demands on trematodes that free-living animals don't face. A blood fluke, for instance, must evade the immune systems of both snails and humans. By mimicking the surface proteins of its hosts, the blood fluke creates a partial immunological camouflage for itself. It also releases molecules that manipulate the hosts' immune systems into tolerating the parasite's existence. These defenses are so effective that individual flukes can survive in humans for more than 40 years.

Most monogeneans are external parasites of fish. The monogenean life cycle is relatively simple, with a ciliated, free-swimming larva initiating the infection on a host. Although monogeneans have been traditionally aligned with the trematodes, some structural and chemical evidence suggests they are more closely related to ciliates.

Pharynx. The mouth is at the tip of a muscular pharynx that extends from the animal's ventral side. Digestive juices are spilled onto prey, and the pharynx sucks small pieces of food into the gastrovascular cavity, where digestion continues.

Undigested wastes are egested through the mouth.

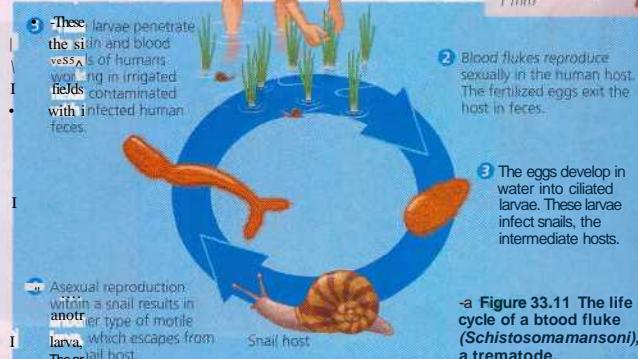

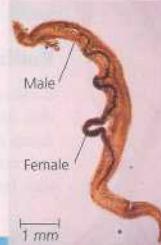

Ganglia. Located at the anterior end of the worm, near the main sources of sensory input, is a pair of ganglia, dense clusters of nerve cells.

Ventral nerve cords. From the ganglia, a pair of ventral nerve cords runs the length of the body.

A Figure 33.10 Anatomy of a planarian, a turbellarian.

- 1 Mature flukes live in the blood vessels of the human intestine. A female fluke fits into a groove running the length of the larger male's body, as shown in the light micrograph at right.

A Figure 33.11 The life cycle of a blood fluke (*Schistosoma mansoni*), a trematode.

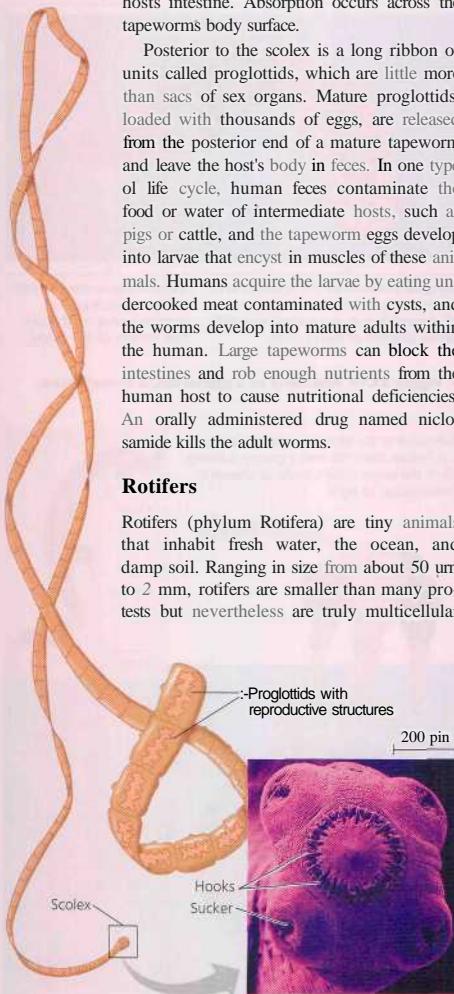

Tapeworms

Tapeworms (class Cestoidea) are also parasitic (Figure 33.12). The adults live mostly inside vertebrates, including humans. In many tapeworms, the anterior end, or scolex, is armed with suckers and often hooks that lock the worm to the intestinal lining of the host. Tapeworms lack a gastrovascular cavity; they absorb nutrients released by digestion in the host's intestine. Absorption occurs across the tapeworms body surface.

Posterior to the scolex is a long ribbon of units called proglottids, which are little more than sacs of sex organs. Mature proglottids, loaded with thousands of eggs, are released from the posterior end of a mature tapeworm and leave the host's body in feces. In one type of life cycle, human feces contaminate the food or water of intermediate hosts, such as pigs or cattle, and the tapeworm eggs develop into larvae that encyst in muscles of these animals. Humans acquire the larvae by eating undercooked meat contaminated with cysts, and the worms develop into mature adults within the human. Large tapeworms can block the intestines and rob enough nutrients from the human host to cause nutritional deficiencies. An orally administered drug named niclosamide kills the adult worms.

Rotifers

Rotifers (phylum Rotifera) are tiny animals that inhabit fresh water, the ocean, and damp soil. Ranging in size from about 50 μm to 2 mm, rotifers are smaller than many protists but nevertheless are truly multicellular

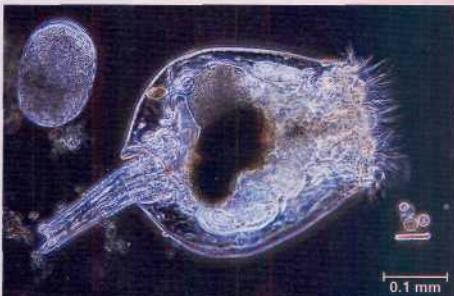

A **Figure 33.12 Anatomy of a tapeworm.** The inset shows a closeup of the scolex (colorized SEM).

and have specialized organ systems (Figure 33.13). In contrast to cnidarians and flatworms, which have a gastrovascular cavity, rotifers have an alimentary canal, a digestive tube with a separate mouth and anus. Internal organs lie within the pseudocoelom, a body cavity that is not completely lined by mesoderm (see Figure 32.8b). Fluid in the pseudocoelom serves as a hydrostatic skeleton (see Chapter 49). Movement of a rotifer's body distributes the fluid throughout the body, circulating nutrients and wastes in these tiny animals.

The word *rotifer* derived from Latin, means "wheel-bearer," a reference to the crown of cilia that draws a vortex of water into the mouth. Posterior to the mouth, a region of the digestive tract called the pharynx bears jaws (trophonts) that grind up food, mostly microorganisms suspended in the water.

Rotifers undergo unusual forms of reproduction. Some species consist only of females that produce more female; from unfertilized eggs, a type of reproduction called parthenogenesis. Other species produce two types of eggs that develop by parthenogenesis, one type forming females and the other type developing into simplified males that cannot even feed themselves. These males survive long enough to produce sperm that fertilize eggs, which form resistant zygotes that can survive when a pond dries up. When conditions are favorable, the zygotes break dormancy and develop into a new female generation that reproduces by parthenogenesis until conditions become unfavorable again.

It is puzzling that so many rotifer species survive without males. The vast majority of animals and plants reproduce sexually at least some of the time, and sexual reproduction has certain advantages over asexual reproduction. For example, species that reproduce asexually tend to accumulate harmful mutations in their genomes faster than sexually reproducing species. As a result, asexual species should experience higher rates of extinction and lower rates of speciation.

A **Figure 33.13 A rotifer.** These pseudocoelomates, smaller than many protists, are generally more anatomically complex than flatworms (LM).

Nobel prize-winning biologist Matthew Meselson, of Harvard University, has been studying a class of asexual rotifers called Bdelloidea. Some 360 species of bdelloid rotifers are known, and all of them reproduce by parthenogenesis without males. Paleontologists have discovered bdelloid rotifers preserved in 35-million-year-old amber, and the morphology of these fossils resembles only the female form, with no evidence of males. By comparing the DNA of bdelloids with that of their best sexually reproducing rotifer relatives, Meselson and his colleagues concluded that bdelloids have likely been asexual for much longer than 35 million years. How these animals manage to flout the general rule against long-lived asexuality is a puzzle.

Lophophorates: Ectoprocts, Phoronids, and Brachiopods

Bilaterians in three phyla—Ectoprocta, Phoronida, and Brachiopoda—are traditionally called lophophorates because they all have a lophophore, a horseshoe-shaped or circular crown of ciliated tentacles that surround the mouth (see Figure 32.13a). As the cilia draw water toward the mouth, the tentacles trap suspended food particles. The common occurrence of this complex apparatus in lophophorates suggests that these three phyla are related, either similarities, such as a U-shaped alimentary canal and the absence of a distinct head, are adaptations to a sessile existence. In contrast to flatworms, which lack a body cavity, and rotifers, which have a pseudocoelom, lophophorates have a true coelom completely lined by endoderm (see Figure 32.8a).

Ectoprocts (from the Greek *ecto*, outside, and *procta*, anus) are colonial animals that superficially resemble plants, (their common name, bryozoans, means "moss animals.") In most species, the colony is encased in a hard exoskeleton with pores through which the lophophores extend (Figure 33.14a). Most ectoproct species live in the sea, where they are among the most widespread and numerous sessile animals. Several species are important reef builders. Ectoprocts also live in lakes and rivers. Colonies of the freshwater ectoproct *Pectinatella magnifica* form on submerged sticks or rocks and can grow into a gelatinous, ball-shaped mass more than 10 cm across.

Phoronids are tube-dwelling marine worms ranging from 1 mm to 50 cm in

length. Some species live buried in the sand within tubes made of chitin, extending their lophophore from the opening of the tube and withdrawing it into the tube when threatened (Figure 33.14b).

Brachiopods, or lamp shells, superficially resemble clams and other hinge-shelled molluscs, but the two halves of the brachiopod shell are dorsal and ventral rather than lateral, as in clams (Figure 33.14c). All brachiopods are marine. Most live attached to the seafloor by a stalk, opening their shell slightly to allow water to flow over the lophophore. The living brachiopods are remnants of a much richer past that included 30,000 Paleozoic and Mesozoic species. *Lingula*, a living brachiopod genus, is nearly identical to brachiopods that lived 400 million years ago.

Nemerteans

Members of the phylum Nemertea are commonly called proboscis worms or ribbon worms (Figure 33.15). A nemertean

(a) Ectoprocts, such as this sea mat (*Membranipora membranacea*), are colonial lophophorates.
(b) In phoronids such as *Phoronis hippocrepia*, the lophophore and mouth are at one end of an elongated trunk.
(c) Brachiopods have a hinged shell. The two parts of the shell are dorsal and ventral.

A Figure 33.14 Lophophorates.

M Figure 33.15 A ribbon worm, phylum Nemertea.

body is structurally acelomate, like that of a flatworm, but it contains a small, fluid-filled sac that may be a reduced version of a coelom. The sac and fluid hydraulically operate an extensible proboscis, which rapidly shoots out of the worm's body, in many cases delivering a toxin to its prey.

Nemerteans range in length from less than 1 mm to several meters. Nearly all members of this phylum are marine, but a few species inhabit fresh water or damp soil. Some are active swimmers; others burrow in the sand.

Nemerteans and flatworms have similar excretory, sensory, and nervous systems. But in addition to the unique proboscis apparatus, two anatomical features not found in flatworms have evolved in the phylum Nemertea: an alimentary canal and a closed circulatory system, in which the blood is contained in vessels and is therefore distinct from fluid in the body cavity. Nemerteans have no heart; their blood is propelled by muscles squeezing the vessels.

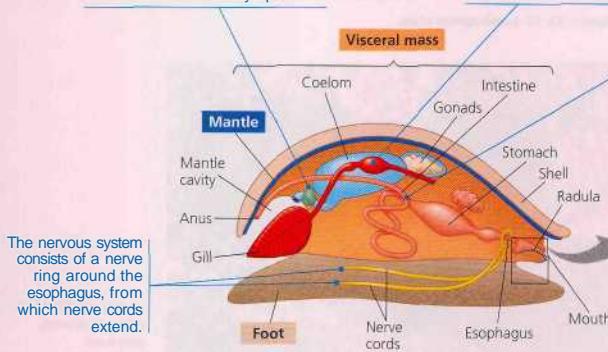

Concept Check 33.3

1. Explain how tapeworms can survive without a coelom, a mouth, a digestive system, or an excretory system.
2. Is the presence or absence of an alimentary canal related to the size of an animal? Support your answer with two examples.
3. Explain how, in terms of function, ectoprocts have more in common with nonbilaterian corals than with their closer bilaterian relatives.

For suggested answers, see Appendix A.

Nephridium. Excretory organs called nephridia remove metabolic wastes from the hemolymph.

650 UNIT FIVE The Evolutionary History of Biological Diversity

Concept 33.4

Molluscs have a muscular foot, a visceral mass, and a mantle

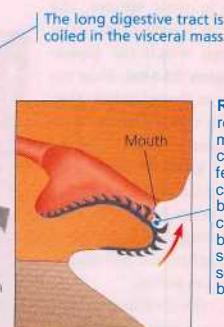

Snails and slugs, oysters and clams, and octopuses and squids are all molluscs (phylum Mollusca). Most molluscs are marine, though some inhabit fresh water, and there are snails and slugs that live on land. Molluscs are soft-bodied animals (from the Latin *molluscus*, soft), but most are protected by a hard shell made of calcium carbonate. Slugs, squids, and octopuses have a reduced internal shell or have lost their shell completely during their evolution.

Despite their apparent differences, all molluscs have a similar body plan (Figure 33.16). The body has three main parts: a muscular **foot**, usually used for movement; a visceral mass containing most of the internal organs; and a mantle, a fold of tissue that drapes over the visceral mass and secretes a shell (if one is present). In many molluscs, the mantle extends beyond the visceral mass, producing a water-filled chamber, the mantle cavity, which houses the gills, anus, and excretory pores. Many molluscs feed by using a straphlike rasping organ called a radula to scrape up food.

Most molluscs have separate sexes, with gonads (ovaries or testes) located in the visceral mass. Many snails, however, are hermaphrodites. The life cycle of many marine molluscs includes a ciliated larval stage, the **trochophore**, which is also characteristic of marine annelids (segmented worms) and some other invertebrates (see Figure 32.13b).

The basic body plan of molluscs has evolved in various ways in the eight classes of the phylum. We examine four of

Heart. Most molluscs have an open circulatory system. The dorsally located heart pumps circulatory fluid called hemolymph through arteries into sinuses (body spaces). The organs of the mollusc are thus continually bathed in hemolymph.

Radula. The mouth region in many mollusc species contains a rasp-like feeding organ called a radula. This belt of backward-curving teeth slides back and forth, scraping and scooping like a backhoe.

those classes here (**Table 33.3**): Polyplacophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams, oysters, and other bivalves), and Cephalopoda (squids, octopuses, cuttlefish, and chambered nautiluses).

Chitons

Chitons have an oval-shaped body and a shell divided into eight dorsal plates (**Figure 33.17**); the body itself, however, is unsegmented. You can find these marine animals clinging to rocks along the shore during low tide. Try to dislodge a chiton by hand, and you will be surprised at how well its foot, acting as a suction cup, grips the rock. A chiton can also use its foot

to creep slowly over the rock surface. Chitons use their radula to cut and ingest algae.

Gastropods

About three-quarters of all living species of molluscs are gastropods (**Figure 33.18**). Most gastropods are marine, but there are also many freshwater species; garden snails and slugs are among the gastropods that have adapted to land.

The most distinctive characteristic of the class Gastropoda is a developmental process known as torsion. As a gastropod embryo develops, its visceral mass rotates up to 180°, causing the animal's anus and mantle cavity to wind up above its head (**Figure 33.19**). After torsion, some of the organs that were bilateral are reduced in size or are lost on one side of the body. Torsion should not be confused with the formation of a coiled shell, which is an independent developmental process.

Most gastropods have a single, spiraled shell into which the animal can retreat when threatened. The shell is often conical but is somewhat flattened in abalones and limpets. Many gastropods have a distinct head with eyes at the tips of tentacles. Gastropods move literally at a snail's pace by a rippling motion of their foot or by means of cilia. Most gastropods use their

Table 33.3 Major Classes of Phylum Mollusca

| Class and Examples | Main Characteristics |
|---|--|
| Polyplacophora (chitons; see Figure 33.17) | Marine; shell with eight plates; foot used for locomotion; radula; no head |
| Gastropoda (snails, slugs; see Figures 33.18 and 33.19) | Marine, freshwater, or terrestrial; asymmetrical body, usually with a coiled shell; shell reduced or absent in some; foot for locomotion; radula |
| Bivalvia (clams, mussels, scallops, oysters; see Figures 33.20 and 33.21) | Marine and freshwater; flattened shell with two valves; head reduced; paired gills; no radula; most are suspension feeders; mantle forms siphons |
| Cephalopoda (squids, octopuses, cuttlefish, chambered nautiluses; see Figure 33.22) | Marine; head surrounded by grasping tentacles, usually with suckers; shell external, internal, or absent; mouth with or without radula; locomotion by jet propulsion using siphon made from foot |

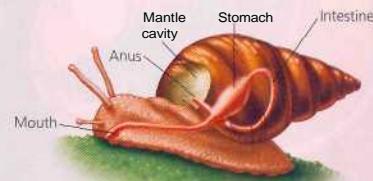

A Figure 33.17 A chiton. Clinging tenaciously to rocks in the intertidal zone, this chiton displays the eight-plate shell characteristic of molluscs in the class Polyplacophora.

(a) A land snail

(b) A sea slug. Nudibranchs, or sea slugs, lost their shell during their evolution.

• Figure 33.19 The results of torsion in a gastropod.

Because of torsion (twisting of the visceral mass) during embryonic development, the digestive tract is coiled and the anus is near the anterior end of the animal.

radula to graze on algae or plants. Several groups, however, are predators, and their radula has become modified for boring holes in the shells of other molluscs or for tearing apart prey. In the cone snails, the teeth of the radula form poison darts that are used to subdue prey.

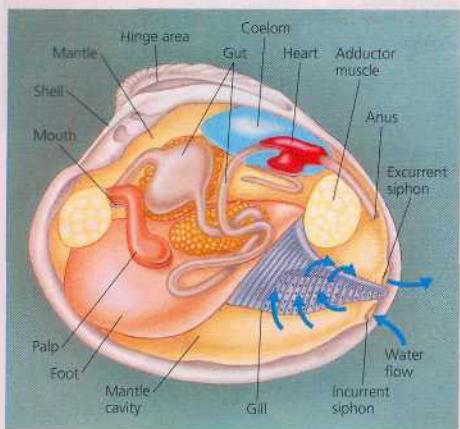

Terrestrial snails lack the gills typical of most aquatic gastropods; instead, the lining of the mantle cavity functions as a lung, exchanging respiratory gases with the air.

Bivalves

The molluscs of class Bivalvia include many species of clams, oysters, mussels, and scallops. Bivalves have a shell divided into two halves (Figure 33.20). The halves are hinged at the mid-

A Figure 33.20 A bivalve. This scallop has many eyes (dark blue spots) peering out from each half of its hinged shell.

A Figure 33.21 Anatomy of a clam. The left half of the clam's shell has been removed. Food particles suspended in water that enters through the incurrent siphon are collected by the gills and passed via cilia and elongated flaps called palps to the mouth.

dorsal line, and powerful adductor muscles draw them tightly together to protect the soft-bodied animal. Bivalves have no distinct head, and the radula has been lost. Some bivalves have eyes and sensory tentacles along the outer edge of their mantle.

The mantle cavity of a bivalve contains gills that are used for feeding as well as gas exchange (Figure 33.21). Most bivalves are suspension feeders. They trap fine food particles in mucus that coats their gills, and cilia then convey the particles to their mouth. Water enters the mantle cavity through an incurrent siphon, passes over the gills, and then exits the mantle cavity through an excurrent siphon.

Most bivalves lead rather sedentary lives, a characteristic suited to suspension feeding. Sessile mussels secrete strong threads that tether them to rocks, docks, boats, and the shells of other animals. However, clams can pull themselves into the sand or mud, using their muscular foot for an anchor, and scallops can skitter along the seafloor by flapping their shell?, rather like the mechanical false teeth sold in novelty shops.

Cephalopods

Cephalopods are active predators. They use their tentacles to grasp prey and their beak-like jaws to inject an immobilizing poison. The foot of a cephalopod has become modified in; to a muscular excurrent siphon and parts of the tentacle and head. (*Cephalopod* means "head foot.") Most octopuses, creep along the seafloor in search of crabs and other foot (Figure 33.22a). Squids dart about by drawing water into the mantle cavity and then firing a jet of water through the excurrent siphon (Figure 33.22b). They steer by pointing the siphon in different directions.

A mantle covers the visceral mass of cephalopods, but the shell is reduced and internal (in squids and cuttlefish) or missing altogether (in many octopuses). One small group of shelled cephalopods, the chambered nautiluses, survive today (Figure 33.22c).

Cephalopods are the only molluscs with a closed circulatory system. They also have well-developed sense organs and a complex brain. The ability to learn and behave in a complex manner is probably more critical to fast-moving predators than to sedentary animals such as clams.

The ancestors of octopuses and squids were probably shelled molluscs that took up a predatory lifestyle; the shell was lost in later evolution. Shelled cephalopods called ammonites, some of them as large as truck tires, were the dominant invertebrate predators of the seas for hundreds of millions of years until their disappearance during the mass extinctions at the end of the Cretaceous period (see Chapter 26).

Most species of squid are less than 75 cm long, but some are considerably larger. The giant squid (*Architeuthis dux*) was for a long time the largest squid known, with a mantle up to 2.25 m long and a total length of 18 m. In 2003, however, a specimen of the rare species *Mesonychoteuthis hamiltoni* with a mantle length of 2.5 m was caught near Antarctica. Some bi-

(j) Octopuses are considered among the most intelligent invertebrates.

(b) Squids are speedy carnivores with beaklike jaws and well-developed eyes.

(c) Chambered nautiluses are the only living cephalopods with an external shell.

Figure 33.22 Cephalopods.

ologists think this specimen was a juvenile and estimate that adults of its species could be twice as large! Unlike *A. dux*, which has large suckers and small teeth on its tentacles, *M. hamiltoni* has rotating bars at the ends of its tentacles that can deliver deadly lacerations.

It is likely that *A. dux* and *M. hamiltoni* spend most of their time in the deep ocean, where they may feed on large fishes, remains of both species have been found in the stomachs of sperm whales, which are probably their only natural predator; scientists have never observed either squid species in its natural habitat. As a result, these marine giants remain among the great mysteries of invertebrate life.

Concept Check 33.4

- Explain how the modification of the molluscan foot in gastropods and cephalopods relates to their respective lifestyles.
- How have bivalves diverged from the basic molluscan body plan?

For suggested answers, see Appendix A.

33.5 Concept

Annelids are segmented worms

Annelida means "little rings," referring to the annelid body's resemblance to a series of fused rings. Annelids live in the sea, most freshwater habitats, and damp soil. They range in length

from less than 1 mm to 3 m, the length of a giant Australian earthworm. The phylum Annelida is divided into three classes (**Table 33.4**): Oligochaeta (earthworms and their relatives), Polychaeta (polychaetes), and Hirudinea (leeches).

Oligochaetes

Oligochaetes (from the Greek *oligos*, few, and *chaite*, long hair) are named for their relatively sparse chaetae, or bristles made of chitin. This class of segmented worms includes the earthworms and a variety of aquatic species. Earthworms eat their way through the soil, extracting nutrients as the soil passes through the alimentary canal. Undigested material, mixed with mucus secreted into the canal, is egested as castings through the anus. Farmers value earthworms because

Table 33.4 Classes of Phylum Annelida

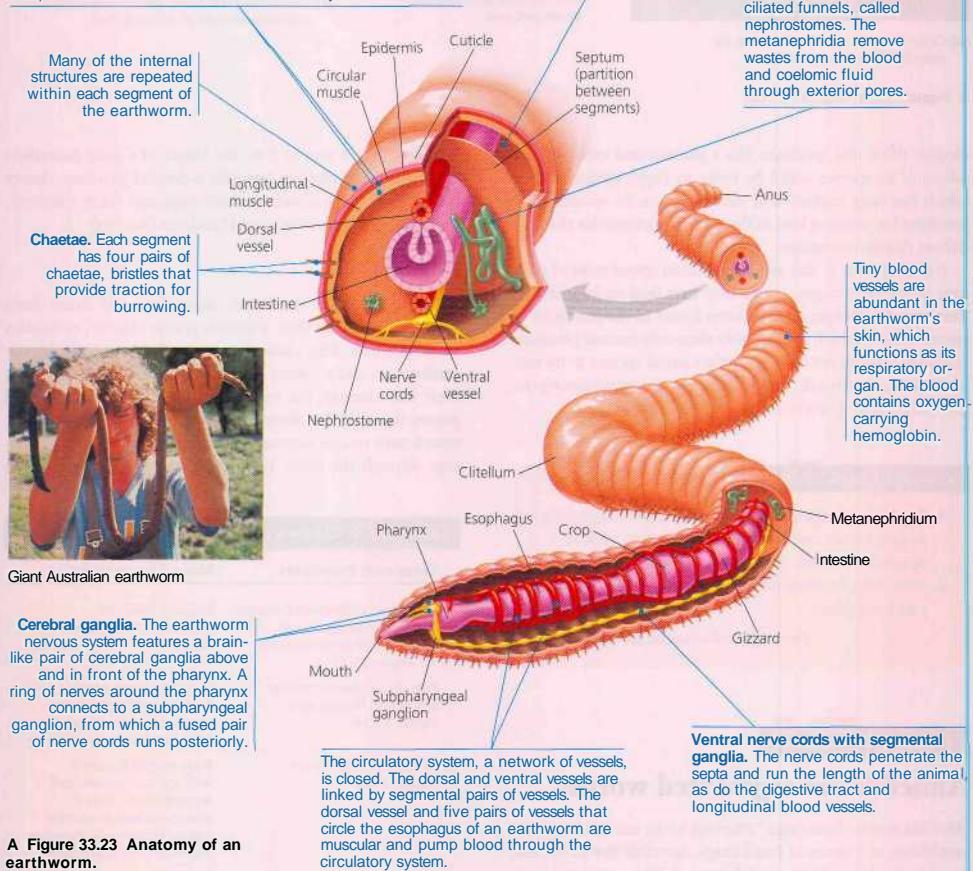

| Class and Examples | Main Characteristics |
|---|--|
| Oligochaeta (freshwater, marine, and terrestrial segmented worms, such as earthworms; see Figure 33.23) | Reduced head; no parapodia, but chaetae present |
| Polychaeta (mostly marine segmented worms; see Figure 33.24) | Well-developed head; each segment usually has parapodia with chaetae; tube-dwelling and free-living |
| Hirudinea (leeches; see Figure 33.25) | Body usually flattened, with reduced coelom and segmentation; chaetae absent; suckers at anterior and posterior ends; parasites, predators, and scavengers |

the animals till the earth, and their castings improve the texture of the soil. (Darwin estimated that 1 acre of British farmland contained about 50,000 earthworms that produced 18 tons of castings per year.) **Figure 33.23** provides a guided tour of the anatomy of an earthworm, which is representative of annelids.

Earthworms are hermaphrodites, but they cross-fertilize. Two earthworms mate by aligning themselves in such a way

that they exchange sperm, and then they separate. The received sperm are stored temporarily while an organ called the clitellum secretes a mucous cocoon. The cocoon slides along the worm, picking up the eggs and then the stored sperm. The cocoon then slips off the worm's head and remains in the soil while the embryos develop. Some earthworms can also reproduce asexually by fragmentation followed by regeneration.

Each segment is surrounded by longitudinal muscle, which in turn is surrounded by circular muscle. Earthworms coordinate the contraction of these two sets of muscles to move (see Figure 49.25). These muscles work against the non-compressible coelomic fluid, which acts as a hydrostatic skeleton.

A Figure 33.23 Anatomy of an earthworm.

Polychaetes

Each segment of a polychaete has a pair of paddle-like or ridge-like structures called parapodia ("almost feet") that function in locomotion (Figure 33.24). Each parapodium has several chaetae, which are more numerous than those in oligochaetes. In many polychaetes, the parapodia are richly supplied with blood vessels and function as gills.

Polychaetes make up a large and diverse class, most of whose members are marine. A few species drift and swim among the plankton, many crawl on or burrow in the seafloor, and many others live in tubes. Some tube-dwellers, such as tunic worms and feather-duster worms, build their tubes by mixing mucus with bits of sand and broken shells. Others, such as Christmas tree worms (see Figure 33.1), construct tubes using only their own secretions.

◀ **Figure 33.24 A polychaete.** *Hesiolyra bergi* lives on the seafloor around deep-sea hydrothermal vents.

Leeches

The majority of leeches inhabit fresh water, but there are also marine species as well as terrestrial leeches found in moist vegetation. Leeches range in length from about 1 to 30 cm. Many are predators that feed on other invertebrates, but some are parasites that suck blood by attaching temporarily to other animals, including humans (Figure 33.25). Some parasitic species use blade-like jaws to slit the skin of the host, whereas others secrete enzymes that digest a hole through the skin. The host is usually oblivious to this attack because the leech secretes an anesthetic. After making the incision, the leech secretes another chemical, hirudin, which keeps the blood of the host from coagulating near the incision. The parasite then sucks as much blood as it can hold, often more than ten times its own weight. After this gorging, a leech can last for months without another meal.

Until this century, leeches were frequently used for bloodletting. Today they are used to drain blood that accumulates in tissues following certain injuries or surgeries. Researchers are also investigating the potential use of hirudin to dissolve unwanted blood clots that form during surgery or as a result of heart disease. A recombinant form of hirudin has been developed and is in clinical trials.

◀ **Figure 33.25 A leech.** A nurse applied this medicinal leech (*Hirudo medicinalis*) to a patient's sore thumb to drain blood from a hematoma (an abnormal accumulation of blood around an internal injury).

Concept Check 33.5

1. Annelid anatomy can be described as "a tube within a tube." Explain.
2. Explain how an earthworm uses its segmental muscles and coelom in movement.

For suggested answers, see Appendix A.

Concept 33.6

Nematodes are nonsegmented pseudocoelomates covered by a tough cuticle

Among the most widespread of all animals, nematodes, or roundworms, are found in most aquatic habitats, in the soil, in the moist tissues of plants, and in the body fluids and tissues of animals. In contrast to annelids, nematodes do not have a segmented body. The cylindrical bodies of nematodes (phylum Nematoda) range from less than 1 mm to more than a meter in length, often tapering to a fine tip at the posterior end and to a more blunt tip at the anterior end (Figure 33.26). The body is covered by a tough coat called a **cuticle**; as the worm grows, it

• **Figure 33.26 A free-living nematode (colorized SEM).**

periodically sheds its old cuticle and secretes a new, larger one. Nematodes have an alimentary canal, though they lack a circulatory system. Nutrients are transported throughout the body via fluid in the pseudocoelom. The muscles of nematodes are all longitudinal, and their contraction produces a thrashing motion.

Nematode reproduction is usually sexual and involves internal fertilization. In most species, the sexes are separate and females are larger than males. A female may deposit 100,000 or more fertilized eggs per day. The zygotes of most species are resistant cells that can survive harsh conditions.

Great numbers of nematodes live in moist soil and in decomposing organic matter on the bottoms of lakes and oceans. While 25,000 species are known, perhaps 20 times that number actually exist. If nothing but nematodes remained, it has been said, they would still preserve the outline of the planet and many of its features. These extremely numerous free-living worms play an important role in decomposition and nutrient cycling, but little is known about most species. One species of soil nematode, *Caenorhabditis elegans*, is well studied and has become a model research organism in developmental biology (see Chapter 21). Ongoing studies on *C. elegans* are revealing some of the mechanisms involved in aging in humans, among other findings.

Phylum Nematoda includes many important agricultural pests that attack the roots of plants. Other species of nematodes parasitize animals. Humans host at least 50 nematode species, including various pinworms and hookworms. One notorious nematode is *Trichinella spiralis*, the worm that causes trichinosis (Figure 33.27). Humans acquire this nematode by eating undercooked infected pork or other meat with juvenile worms encysted in the muscle tissue. Within the human intestine, the juveniles develop into sexually mature adults. Females burrow into the intestinal muscles and produce

more juveniles, which bore through the body or travel in lymphatic vessels to other organs, including skeletal muscles where they encyst.

Parasitic nematodes have an extraordinary molecular toolkit that enables them to redirect some of the cellular functions of their hosts. Plant-parasitic nematodes inject molecules that induce the development of root cells, which then supply nutrients to the parasites. *Trichinella* invades individual muscle cells and controls the expression of specific muscle genes, which code for proteins that make the cell elastic enough to house the nematode. Additionally, the cell releases signals that attract blood vessels, which then supply the nematode with nutrients. These extraordinary parasites have been dubbed "animals that act like viruses."

Concept Check 33.6

1. Why would it be risky to order pork chops "rare" in a restaurant?
2. How does the nematode body plan differ from that of annelids?

For suggested answers, see Appendix A.

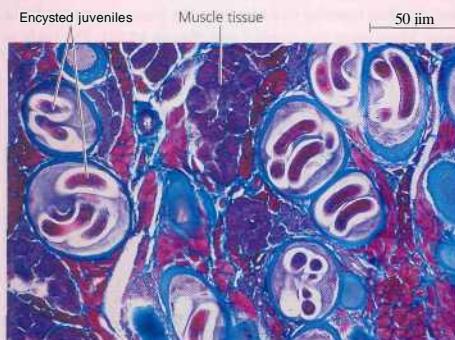

Concept 33.7

Arthropods are segmented coelomates that have an exoskeleton and jointed appendages

Zoologists estimate that the arthropod population of the world, including crustaceans, spiders, and insects, numbers about a billion billion (10^{18}) individuals. More than 1 million arthropod species have been described, most of which are insects. In fact, two out of every three species known are arthropods, and members of the phylum Arthropoda can be found in nearly all habitats of the biosphere. On the criteria of species diversity, distribution, and sheer numbers, arthropods must be regarded as the most successful of all animal phyla.

General Characteristics of Arthropods

The diversity and success of arthropods are largely related to their segmentation, hard exoskeleton, and jointed appendages (arthropod means "jointed feet"). Early arthropods, such as the trilobites, had pronounced segmentation, but their appendages showed little variation from segment to segment (Figure 33.28). As arthropods continued to evolve, the segments tended to fuse and become fewer in number, and the appendages became specialized for a variety of functions.

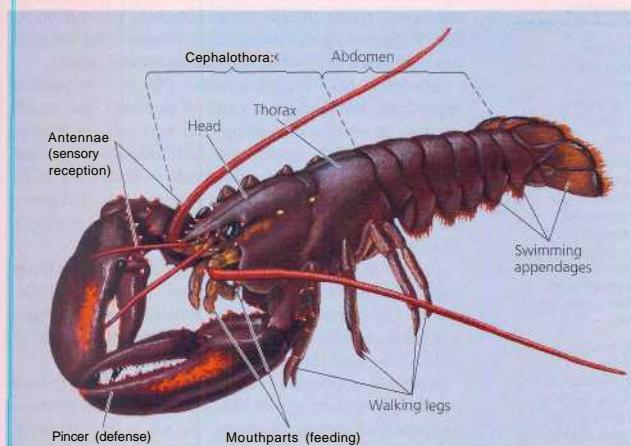

A Figure 33.27 Juveniles of the parasitic nematode *Trichinella spiralis* encysted in human muscle tissue (LM).

These evolutionary changes resulted not only in great diversification but also in an efficient body plan that permits the division of labor among different regions. For example, the various appendages of some living arthropods are modified for walking, feeding, sensory reception, copulation, and defense. **Figure 33.29** illustrates the diverse appendages and other arthropod characteristics of a lobster.

▲ **Figure 33.28 A trilobite fossil.** Trilobites were common denizens of the shallow seas throughout the Paleozoic era but disappeared with the great Permian extinctions about 250 million years ago. Paleontologists have described about 4,000 trilobite species.

▲ **Figure 33.29 External anatomy of an arthropod.** Many of the distinctive features of arthropods are apparent in this dorsal view of a lobster, along with some uniquely crustacean characteristics. The body is segmented, but this characteristic is obvious only in the abdomen. The appendages (including antennae, pincers, mouthparts, walking legs, and swimming appendages) are jointed. The head bears a pair of compound (multilens) eyes, each situated on a movable stalk. The whole body, including appendages, is covered by an exoskeleton.

The body of an arthropod is completely covered by the cuticle, an **exoskeleton** (external skeleton) constructed from layers of protein and the polysaccharide chitin. The cuticle can be thick and hard over some parts of the body and paper-thin and flexible over others, such as the joints. The rigid exoskeleton protects the animal and provides points of attachment for the muscles that move the appendages. But it also means that an arthropod cannot grow without occasionally shedding its exoskeleton and producing a larger one. This process, called **molting** or **ecdysis**, is energetically expensive. A recently molted arthropod is also vulnerable to predation and other dangers until its new, soft exoskeleton hardens.

When the arthropod exoskeleton first evolved in the seas, its main functions were probably protection and anchorage for muscles, but it later additionally enabled certain arthropods to live on land. The exoskeleton's relative impermeability to water helped prevent desiccation, and its strength solved the problem of support when arthropods left the buoyancy of water. Arthropods began to diversify on land following the colonization of land by plants in the early Paleozoic. In 2004, an amateur fossil hunter in Scotland found a 428-million-year-old fossil of a millipede. Fossilized tracks of other terrestrial arthropods date from about 450 million years ago.

Arthropods have well-developed sensory organs, including eyes, olfactory (smell) receptors, and antennae that function in both touch and smell. Most sensory organs are concentrated at the anterior end of the animal.

Like many molluscs, arthropods have an **open circulatory system** in which fluid called hemolymph is propelled by a heart through short arteries and then into spaces called sinuses surrounding the tissues and organs. (The term *blood* is best reserved for fluid in a closed circulatory system.) Hemolymph reenters the arthropod heart through pores that are usually equipped with valves. The body sinuses are collectively called the hemocoel, which is not part of the coelom. In most arthropods, the coelom that forms in the embryo becomes much reduced as development progresses, and the hemocoel becomes the main body cavity in adults. Despite their similarity, the open circulatory systems of molluscs and arthropods probably arose independently.

A variety of organs specialized for gas exchange have evolved in arthropods. These organs allow the diffusion of respiratory gases in spite of the exoskeleton. Most aquatic species have gills with thin, feathery extensions that place an extensive surface area in contact with the

surrounding water. Terrestrial arthropods generally have internal surfaces specialized for gas exchange. Most insects, for instance, have tracheal systems, branched air ducts leading into the interior from pores in the cuticle.

Findings from molecular systematics are leading biologists to develop new hypotheses about arthropod evolutionary relationships, just as they are for other branches of the tree of life. Evidence now suggests that living arthropods consist of four major lineages that diverged early in the evolution of the phylum (**Table 33.5**): cheliceriforms (sea spiders, horseshoe crabs, scorpions, ticks, mites, and spiders); myriapods (centipedes and millipedes); hexapods (insects and their wingless, six-legged relatives); and crustaceans (crabs, lobsters, shrimps, barnacles, and many others).

Cheliceriforms

Cheliceriforms (subphylum Cheliceriformes; from the Greek *cheilos*, lips, and *cheir*, arm) are named for clawlike feeding appendages called chelicerae, which serve as pincers or fangs. Cheliceriforms have an anterior cephalothorax and a posterior abdomen. They lack antennae, and most have simple eyes (eyes with a single lens).

Table 33.5 Subphyla of Phylum Arthropoda

| Subphylum and Examples | Main Characteristics |
|--|--|
| Cheliceriformes (horseshoe crabs, spiders, scorpions, ticks, mites; see Figures 33.30–33.32) | Body having one or two main parts; six pairs of appendages (chelicerae, pedipalps, and four pairs of walking legs); mostly terrestrial or marine |
| Myriapoda (millipedes and centipedes; see Figures 33.33 and 33.34) | Distinct head bearing antennae and chewing mouthparts; terrestrial; millipedes are herbivorous and have two pairs of walking legs per trunk segment; centipedes are carnivorous and have one pair of walking legs per trunk segment and poison claws on first body segment |
| Hexapoda (insects, springtails; see Figures 33.35–33.37) | Body divided into head, thorax, and abdomen; antennae present; mouthparts modified for chewing, sucking, or lapping; three pairs of legs and usually two pairs of wings; mostly terrestrial |
| Crustacea (crabs, lobsters, crayfish, shrimp; see Figures 33.29 and 33.38) | Body of two or three parts; antennae present; chewing mouthparts; three or more pairs of legs; mostly marine and freshwater |

A Figure 33.30 Horseshoe crabs (*Limulus polyphemus*).

Common on the Atlantic and Gulf coasts of the United States, these "living fossils" have changed little in hundreds of millions of years. They have survived from a rich diversity of cheliceriforms that once filled the seas.

The earliest cheliceriforms were eurypterids, or water scorpions. These mainly marine and freshwater predators grew up to 3 m long. Most of the marine cheliceriforms, including all of the eurypterids, are extinct; among the marine species that survive today are the sea spiders (pyenogonids) and the horseshoe crabs (**Figure 33.30**).

The bulk of modern cheliceriforms are arachnids, a group that includes scorpions, spiders, ticks, and mites (**Figure 33.31**). Ticks and many mites are among a large group of parasitic arthropods. Nearly all ticks are bloodsucking parasites on the body surfaces of reptiles or mammals. Parasitic mites live on or in a wide variety of vertebrates, invertebrates, and plants.

Arachnids have a cephalothorax that has six pairs of appendages: the chelicerae, a pair of pedipalps that usually function in sensing or feeding, and four pairs of walking legs (**Figure 33.32**). Spiders use their fang-like chelicerae, which are equipped with poison glands, to attack prey. As the chelicerae masticate (chew) the prey, the spider spills digestive juices onto the torn tissues. The food softens, and the spider sucks up the liquid meal.

In most spiders, gas exchange is carried out by book lungs stacked plates contained in an internal chamber (see Figure 33.32). The extensive surface area of these respiratory organs is a structural adaptation that enhances the exchange of O₂ and CO₂ between the hemolymph and air.

A unique adaptation of many spiders is the ability to catch insects by constructing webs of silk, a liquid protein produced by specialized abdominal glands. The silk is spun by organs called spinnerets into fibers that solidify. Each spider engineers a style of web characteristic of its species and builds it perfectly on the first try. This complex behavior is apparently inherited. Various spiders also use silk in other ways: a dropline for rapid escape, as a cover for eggs, and even a "gift wrap" for food that males offer females during courtship.

(a) Scorpions have pedipalps that are pincers specialized for defense and the capture of food. The tip of the tail bears a poisonous stinger.

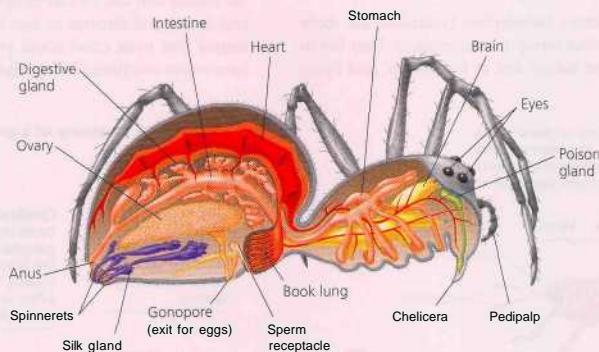

(b) Dust mites are ubiquitous scavengers in human dwellings but are harmless except to those people who are allergic to them (colorized SEM).

(c) Web-building spiders are generally most active during the daytime.

▲ Figure 33.31 Arachnids.

► Figure 33.22 Anatomy of a spider.

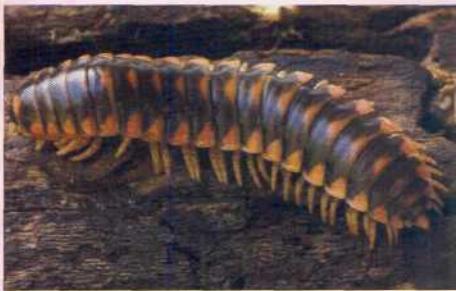

Myriapods

Millipedes and centipedes belong to the subphylum Myriapoda, the myriapods. All living myriapods are terrestrial. Their head has a pair of antennae and three pairs of appendages modified as mouthparts, including the jaw-like mandibles.

Millipedes (class Diplopoda) have a large number of legs, though fewer than the thousand their name implies (Figure 33.33). Each trunk segment is formed from two fused segments and has two pairs of legs. Millipedes eat decaying leaves and other plant matter. They may have been among the earliest animals on land, living on mosses and primitive vascular plants.

Unlike millipedes, centipedes (class Chilopoda) are carnivores. Each segment of a centipede's trunk region has one pair

A Figure 33.33 A millipede.

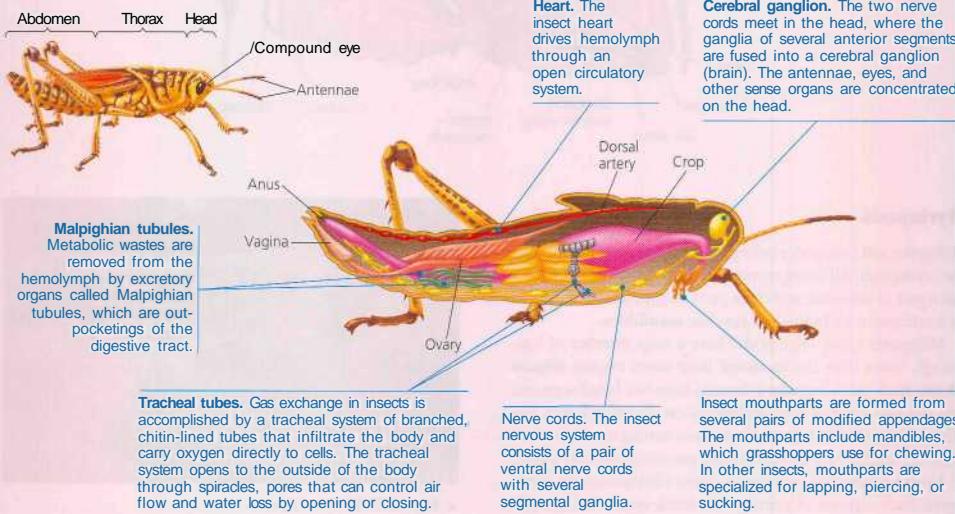

A Figure 33.34 A centipede.

of legs (Figure 33.34). Centipedes have poison claws on their foremost trunk segment that paralyze prey and aid in defense.

Insects

Insects and their relatives (subphylum Hexapoda) are more species-rich than all other forms of life combined. They live in almost every terrestrial habitat and in fresh water, and flying

The insect body has three regions: head, thorax, and abdomen. The segmentation of the thorax and abdomen are obvious, but the segments that form the head are fused.

insects fill the air. Insects are rare, though not absent, in the seas, where crustaceans are the dominant arthropods. The internal anatomy of an insect includes several complex organ systems, which are highlighted in Figure 33.35.

The oldest insect fossils date from the Devonian period, which began about 416 million years ago. However, when flight evolved during the Carboniferous and Permian periods, it spurred an explosion in insect variety. A fossil record of diverse insect mouthparts indicates that specialized feeding on gymnosperms and other Carboniferous plants also contributed to the adaptive radiation of insects. A widely held hypothesis is that the greatest diversification of insects paralleled the evolutionary radiation of flowering plants during the Cretaceous and early Tertiary periods about 65–60 million years ago. This view is challenged by new research suggesting that insects diversified extensively before the angiosperm radiation. Thus, during the evolution of flowering plants and the herbivorous insects that pollinated them, insect diversity may have been as much a cause of angiosperm radiation as an effect.

Flight is obviously one key to the great success of insects. An animal that can fly can escape many predators, find food and mates, and disperse to new habitats much faster than an animal that must crawl about on the ground. Many insects have one or two pairs of wings that emerge from the dorsal side.

▼ Figure 33.35 Anatomy of a grasshopper, an insect.

of the thorax. Because the wings are extensions of the cuticle and not true appendages, insects can fly without sacrificing any walking legs. By contrast, the Ewing vertebrates—birds and bats—have one of their two pairs of walking legs modified into wings and are generally quite clumsy on the ground.

Insect wings may have first evolved as extensions of the cuticle that helped the insect body absorb heat, only later becoming organs for flight. Other views suggest that wings allowed insects to glide from vegetation to the ground, or even that they served as gills in aquatic insects. Still another hypothesis is that insect wings functioned for swimming before they functioned for flight.

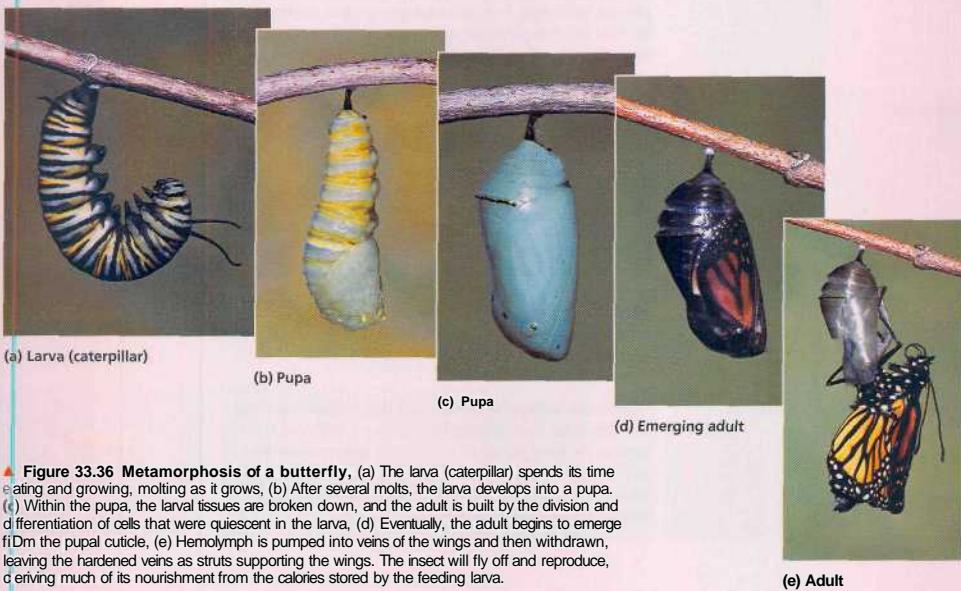

Morphological and molecular data indicate that wings evolved only once in insects. Dragonflies, which have two similar pairs of wings, were among the first insects to fly. Several insect orders that evolved later than dragonflies have modified flight equipment. The wings of bees and wasps, for instance, are hooked together and move as a single pair. Butterflies operate in a similar fashion because the anterior wing overlaps the posterior wings. In beetles, the posterior wings function in flight, while the anterior ones are modified as covers that protect the flight wings when the beetle is on the ground or is burrowing.

Many insects undergo metamorphosis during their development. In the incomplete metamorphosis of grasshoppers and some other orders, the young (called nymphs) resemble adults

but are smaller, have different body proportions, and lack wings. The nymph goes through a series of molts, each time looking more like an adult. With the final molt, the insect reaches full size, acquires wings, and becomes sexually mature. Insects with complete metamorphosis have larval stages specialized for eating and growing that are known by such names as maggot, grub, or caterpillar. The larval stage looks entirely different from the adult stage, which is specialized for dispersal and reproduction. Metamorphosis from the larval stage to the adult occurs during a pupal stage (**Figure 33.36**).

Reproduction in insects is usually sexual, with separate male and female individuals. Adults come together and recognize each other as members of the same species by advertising with bright colors (as in butterflies), sound (as in crickets), or odors (as in moths). Fertilization is generally internal. In most species, sperm are deposited directly into the female's vagina at the time of copulation, though in some species the male deposits a sperm packet outside the female, and the female picks it up. An internal structure in the female called the spermatheca stores the sperm, usually enough to fertilize more than one batch of eggs. Many insects mate only once in a lifetime. After mating, a female often lays her eggs on an appropriate food source where the next generation can begin eating as soon as it hatches.

Insects are classified in about 26 orders, 15 of which are explored in **Figure 33.37**, on the next two pages.

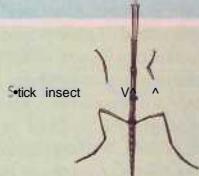

▲ **Figure 33.36 Metamorphosis of a butterfly.** (a) The larva (caterpillar) spends its time eating and growing, molting as it grows. (b) After several molts, the larva develops into a pupa. (c) Within the pupa, the larval tissues are broken down, and the adult is built by the division and differentiation of cells that were quiescent in the larva. (d) Eventually, the adult begins to emerge from the pupal cuticle. (e) Hemolymph is pumped into veins of the wings and then withdrawn, leaving the hardened veins as struts supporting the wings. The insect will fly off and reproduce, deriving much of its nourishment from the calories stored by the feeding larva.

Figure 33.37

Exploring Insect Diversity

| ORDER | APPROXIMATE NUMBER OF SPECIES | MAIN CHARACTERISTICS | EXAMPLES |
|-------------|-------------------------------|---|---|
| Blattodea | 4,000 | Cockroaches have a dorsoventrally flattened body, with legs modified for rapid running. Forewings, when present, are leathery*, whereas hind wings are fanlike. (Over than 40 cockroach species live in houses; the rest exploit habitats ranging from tropical forest floors to caves and deserts. | German cockroach  |
| Coleoptera | 350,000 | Beetles comprise the most species-rich order of insects. They have two pairs of wings, one of which is thick and leathery, the other membranous. They have an armored exoskeleton and mouthparts adapted for biting and chewing. Beetles undergo complete metamorphosis. | Japanese beetle  |
| Dermaptera | 1,200 | Earwigs are generally nocturnal scavengers. While some species are wingless, others have two pairs of wings, one of which is thick and leathery, the other membranous. Earwigs have biting mouthparts and large posterior pincers. They undergo incomplete metamorphosis. | Earwig  |
| Diptera | 151,000 | Dipterans have one pair of wings; the second pair has become modified into balancing organs called halteres. Their head is large and mobile; their mouthparts are adapted for sucking, piercing, or lapping. Dipterans undergo complete metamorphosis. Flies and mosquitoes are among the best-known dipterans, which live as scavengers, predators, and parasites. | Horsefly  |
| Hemiptera | 85,000 | Hemipterans are so-called "true bugs," including bed bugs, assassin bugs, and chinch bugs. (Insects in other orders are sometimes erroneously called bugs.) Hemipterans have two pairs of wings, one pair thick and leathery, the other membranous. They have piercing or sucking mouthparts and undergo incomplete metamorphosis. | Leaf-footed bug  |
| Hymenoptera | 125,000 | Ants, bees, and wasps are generally highly social insects. They have two pairs of membranous wings, a mobile head, and chewing or sucking mouthparts. The females of many species have a posterior stinging organ. Hymenopterans undergo complete metamorphosis. | Cicada-killer wasp  |
| Isoptera | 2,000 | Termites are widespread social insects that produce enormous colonies. It has been estimated that there are 700 kg of termites for every person on Earth! Some termites have two pairs of membranous wings, while others are wingless. They feed on wood with the aid of microbial symbionts carried in specialized chambers in their hindgut. | Termite  |

| ORDER | APPROXIMATE NUMBER OF SPECIES | MAIN CHARACTERISTICS | EXAMPLES |
|--------------|-------------------------------|--|--|
| Lepidoptera | 120,000 | Butterflies and moths are among the best-known insects. They have two pairs of wings covered with tiny scales. To feed, they uncoil a long proboscis. Most feed on nectar, but some species feed on other substances, including animal blood or tears. |  Swallowtail butterfly. |
| Odonata | 5,000 | Dragonflies and damselflies have two pairs of large, membranous wings. They have an elongated abdomen, large, compound eyes, and chewing mouthparts. They undergo incomplete metamorphosis and are active predators. |  Dragonfly |
| Orthoptera | 13,000 | Grasshoppers, crickets, and their relatives are mostly herbivorous. They have large hind legs adapted for jumping, two pairs of wings (one leathery, one membranous), and biting or chewing mouthparts. Males commonly make courtship sounds by rubbing together body parts, such as a ridge on their hind leg. Orthopterans undergo incomplete metamorphosis. |  Katydid |
| Phasmida | 2,600 | Stick insects and leaf insects are exquisite mimics of plants. The eggs of some species even mimic seeds of the plants on which the insects live. Their body is cylindrical or flattened dorsoventrally. They lack forewings but have fanlike hind wings. Their mouthparts are adapted for biting or chewing. |  Stick insect |
| Phthiraptera | 2,400 | Commonly called sucking lice, these insects spend their entire life as an ectoparasite feeding on the hair or feathers of a single host. Their legs, equipped with clawlike tarsi, are adapted for clinging to their hosts. They lack wings and have reduced eyes. Sucking lice undergo incomplete metamorphosis. |  Human body louse |
| Siphonaptera | 2,400 | Fleas are bloodsucking ectoparasites on birds and mammals. Their body is wingless and laterally compressed. Their legs are modified for clinging to their hosts and for long-distance jumping. They undergo complete metamorphosis. |  Flea |
| Thysanura | 450 | Silverfish are small, wingless insects with a flattened body and reduced eyes. They live in leaf litter or under bark. They can also infest buildings, where they can become pests. |  Silverfish |
| Trichoptera | 7,100 | The larvae of caddisflies live in streams, where they make houses from sand grains, wood fragments, or other material held together by silk. Adults have two pairs of hairy wings and chewing or lapping mouthparts. They undergo complete metamorphosis. |  Caddisfly |

Animals as numerous, diverse, and widespread as insects are bound to affect the lives of all other terrestrial organisms, including humans. On the one hand, we depend on bees, flies, and many other insects to pollinate our crops and orchards. On the other hand, insects are carriers for many diseases, including African sleeping sickness (spread by tsetse flies that carry *Trypanosoma*; see Figure 28.7) and malaria (spread by mosquitoes that carry *Plasmodium*; see Figure 28.11). Furthermore, insects compete with humans for food. In parts of Africa, for instance, insects claim about 75% of the crops. Trying to minimize their losses, farmers in the United States spend billions of dollars each year on pesticides, spraying crops with massive doses of some of the deadliest poisons ever invented. Try as they may, not even humans have challenged the preeminence of insects and their arthropod kin. As Cornell University entomologist Thomas Eisner puts it: "Bugs are not going to inherit the Earth. They own it now. So we might as well make peace with the landlord."¹

Crustaceans

While arachnids and insects thrive on land, crustaceans, for the most part, have remained in marine and freshwater environments. Crustaceans (subphylum Crustacea) typically have biramous (branched) appendages that are extensively specialized. Lobsters and crayfish, for instance, have a toolkit of 19 pairs of appendages (see Figure 33.29). The anterior-most appendages are antennae; crustaceans are the only arthropods with two pairs. Three or more pairs of appendages are modified as mouthparts, including the hard mandibles. Walking legs are present on the thorax, and, unlike insects, crustaceans have appendages on the abdomen. A lost appendage can be regenerated.

Small crustaceans exchange gases across thin areas of the cuticle; larger species have gills. Nitrogenous wastes also diffuse through thin areas of the cuticle, but a pair of glands regulates the salt balance of the hemolymph.

Sexes are separate in most crustaceans. In the case of lobsters and crayfish, the male uses a specialized pair of abdominal appendages to transfer sperm to the reproductive pore of the female during copulation. Most aquatic crustaceans go through one or more swimming larval stages.

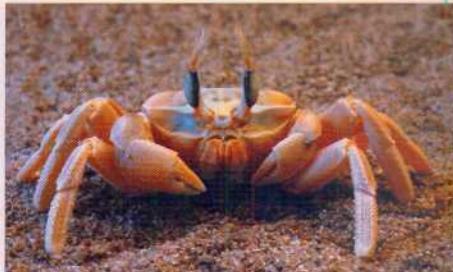

One of the largest groups of crustaceans (numbering about 10,000 species) is the isopods, which include terrestrial, freshwater, and marine species. Some isopod species are abundant in habitats at the bottom of the deep ocean. Among the terrestrial isopods are the pill bugs, or wood lice, common on the undersides of moist logs and leaves.

Lobsters, crayfish, crabs, and shrimp are all relatively large crustaceans called decapods (Figure 33.38a). The cuticle of decapods is hardened by calcium carbonate; the portion that covers the dorsal side of the cephalothorax forms a shield called the carapace. Most decapod species are ma-

rine. Crayfish, however, live in fresh water, and some tropical crabs live on land.

Many small crustaceans are important members of marine and freshwater plankton communities. Planktonic crustaceans include many species of copepods, which are among the most numerous of all animals, and the shrimplike krill, which grow to about 3 cm long (Figure 33.38b). A major food source for baleen whales (including blue whales and right whales), krill are now⁷ being harvested in great numbers by humans for food and agricultural fertilizer. The larvae of many larger-bodied crustaceans are also planktonic.

Barnacles are a group of mostly sessile crustaceans whose cuticle is hardened into a shell containing calcium carbonate (Figure 33.38c). Most barnacles anchor themselves to rocks, boat hulls, pilings, and other submerged surfaces. The ad-

(a) Ghost crabs (genus *Ocypode*) live on sandy ocean beaches worldwide. Primarily nocturnal, they take shelter in burrows during the day.

(b) Planktonic crustaceans known as krill are consumed in vast quantities by whales.

(c) The jointed appendages projecting from the shells of these barnacles capture organisms and organic particles suspended in the water.

A Figure 33.38 Crustaceans.

size they use is as strong as any synthetic glue. To feed, they extend appendages from their shell to strain food from the water. Other barnacles live as parasites inside hosts such as crabs, where their bodies resemble the roots of a plant. Barnacles were not recognized as crustaceans until the 1800s. When naturalists discovered that barnacle larvae resemble those of other crustaceans, the remarkable mix of unique traits and crustacean homologies found in barnacles was a major inspiration to Charles Darwin as he developed his theory of evolution.

Concept 33.8

Echinoderms and chordates are deuterostomes

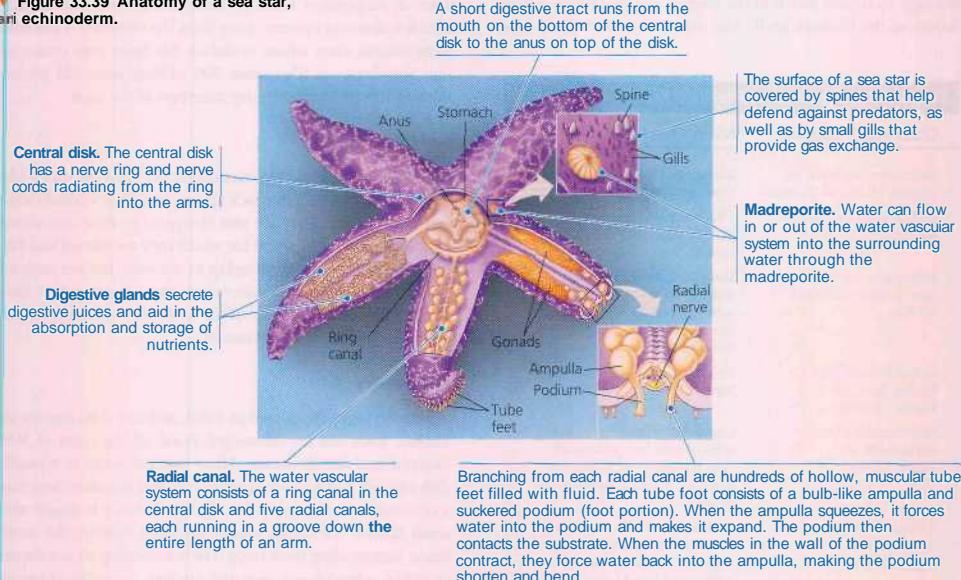

Sea stars and other echinoderms (phylum Echinodermata) may seem to have little in common with phylum Chordata, which includes the vertebrates—animals that have a backbone. In fact, all these animals share features characteristic of deuterostomes: radial cleavage, development of the coelom from the archenteron, and formation of the mouth at the end of the embryo opposite the blastopore (see Figure 32.9). Molecular systematics has reinforced Deuterostomia as a clade of bilaterian animals.

Concept Check 33.7

- In contrast to our jaws, which move up and down, the mouthparts of arthropods move side to side. Explain this feature of arthropods in terms of the origin of their mouthparts.
- Would it be reasonable to call phylum Arthropoda the most successful animal phylum? Explain your answer.
- Describe two adaptations that enabled insects to thrive on land.

For suggested answers, see Appendix A.

Figure 33.39 Anatomy of a sea star, ari echinoderm.

usually involves separate male and female individuals that release their gametes into the water.

The internal and external parts of most echinoderms radiate from the center, often as five spokes. HoWeVer, the radial anatomy of adult echinoderms is a secondary adaptation, as echinoderm larvae have bilateral symmetry. Furthermore, the symmetry of adult echinoderms is not perfectly radial. For example, the opening (madreporite) of a sea stars water vascular system is not central but shifted to one side.

Living echinoderms are divided into six classes (**Table 33.6; Figure 33.40**): **Astroidea** (sea stars), **Ophiuroidea** (brittle stars), **Echinoidea** (sea urchins and sand dollars), **Crinoidea** (sea lilies and feather stars), **Holothuroidea** (sea cucumbers), and **Concentricycloidea** (sea daisies).

Sea Stars

Sea stars have multiple arms radiating from a central disk. The undersurfaces of the arms bear tube feet, each of which can act like a suction disk. By a complex set of hydraulic and muscular actions, the suction can be created or released (see Figure 33.39). The sea star adheres firmly to rocks or creeps along slowly as the tube feet extend, grip, contract, release, extend, and grip again. Sea stars also use their tube feet to grasp prey, such as clams and oysters. The arms of the sea star embrace the closed bivalve, hanging on tightly by the tube feet. The sea star then turns its stomach inside out, evertit through its mouth and into the narrow opening between the halves of the bivalves shell. The digestive system of the sea

star secretes juices that begin digesting the soft body of the mollusc within its own shell.

Sea stars and some other echinoderms have considerable powers of regeneration. Sea stars can regrow lost arms, and members of one genus can even regrow an entire body from a single arm.

Brittle Stars

Brittle stars have a distinct central disk and long, flexible arm. They move by serpentine lashing of their arms, as their tube feet lack suckers and thus cannot be used for gripping. Some species are suspension feeders; others are predators or scavengers.

Sea Urchins and Sand Dollars

Sea urchins and sand dollars have no arms, but they do have five rows of tube feet that function in slow movement. Sea urchins also have muscles that pivot their long spines, which aids in locomotion. The mouth of a sea urchin is ringed by complex, jaw-like structures adapted for eating seaweeds and other food. Sea urchins are roughly spherical, whereas sand dollars are flattened and disk-shaped.

Sea Lilies and Feather Stars

Sea lilies live attached to the substrate by a stalk; feather stars crawl about by using their long, flexible arms. Both use the arms in suspension feeding. The arms encircle the mouth, which is directed upward, away from the substrate. Crinoidea is an ancient class whose evolution has been very conservative; fossilized sea lilies some 500 million years old are extremely similar to present-day members of the class.

Sea Cucumbers

On casual inspection, sea cucumbers do not look much like other echinoderms. They lack spines, and their endoskeleton is much reduced. They are also elongated in their oral-aboral axis, giving them the shape for which they are named and further distinguishing their relationship to sea stars and sea urchins. Closer examination, however, reveals that sea cucumbers have five rows of tube feet. Some of the tube feet around the mouth are developed as feeding tentacles.

Sea Daisies

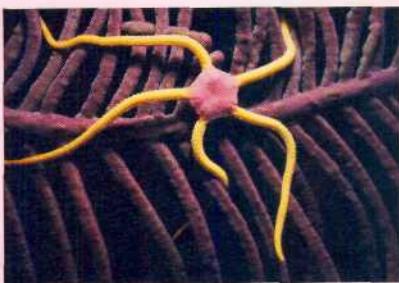

Sea daisies were discovered in 1986, and only two species are known. Both live on submerged wood off the coast of New Zealand and the Bahamas. Their armless body is typically disk-shaped, has a five-fold symmetry, and measures less than a centimeter in diameter. The edge of the body is ringed with small spines. Sea daisies absorb nutrients through the membrane surrounding their body. The relationship of sea daisies to other echinoderms remains unclear; some taxonomists consider sea daisies to be highly derived sea stars.

Table 33.6 Classes of Phylum Echinodermata

| Class and Examples | Main Characteristics |
|---|---|
| Astroidea (sea stars; see Figures 33.39 and 33.40a) | Star-shaped body with multiple arms; mouth directed to substrate |
| Ophiuroidea (brittle stars; see Figure 33.40b) | Distinct central disk; long, flexible arms; tube feet lack suckers |
| Echinoidea (sea urchins, sand dollars; see Figure 33.40c) | Roughly spherical or disk-shaped; no arms; five rows of tube feet enable slow movement; mouth ringed by complex, jaw-like structure |
| Crinoidea (sea lilies, feather stars; see Figure 33.40d) | Feathered arms surrounding upward-pointing mouth |
| Holothuroidea (sea cucumbers; see Figure 33.40e) | Cucumber-shaped body; five rows of tube feet; additional tube feet modified as feeding tentacles; reduced skeleton; no spines |
| Concentricycloidea (sea daisies; see Figure 33.40f) | Disk-shaped body ringed with small spines; incomplete digestive system; live on submerged wood |

▲ Figure 33.40 Echinoderms.

Chordates

The phylum Chordata consists of two subphyla of invertebrates as well as the hagfishes and the vertebrates. The close relationship between echinoderms and chordates does not mean that one phylum evolved from the other. Echinoderms and chordates have existed as distinct phyla for at least half a billion years. We will trace the phylogeny of chordates in Chapter 34, focusing on the history of vertebrates.

Concept Check 33.8

- Explain how the symmetry of echinoderms and cnidarians exemplifies convergent evolution.
- Describe the hydraulic and muscular actions by which a sea star moves its tube feet.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Table 33.7 summarizes the groups of animals surveyed in this chapter.

Table 33.7 Selected Animal Phyla

| Phylum | Description |
|---|---|
| Porifera (sponges) | Lack true tissues; have choanocytes (collar cells—unique flagellated cells that ingest bacteria and tiny food particles) |
| Cnidaria (hydras, jellies, sea anemones, corals) | Unique stinging structures (cnidae), each housed in a specialized cell (cnidocyte); gastrovascular cavity (digestive compartment with a single opening) |
| Platyhelminthes (flatworms) | Dorsally flattened, unsegmented acelomates; gastrovascular cavity or no digestive tract |
| Rotifera (rotifers) | Pseudocoelomates with alimentary canal (digestive tube with mouth and anus); jaws (trophont) in pharynx; head with ciliated crown |
| Lophophorates: Ectoprocta, Phoronida, Brachiopoda | Cocloimates with lophophore? (feeding structures bearing ciliated tentacles) |
| Nemertea (proboscis worms) | Unique anterior proboscis surrounded by fluid-filled sac; alimentary canal; closed circulatory system |
| Mollusca (clams, snails, squids) | Cocloimates with three main body parts (muscular foot, visceral mass, mantle); coelom reduced; most have hard shell made of calcium carbonate |
| Annelida (segmented worms) | Cocloimates with body wall and internal organs (except digestive tract) segmented |
| Nematoda (roundworms) | Cylindrical, unsegmented pseudocoelomates with tapered ends; no circulatory system |
| Arthropoda (crustaceans, insects, spiders) | Cocloimates with segmented body, jointed appendages, and exoskeleton made of protein and chitin |
| Echinodermata (sea stars, sea urchins) | Cocloimates with secondary radial anatomy (larvae bilateral; adults radial); unique water vascular system; endoskeleton |
| Chordata (lancelets, tunicates, vertebrates) | Cocloimates with notochord; dorsal, hollow nerve cord; pharyngeal slits; muscular, post-anal tail |

Concept 33.1

Sponges are sessile and have a porous body and choanocytes

- Sponges lack true tissues and organs. They suspension feed by drawing water through pores; choanocytes (flagellated collar cells) ingest suspended food (pp. 642–643).

Concept 33.2

Cnidarians have radial symmetry, a gastrovascular cavity, and cnidocytes

- ▶ Cnidarians are mainly marine carnivores possessing tentacles armed with cnidocytes that aid in defense and the capture of prey. Two body forms are sessile polyps and floating medusae (pp. 643–644).
- **Hydrozoans** (pp. 644–645) Class Hydrozoa usually alternates polyp and medusa forms, although the polyp is more conspicuous.
- ▶ **Scyphozoans** (p. 644) In class Scyphozoa, jellies (medusae) are the prevalent form of the life cycle.
- ▶ **Cubozoans** (p. 645) In class Cubozoa (boxjellies and sea wasps), the medusa is box-shaped and has complex eyes.
- ▶ **Anthozoans** (pp. 645–646) Class Anthozoa contains the sea anemones and corals, which occur only as polyps.

Concept 33.3

Most animals have bilateral symmetry

- **Flatworms** (pp. 646–648) Flatworms are dorsoventrally flattened animals with a gastrovascular cavity. Class Turbellaria is made up of mostly free-living, primarily marine species. Members of the classes Trematoda and Monogenea live as parasites in or on animals. Class Cestoda consists of tapeworms, all of which are parasites and lack a digestive tract.
- ▶ **Rotifers** (pp. 648–649) Found mainly in fresh water, many rotifer species are parthenogenetic.
- ▶ **Lophophorates: Ectoprocts, Phoronids, and Brachiopods** (p. 649) Lophophorates are coelomates that have a lophophore, a horseshoe-shaped, suspension-feeding organ bearing ciliated tentacles.
- ▶ **Nemerteans** (pp. 649–650) Nemerteans have a unique retractable tube (proboscis) used for defense and prey capture. A fluid-filled sac is used to extend the proboscis.

Concept 33.4

Molluscs have a muscular foot, a visceral mass, and a mantle

- **Chitons (p. 651)** Class Polyplacophora is composed of the chitons, oval-shaped marine animals encased in an armor of eight dorsal plates.
- ▶ **Gastropods** (pp. 651–652) Most members of class Gastropoda, the snails and their relatives, possess a single, spiraled shell. Embryonic torsion of the body is a distinctive characteristic. Many slugs lack a shell or have a reduced shell.
- **Bivalves (p. 652)** Class Bivalvia (clams and their relatives) have a hinged shell divided into two halves.
- **Cephalopods** (pp. 652–653) Class Cephalopoda includes squids and octopuses, carnivores with beak-like jaws surrounded by tentacles of their modified foot.

Concept 33.5

annelids are segmented worms

- ▶ **Oligochaetes** (pp. 653–654) Class Oligochaeta includes earthworms and various aquatic species.
- ▶ **Polychaetes** (p. 655) Members of class Polychaeta possess paddle-like parapodia that function as gills and aid in locomotion.

- **Leeches** (p. 655) Many members of class Hirudinea are blood-sucking parasites.

Concept 33.6

Nematodes are nonsegmented pseudocoelomates covered by a tough cuticle

- Among the most widespread and numerous animals, nematodes inhabit the soil and most aquatic habitats. Some species are important parasites of animals and plants (pp. 655–656).

Concept 33.7

Arthropods are segmented coelomates that have an exoskeleton and jointed appendages

- **General Characteristics of Arthropods** (pp. 656–658) Variation in arthropod morphology consists mainly in specializations of groups of segments and in appendages. The arthropod exoskeleton, made of protein and chitin, undergoes regular ecdysis (molting).
- **Cheliceriforms** (pp. 658–659) Cheliceriforms include spiders, ticks, and mites. They have an anterior cephalothorax and a posterior abdomen. The most anterior appendages are modified as chelicerae (either pincers or fangs).
- **Myriapods** (pp. 659–660) Millipedes are wormlike, with a large number of walking legs. They were among the first animals to live on land. Centipedes are terrestrial carnivores with poison claws.
- **Insects** (pp. 660–664) Insects exceed all other animals combined in species diversity. Flight has been an important factor in the success of insects.
Investigation How Are Insect Species Identified?
- **Crustaceans** (pp. 664–665) Crustaceans, which include lobsters, crabs, shrimp, and barnacles, are primarily aquatic. They have numerous appendages, many of which are specialized for feeding and locomotion.

Concept 33.8

Echinoderms and chordates are deuterostomes

- **Echinoderms** (pp. 665–667) Echinoderms (sea stars and their relatives) have a water vascular system ending in tube feet used for locomotion and feeding. The radial anatomy of many species evolved secondarily from the bilateral symmetry of ancestors. A thin, bumpy, or spiny skin covers a calcareous endoskeleton.
Activity Characteristics of Invertebrates
- **Chordates** (p. 667) Chordates include two invertebrate subphyla and all vertebrates. Chordates share many features of embryonic development with echinoderms.

TESTING YOUR KNOWLEDGE

Evolution Connection

Horseshoe crabs are called "living fossils" because the fossil record shows that they have remained essentially unchanged in morphology for many millions of years. Why might these organisms have retained the same morphology for such a long time? What other aspects of their biology, less obvious than structure, do you think may have evolved over that time?

Scientific Inquiry

A marine biologist has dredged up an unknown animal from the seafloor. Describe some of the characteristics she should look at to determine the phylum to which the animal should be assigned.

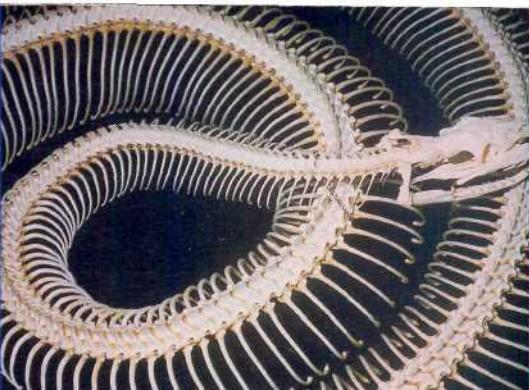

Investigation How Are Insect Species Identified?

Science, Technology, and Society

Construction of a dam and irrigation canals in an African country has enabled farmers to increase the amount of food they can grow. In the past, crops were planted only after spring floods; the fields were too dry the rest of the year. Now fields can be watered year-round. Improvement in crop yield has had an unexpected cost—a tremendous increase in the incidence of schistosomiasis. Look at the blood fluke life cycle in Figure 33.11 and imagine that your Peace Corps assignment is to help local health officials control the disease. Why do you think the irrigation project increased the incidence of schistosomiasis? It is difficult and expensive to control the disease with drugs. Suggest three other methods that could be tried to prevent people from becoming infected.

34

Vertebrates

A Figure 34.1 The vertebrae and skull of a snake, a terrestrial vertebrate.

Key Concepts

- 34.1 Chordates have a notochord and a dorsal, hollow nerve cord
- 34.2 Craniates are chordates that have a head
- 34.3 Vertebrates are craniates that have a backbone
- 34.4 Gnathostomes are vertebrates that have jaws
- 34.5 Tetrapods are gnathostomes that have limbs and feet
- 34.6 Amniotes are tetrapods that have a terrestrially adapted egg
- 34.7 Mammals are amniotes that have hair and produce milk
- 34.8 Humans are bipedal hominoids with a large brain

Overview

Half a Billion Years of Backbones

By the dawn of the Cambrian period, some 540 million years ago, an astonishing variety of animals inhabited Earth's oceans. Predators used claws and mandibles to skewer their prey. Many animals had protective spikes and armor as well as complex mouthparts that enabled their bearers to filter food from the water. Worms slithered into the muck to feed on organic matter. Amidst all this bustle, it would have been easy to overlook certain slender, 2-cm-long creatures gliding through the water. Although they lacked armor, eyes, and appendages, they would leave behind a remarkable legacy; these animals gave rise to one of the most successful groups of animals ever to swim, walk, or fly: the vertebrates, which derive their name from vertebrae, the series of bones that make up the vertebral column, or backbone (**Figure 34.1**). For nearly

200 million years, vertebrates were restricted to the oceans, but about 360 million years ago the evolution of legs and feet in one lineage of vertebrates accompanied these vertebrates' move to land. There they diversified into amphibians, reptiles (including birds), and mammals.

There are approximately 52,000 species of vertebrates, a relatively small number compared to the 1 million insect species on Earth. But what vertebrates lack in species diversity they have made up for with other statistics. Plant-eating dinosaurs as massive as 40,000 kg were the heaviest animals ever to walk on land. The biggest animal ever to exist on Earth is the blue whale (a mammal), which can exceed a mass of 100,000 kg. Vertebrates are capable of global journeys: For example, birds called Arctic terns, which breed mainly around the shores of the Arctic Ocean, travel to Antarctica to spend the rest of the year before making a return trip. Vertebrates also include the only species capable of full-blown language, complex toolmaking, and symbolic art—humans.

In this chapter, you will learn about current hypotheses regarding the origins of vertebrates from invertebrate ancestors. We will track the stepwise evolution of the vertebrate body plan, from a notochord to a bead to a mineralized skeleton, and explore the major groups of vertebrates (both living and extinct) as well as the evolutionary history of our own species.

Concept 34.1

Chordates have a notochord and a dorsal, hollow nerve cord

Vertebrates are a subphylum of the phylum Chordata (the chordates). Chordates are bilaterian (bilaterally symmetrical) animals, and within Bilateria, they belong to the clade of

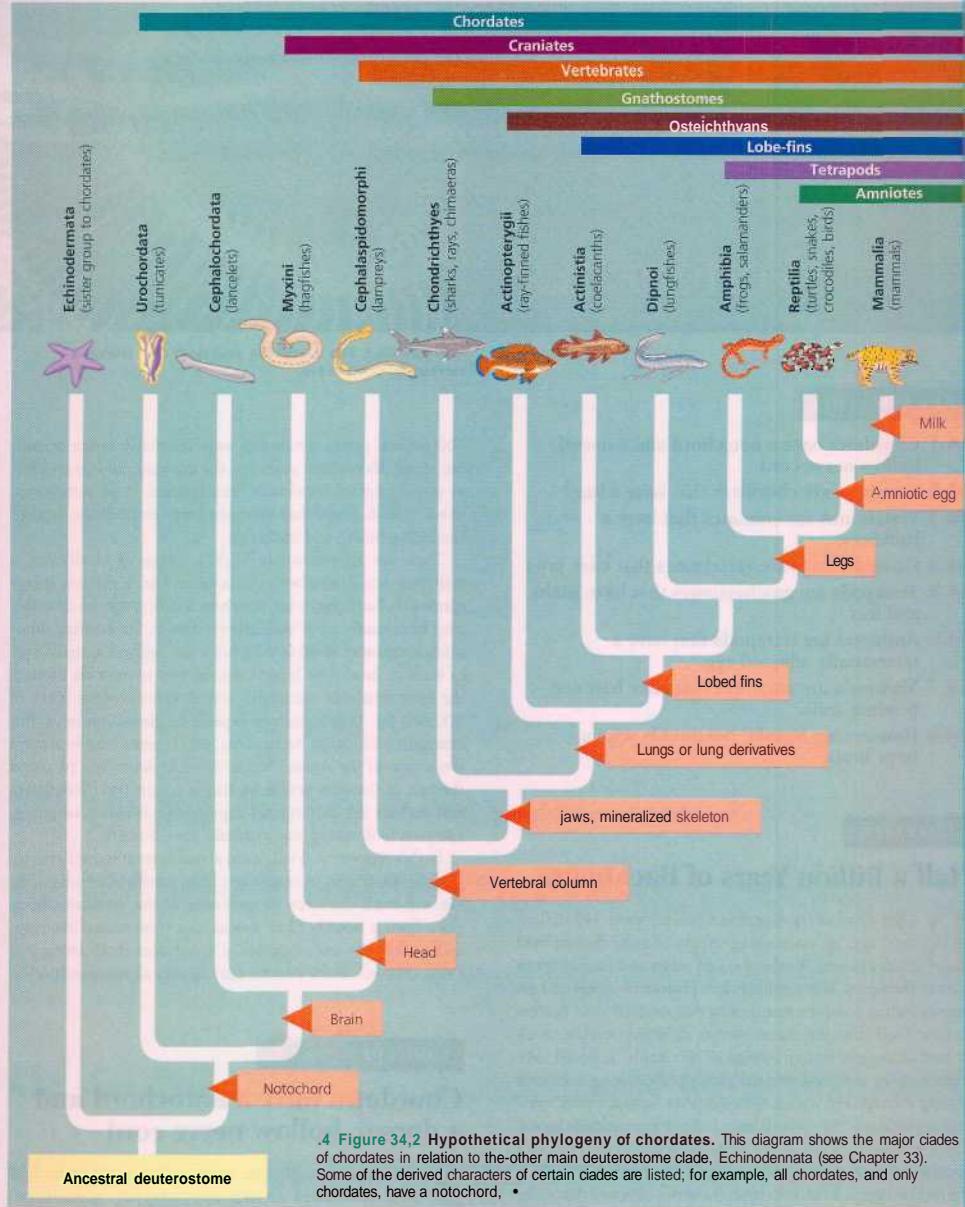

Figure 34.2 Hypothetical phylogeny of chordates. This diagram shows the major clades of chordates in relation to the other main deuterostome clade, Echinodermata (see Chapter 33). Some of the derived characters of certain clades are listed; for example, all chordates, and only chordates, have a notochord. •

animals known as Deuterostomia (see Chapter 32). The best-known deuterostomes, aside from vertebrates, are the echinoderms, members of the phylum that includes sea stars and sea urchins. However, as shown in **Figure 34.2**, on the facing page, two groups of invertebrate deuterostomes, the urochordates and the cephalochordates, are more closely related to vertebrates than to other invertebrates. Along with the hagfishes and the vertebrates, they make up the chordate phylum.

derived Characters of Chordates

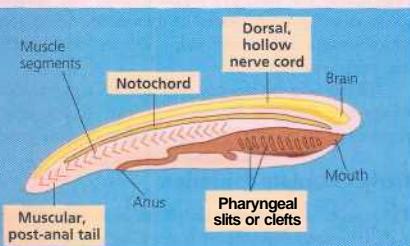

All chordates share a set of derived characters, though many species possess some of these traits only during embryonic development. **Figure 34.3** illustrates the four key characters of chordates: a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.

Notochord

Chordates are named for a skeletal structure, the notochord, present in all chordate embryos as well as in some adult chordates. The notochord is a longitudinal, flexible rod located between the digestive tube and the nerve cord. It is composed of large, fluid-filled cells encased in fairly stiff, fibrous tissue. The notochord provides skeletal support throughout most of the length of a chordate, and in larvae or adults that retain it, also provides a firm but flexible structure against which muscles can work during swimming. In most vertebrates, a more complex, jointed skeleton develops, and the adult retains only remnants of the embryonic notochord. In humans, the notochord is reduced to gelatinous disks sandwiched between the vertebrae.

dorsal, Hollow Nerve Cord

The nerve cord of a chordate embryo develops from a plate of ectoderm that rolls into a tube located dorsal to the notochord. The resulting dorsal, hollow nerve cord is unique to

A Figure 34.3 Chordate characteristics. All chordates possess the four structural trademarks of the phylum at some point during their development.

chordates. Other animal phyla have solid nerve cords, and in most cases they are ventrally located. The nerve cord of a chordate embryo develops into the central nervous system: the brain and spinal cord.

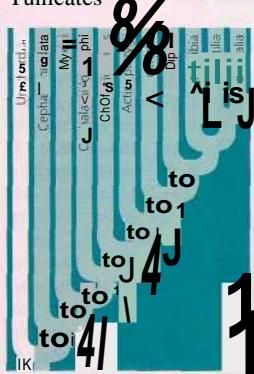

Pharyngeal Slits or Clefts

The digestive tube of chordates extends from the mouth to the anus. The region just posterior to the mouth is the pharynx. In all chordate embryos, a series of pouches separated by grooves forms along the sides of the pharynx; in most chordates, these grooves (known as pharyngeal clefts) develop into slits that open to the outside of the body. These pharyngeal slits allow water entering the mouth to exit the body without passing through the entire digestive tract. Pharyngeal slits function as suspension-feeding devices in many invertebrate chordates. In vertebrates (with the exception of terrestrial vertebrates, the tetrapods), these slits and the structures that support them have been modified for gas exchange and are known as gill slits. In tetrapods, the pharyngeal clefts do not develop into slits. Instead, they play an important role in the development of parts of the ear and other structures in the head and neck.

Muscular, Post-Anal Tail

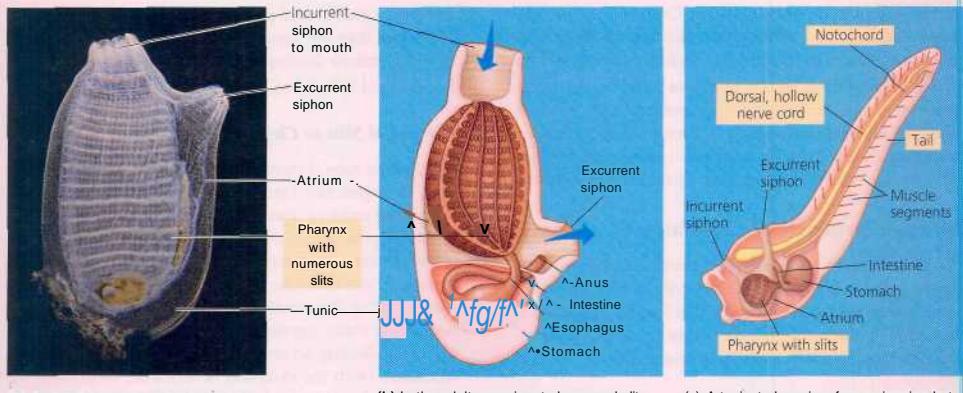

Chordates have a tail extending posterior to the anus, although in many species it is lost during embryonic development. In contrast, most nonchordates have a digestive tract that extends nearly the whole length of the body. The chordate tail contains skeletal elements and muscles, and it provides much of the propelling force in many aquatic species.

Tunicates

Data from various morphological and molecular studies support the hypothesis that tunicates (subphylum Urochordata) belong to the deepest-branching lineage of chordates. The tunicates most resemble other chordates during their larval stage, which may be as brief as a few minutes. In many species, the larva uses its tail muscles and notochord to swim through water in search of a suitable substrate on which it can settle, guided by cues it receives from light- and gravity-sensitive cells.

Once a tunicate has settled on a substrate, it goes through a radical metamorphosis in which many of its chordate

(a) An adult tunicate, or sea squirt, is a sessile animal (photo is approximately life-sized).

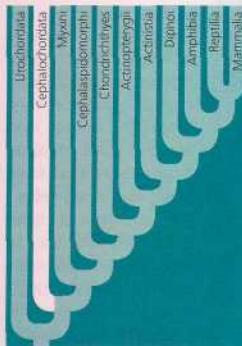

(b) In the adult, prominent pharyngeal slits function in suspension feeding, but other chordate characters are not obvious.

(c) A tunicate larva is a free-swimming but nonfeeding "tadpole" in which all four chief characters of chordates are evident.

A Figure 34.4 A tunicate, a urochordate.

characters disappear. Its tail and notochord are resorbed; its nervous system degenerates; and its remaining organs rotate 90°. As an adult, a tunicate draws in water through an incurrent siphon; the water then passes through the pharyngeal slits into a chamber called the atrium and exits through an excurrent siphon (**Figure 34.4**). Food particles are filtered from the water by a mucous net and transported by cilia to the esophagus. The anus empties into the excurrent siphon. Some tunicate species shoot a jet of water through their excurrent siphon when attacked, earning them the informal name of "sea squirts."

Lancelets

Lancelets (subphylum Cephalochordata) get their name from their bladelike shape (**Figure 34.5**). As larvae, lancelets develop a notochord, a dorsal, hollow nerve cord, numerous pharyngeal slits, and a post-anal tail. They feed on plankton in the water column, alternating between upward swimming and passive sinking. As they sink, they trap plankton and other suspended matter in their pharynx.

Adult lancelets can be up to 5 cm long. They retain key chordate traits, closely resembling the idealized chordate shown in

Figure 34.3. Following metamorphosis, adult lancelets swim down to the seafloor and wriggle backward into the sand, leaving only their anterior end exposed. A mucous net secreted across the pharyngeal slits removes tiny food particles from seawater drawn into the mouth by ciliary pumping. The water passes through the slits, and the trapped food enters the intestine. The pharynx and pharyngeal slits play a minor role in gas exchange, which occurs mainly across the external body surface.

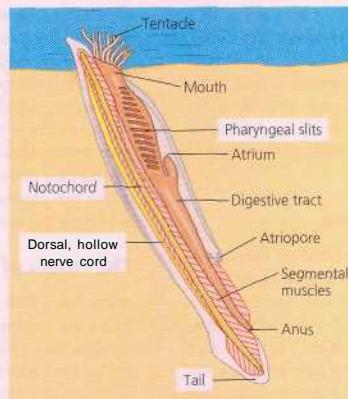

A lancelet frequently leaves its burrow to swim to a new location. Though feeble swimmers, these invertebrate chordates display, in a simple form, the swimming mechanism of fishes. Coordinated contraction of muscles serially arranged like rows of chevrons (<<><>) along the sides of the notochord flexes the notochord, producing side-to-side undulations that thrust the body forward. This serial musculature is evidence of the lancelets segmentation. The muscle segments develop from blocks of mesoderm called somites, which are found along each side of the notochord in all chordate embryos.

Globally, lancelets are rare, but in a few regions (including Tampa Bay, along the Florida coast) they occasionally reach densities in excess of 5,000 individuals per square meter.

Early Chordate Evolution

Although tunicates and lancelets are relatively obscure animals, the rise of evolutionary biology has focused much attention on them. Possessing many—but not all—of the derived characters shared by vertebrates, they can provide clues about the evolutionary origin of the vertebrate body plan.

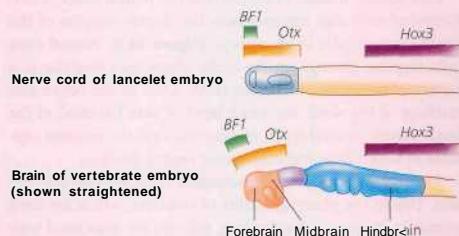

Figure 34.5 The lancelet *B. anchistoma*, a cephalochordate. This small invertebrate displays all four main chordate characters. Water enters the mouth and passes through the pharyngeal slits into the atrium, a chamber that vents to the outside via the atriose. The serially arranged segmental muscles produce the lancelet's undulatory (wavelike) swimming movements.

As you have read, tunicates display a number of chordate characters only as larvae, whereas lancelets retain those characters as adults. Thus, an adult lancelet looks much more like a larval tunicate than like an adult tunicate. In the 1920s, based on these observations, biologist William Garstang proposed that tunicates represent an early stage in chordate evolution. He suggested that ancestral tunicate-like chordates accelerated their sexual maturity, becoming mature while still in their larval stage. Thus, they and the chordates that evolved from them retained the notochord and other features as adults. This process, which has been documented in a number of evolutionary transitions, is known as paedomorphosis (see Chapter 24).

While Garstang's idea was popular for several decades, today the weight of evidence is against it in the case of tunicates. The degenerate adult stage of tunicates appears to be a derived trait that evolved only after the tunicate lineage branched off from other chordates. Even the tunicate larva appears to be highly derived, rather than a faithful reproduction of the body plan of early chordates. Studies of *Hox* gene expression (see Chapter 21) suggest that the tunicate larva does not develop the posterior regions of its body axis. Rather, the anterior region is elongated and contains a heart and digestive system.

Research on lancelets has revealed several important clues about the evolution of the chordate brain. Rather than a full-fledged brain, lancelets have only a slightly swollen tip on the interior end of their dorsal nerve cord. But the same *Hox* genes that organize major regions of the forebrain, midbrain, and hindbrain of vertebrates express themselves in a corresponding pattern in this small cluster of cells in the lancelet's nerve cord (Figure 34.6). This suggests that the vertebrate brain apparently is an elaboration of an ancestral structure similar to the lancelet's simple nerve cord tip.

A. Figure 34.6 Expression of developmental genes in lancelets and vertebrates. *Hox* genes (including *BF1*, *Otx*, and *Hox3*) control the development of major regions of the vertebrate brain. These genes are expressed in the same anterior-to-posterior order in lancelets and vertebrates.

Concept Check 34.1

- Humans are chordates, yet they lack most of the main derived characters of chordates. Explain.
- How do pharyngeal slits function in feeding in tunicates and lancelets?

For suggested answers, see Appendix A.

Concept 34.2

Craniates are chordates that have a head

After the evolution of the basic chordate body plan, seen in tunicates and lancelets, the next major transition in chordate

evolution was the appearance of a head. Chordates with a head are known as craniates (from the word *cranium*, skull). The origin of a head—consisting of a brain at the anterior end of the dorsal nerve cord, eyes and other sensory organs, and a skull—opened up a completely new way of feeding for chordates: active predation. (Note that heads evolved independently in other animal lineages as well, as described in Chapter 33.)

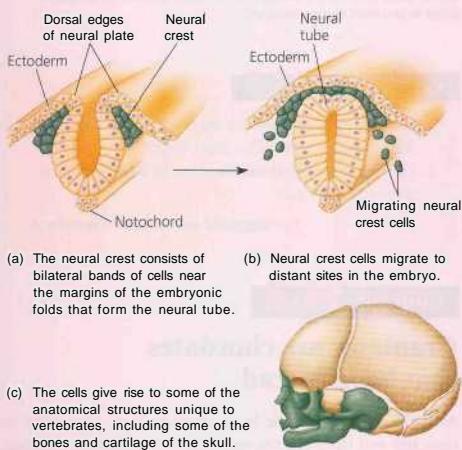

Derived Characters of Craniates

Living craniates share a set of derived characters that distinguish them from other chordates. On a genetic level, they possess two clusters of *Box* genes (lancelets and tunicates have only one). Other important families of genes that produce signaling molecules and transcription factors are also duplicated in craniates. This additional genetic complexity made it possible for craniates to develop more complex morphologies than those of tunicates and lancelets.

One feature unique to craniates is the neural crest, a collection of cells that appears near the dorsal margins of the closing neural tube in an embryo (**Figure 34.7**). Neural crest cells disperse throughout the body, where they give rise to a variety of structures, including teeth, some of the bones and cartilage of the skull, the inner layer of skin (dermis) of the facial region, several types of neurons, and the sensory capsules in which eyes and other sense organs develop.

In aquatic craniates, the pharyngeal clefts evolved into gill slits. Unlike the pharyngeal slits of lancelets, which are used primarily for suspension feeding, gill slits are associated with

Figure 34.7 The neural crest, embryonic source of many unique vertebrate characters.

muscles and nerves that allow water to be pumped through the slits. This pumping can assist in sucking in food, and it facilitates gas exchange. (In terrestrial craniates, the pharyngeal clefts develop into other structures, as explained later.)

Craniates, which are more active than tunicates and lancelets, also have a higher metabolism and a much more extensive muscular system. Muscles lining their digestive tract aid digestion by moving food through the tract. Craniates also have a heart with at least two chambers, red blood cells, and hemoglobin, as well as kidneys that remove waste products from the blood.

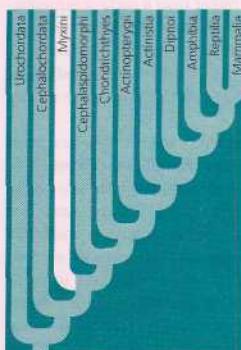

The Origin of Craniates

In the late 1990s, paleontologists working in China discovered a vast supply of fossils of early chordates that appear to straddle the transition to craniates. The fossils were formed during the Cambrian explosion 530 million years ago, when many groups of animals were diversifying (see Chapter 32).

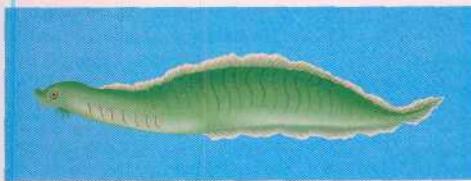

The most primitive of the fossils are those of the 3-cm-long *Haikouella* (**Figure 34.8a**). In many ways, *Haikouella* resembled a lancelet. Its mouth structure indicates that, like lancelets, it probably was a suspension feeder. However, *Haikouella* also had some of the characters of craniates. For example, it had a small but well-formed brain, eyes, and muscular segments that resemble those of vertebrates. It also had hardened structures in its pharynx that may have been tooth-like "denticles." However, *Haikouella* did not have a skull, suggesting that this character emerged with innovations to the chordate nervous system.

In other Cambrian rocks, paleontologists have found fossils of even more advanced chordates, such as *Haikouichthys*. About the same size as *Haikouella*, *Haikouichthys* had a skull that may have been composed of cartilage (**Figure 34.8b**). Based on this and other characters, paleontologists have identified *Haihnichthys* as a true craniate.

Hagfishes

The least derived craniate lineage that still survives is class Myxini, the hagfishes (**Figure 34.9**). Hagfishes have a skull made of cartilage, but they lack jaws and vertebrae. They swim in a snake-like fashion by using their segmental muscles to exert force against their notochord, which they retain in adulthood as a strong, flexible rod of cartilage. Hagfishes have a small brain, eyes, ears, and a nasal opening.

(a) *Haikouella*. Discovered in 1999 in southern China, *Haikouella* had eyes and a brain but lacked a skull, a derived trait of craniates.

(b) *Haikouichthys*. *Haikouichthys* had a skull and thus is considered a true craniate.

A **Figure 34.8 Fossils of primitive chordates.** The colors in the illustrations are fanciful.

* **Figure 34.9 A hagfish.**

that connects with the pharynx. They also have tooth-like formations made of the protein keratin in their mouth.

All of the 30 living species of hagfishes are marine. Measuring up to 60 cm in length, most are bottom-dwelling scavengers that feed on worms and sick or dead fish. Rows of slime glands on a hagfish's flanks secrete a substance that absorbs water, forming a slime that may repulse other scavengers when a hagfish is feeding (see Figure 34.9). When a hagfish is attacked by a potential predator, it can produce

several liters of slime in less than a minute. The slime coats the gills of an attacking fish, sending it into retreat or even suffocating it. Several teams of biologists and engineers are investigating the properties of hagfish slime in hopes of producing an artificial slime that could act as a space-filling gel. Such a gel might be used, for instance, to curtail bleeding during surgery.

Vertebrate systematists do not consider hagfishes to be fishes, despite their common name. Traditionally, the term fish has been applied to any craniate except tetrapods. But used in this way, it does not refer to a monophyletic group; therefore, systematists use the term fish to refer only to a specific clade of vertebrates, the actinopterygians (see Concept 34.4). We will follow that practice in this chapter.

Concept Check 34.2

1. Which extinct chordate is more closely related to humans, *Ikiikouichthys* or *Hatkouella*? Explain your answer.
2. What characteristics do hagfishes have that tunicates and lancelets lack?

For suggested answers, see Appendix A.

Concept 34.3

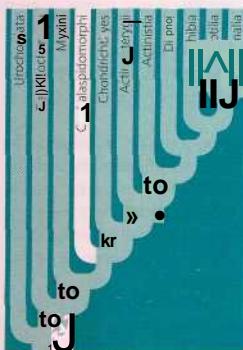

Vertebrates are craniates that have a backbone

During the Cambrian period, a lineage of craniates evolved into vertebrates. With a more complex nervous system and a more elaborate skeleton than those of their ancestors, vertebrates became active predators.

Derived Characters of Vertebrates

After vertebrates branched off from other craniates, they underwent another gene duplication, this one involving a group of transcription factor genes called the *Dlx* family. The resulting additional genetic complexity was associated with the development of innovations in the vertebrate nervous system and skeleton, including the presence of a more extensive skull and a backbone composed of vertebrae. In some vertebrates, the vertebrae are little more than small prongs of cartilage arrayed dorsally along the notochord. In the majority of vertebrates, however, the vertebrae enclose the spinal cord and have taken over the mechanical roles of the notochord. Aquatic vertebrates also acquired dorsal, ventral, and anal fins stiffened by fin rays, which provide thrust and steering control during swimming. Faster swimming was supported by other adaptations, including a more efficient gas exchange system in the gills.

Lampreys

Lampreys (class Cephalaspidomorphi) represent the oldest living lineage of vertebrates. Like hagfishes, lampreys may offer clues to early chordate evolution but have also acquired unique characters.

There are about 35 species of lampreys inhabiting various marine and freshwater environments (Figure 34.10). Most are parasites that feed by clamping their round, jawless mouth onto the flank of a live fish. They then use their rasping tongue to penetrate the skin of the fish and ingest the fish's blood.

As larvae, lampreys live in freshwater streams. The larva is a suspension feeder that resembles a lancelet and spends much of its time partially buried in sediment. Some species of lampreys feed only as larvae; following several years in streams, they attain sexual maturity, reproduce, and die within a few

A. Figure 34.10 A sea lamprey. Most lampreys use their mouth (enlarged, right) and tongue to bore a hole in the side of a fish. The lamprey then ingests the blood and other tissues of its host.

days. Most lampreys, however, migrate to the sea or lakes *if* they mature into adults. The sea lamprey (*Petromyzon marinus*) has invaded the Great Lakes over the past 170 years, where it has devastated a number of fisheries.

The skeleton of lampreys is made of cartilage. Unlike the cartilage found in most vertebrates, lamprey cartilage contains no collagen. Instead, it is a stiff protein matrix. The notochord of lampreys persists as the main axial skeleton in the adult, as it does in hagfishes. However, lampreys also have a cartilaginous pipe around their rodlike notochord. Along the length of this pipe, pairs of cartilaginous projections related to vertebrae extend dorsally, partially enclosing the nerve cord.

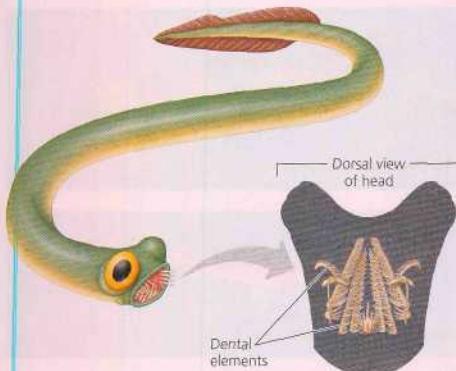

Fossils of Early Vertebrates

After the ancestors of lampreys branched off from other vertebrates during the Cambrian period, many other lineages of vertebrates emerged. Like lampreys, the early members of these lineages lacked jaws, but the resemblance stopped there.

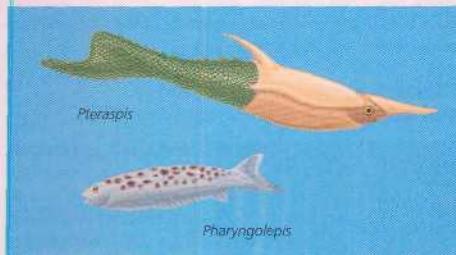

Conodonts were slender, soft-bodied vertebrates with prominent eyes controlled by numerous muscles. At the anterior end of their mouth, they had a set of barbed hooks made of mineralized dental tissues (Figure 34.11). Most conodonts were 3–10 cm in length, although some may have been as long as 30 cm. They probably hunted with the help of their large eyes impaling prey on their hooks. The food then passed back to the pharynx, where a different set of dental elements sliced and crushed the food.

Conodonts were extremely abundant for over 300 million years. Their fossilized dental elements are so plentiful that they have been used for decades by petroleum geologists as guides to the age of rock layers in which they search for oil. (These elements also gave conodonts their name, which means "cone teeth.")

Vertebrates with additional innovations emerged during the Ordovician, Silurian, and Devonian periods. These vertebrates had paired fins and an inner ear with two semicircular canals that provided a sense of balance. Although they, too, lacked jaws, they had a muscular pharynx, which they may

▲ Figure 34.11 A conodont. Conodonts were early vertebrates that lived from the late Cambrian until the late Triassic. Unlike lampreys, conodonts had mineralized mouthparts, which they used for either predation or scavenging.

▲ Figure 34.12 Jawless armored vertebrates. *Pteraspis* and *Pharyngolepis* were two of many genera of jawless vertebrates that emerged during the Ordovician, Silurian, and Devonian periods.

have used to suck in bottom-dwelling organisms or detritus. They were also armored with mineralized bone, which covered varying amounts of their body (Figure 34.12). The armor, which in some species included spines, may have offered protection from predators. These armored vertebrates were formerly placed in a group called the *ostmcoderms* ("shelled skin"). However, more recent research indicates that this group is paraphyletic: Some lineages are more closely related to jawed vertebrates than to other members of the group. These armored jawless vertebrates were exceptionally diverse, but they all became extinct by the end of the Devonian period.

Origins of Bone and Teeth

The human skeleton is heavily mineralized, and cartilage plays a fairly minor role. But this is a relatively recent development in the history of vertebrates. As we've seen, the vertebrate

skeleton evolved initially as a structure made of unmineralized cartilage. Its mineralization began only after lampreys diverged from other vertebrates.

What initiated the process of mineralization in vertebrates? Philip Donoghue, of the University of Birmingham, England, hypothesizes that mineralization was associated with a transition in feeding mechanisms. Early chordates probably were suspension feeders, like lancelets, but over time they became larger and were therefore able to ingest larger particles, including some small animals. The earliest known mineralized structures in vertebrates—conodont dental elements—were an adaptation that allowed these animals to become scavengers and predators. The armor seen in later jawless vertebrates was derived from dental mineralization. Thus, mineralization of the vertebrate body began in the mouth, according to Donoghue. Only in more derived vertebrates did the endoskeleton begin to mineralize, starting with the skull. As you'll learn in the next section, younger lineages of vertebrates underwent even further mineralization.

Concept Check 34.3

1. How are differences in lamprey and conodont anatomy reflected in each animal's feeding method?
2. What key roles did mineralized bone play in the first vertebrates?

For suggested answers, see Appendix A.

Concept 34.4

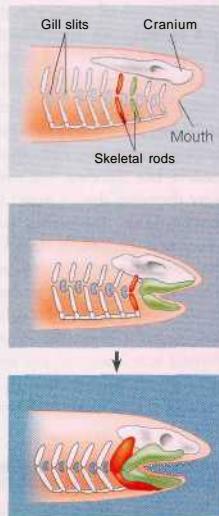

Gnathostomes are vertebrates that have jaws

Hagfishes and lampreys are survivors from an age when jawless craniates were common. Today they are far outnumbered by jawed vertebrates, known as gnathostomes.

Derived Characters of Gnathostomes

Gnathostomes ("jaw mouth") are named for their jaws, hinged structures that, especially with the help of teeth, enable gnathostomes to grip food items firmly and slice them up. According to one hypothesis, gnathostome jaws evolved by modification of the skeletal rods that had previously supported the anterior pharyngeal (gill) slits (Figure 34.13, on the next page). The remaining gill slits, no longer required for suspension feeding, remained as the major sites of respiratory gas exchange with the external environment. Other hypotheses posit different structures as the origin of jaws. Researchers comparing genes involved in the development of the mouth in lampreys and gnathostomes are testing these hypotheses.

Figure 34.13 Hypothesis for the evolution of vertebrate jaws. The skeleton of the jaws and their supports evolved from two pairs of skeletal rods (red and green) located between gill slits near the mouth. Pairs of rods anterior to those that formed the jaws were either lost or incorporated into the cranium or jaws.

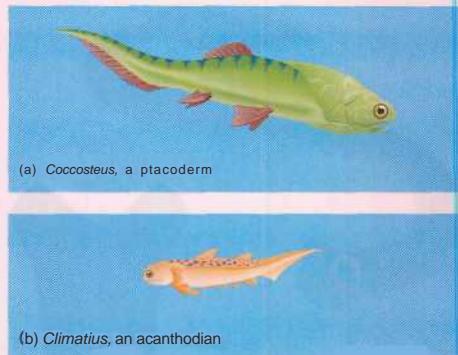

Gnathostomes share other derived characters besides jaws. The common ancestors of all gnathostomes underwent an additional duplication of *Hox* genes, such that the single cluster present in early chordates became four. Other gene clusters also duplicated, allowing further complexity in the development of gnathostome embryos. The gnathostome forebrain is enlarged compared to that of other craniates, mainly in association with enhanced senses of smell and vision. Running the length of each side of the body in aquatic gnathostomes is the lateral line system, a row of microscopic organs sensitive to vibrations in the surrounding water.

As mentioned earlier, the ancestors of gnathostomes began to acquire a mineralized endoskeleton. In the common ancestor of living gnathostomes, the axial skeleton, shoulder girdle, and paired appendages were mineralized.

Fossil Gnathostomes

Gnathostomes appeared in the fossil record in the mid-Ordovician period, about 470 million years ago, and steadily became more diverse. Their success probably lies in two features of their anatomy: Their paired fins and tail allowed them to swim efficiently after prey, and their jaws enabled them to grab prey or simply bite off chunks of flesh.

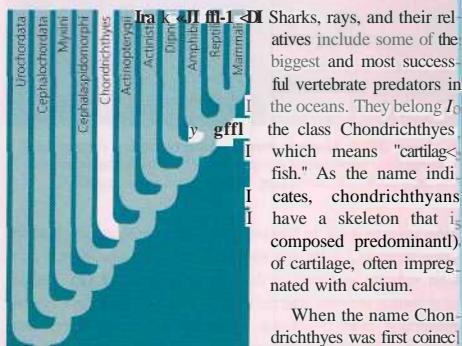

The earliest gnathostomes in the fossil record are an extinct lineage of armored vertebrates called placoderms, which means "plate-skinned" (Figure 34.14a). Most placoderms were less than a meter long, though some giants measured more than 10 m. Another group of jawed vertebrates called acanthodians radiated during the Devonian period, and many new forms

A Figure 34.14 Early gnathostomes.

evolved in fresh and salt water (Figure 34.14b). Acanthodians were closely related to the ancestors of osteichthyans (ray-finned fishes and lobe-fins). Both placoderms and acanthodians had disappeared by the beginning of the Carboniferous period, about 360 million years ago.

Chondrichthyans (Sharks, Rays, and Their Relatives)

Sharks, rays, and their relatives include some of the biggest and most successful vertebrate predators in the oceans. They belong to the class Chondrichthyes, which means "cartilage fish." As the name indicates, chondrichthians have a skeleton that is composed predominantly of cartilage, often impregnated with calcium.

When the name Chondrichthyes was first coined in the 1800s, scientists

thought that chondrichthians represented a primitive stage in the evolution of the vertebrate skeleton, and that mineralization had evolved only in more derived lineages (such as "bonfishes"). Strengthening this notion was the fact that embryos in these derived lineages first develop a skeleton made largely of cartilage. Later, much of the cartilage is replaced by bone, a hard matrix of calcium phosphate. However, this view has been abandoned. As conodonts and armored jawless vertebrates demonstrate, the mineralization of the vertebrate skeleton had already begun before the chondrichthyan lineage,

blanched off from other vertebrates. Moreover, traces of bone can be found in living chondrichthyans—in their scales, at the base of their teeth, and, in some sharks, in a thin layer on the surface of their vertebrae. The restricted distribution of bone in the chondrichthyan body appears to be a derived condition, which emerged after they diverged from other gnathostomes.

There are about 750 species of living chondrichthyans. The largest and most diverse subclass consists of the sharks and rays (Figure 34.15a and b). A second subclass is composed of a few dozen species of ratfishes, or chimaeras (Figure 34.15c).

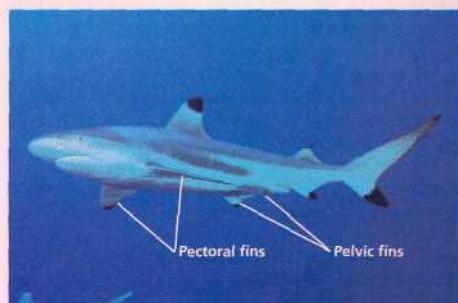

Most sharks have a streamlined body and are swift swimmers, but they do not maneuver very well. Powerful movements of the trunk and the caudal (tail) fin propel them forward. The dorsal fins function mainly as stabilizers, and the paired pectoral (fore) and pelvic (hind) fins provide lift when a shark swims. Although a shark gains buoyancy by storing a large amount of oil in its huge liver, the animal is still more dense than water, and if it stops swimming it sinks. Continual flapping also ensures that water flows into the shark's mouth and out through the gills, where gas exchange occurs. However, some sharks and many skates and rays spend a good deal of time resting on the seafloor. When resting, they use muscles in their jaws and pharynx to pump water over the gills.

The largest sharks and rays are suspension feeders that consume plankton. Most sharks, however, are carnivores that allow their prey whole or use their powerful jaws and sharp teeth to tear flesh from animals too large to swallow in one bite. Sharks have several rows of teeth that gradually move to the front of the mouth as old teeth are lost. The digestive tract of many sharks is proportionately shorter than that of many other vertebrates. Within the shark intestine is a spiral valve, a corkscrew-shaped ridge that increases surface area and prolongs the passage of food through the digestive tract.

Acute senses are adaptations that go along with the active, carnivorous lifestyle of sharks. Sharks have sharp vision but cannot distinguish colors. The nostrils of sharks, like those of most aquatic vertebrates, open into dead-end cups. They function only for olfaction (smelling), not for breathing; sharks also have a pair of regions in the skin of their head that detect electric fields generated by the muscle contractions of nearby animals. Like other aquatic vertebrates, sharks have lateral line structures that terrestrial vertebrates use to transmit sound waves in air to the auditory organs. Sound reaches a shark through water, and the animal's entire body transmits the sound to the hearing organs of the inner ear.

Shark eggs are fertilized internally. The male has a pair of claspers on its pelvic fins that transfer sperm into the reproductive tract of the female. Some species of sharks are oviparous; they lay eggs that hatch outside the mother's body. These sharks release their eggs after encasing them in protective coats. Other species are oovoviparous; they retain the fertilized eggs in the oviduct. Nourished by the egg yolk, the embryos develop into young that are born after hatching

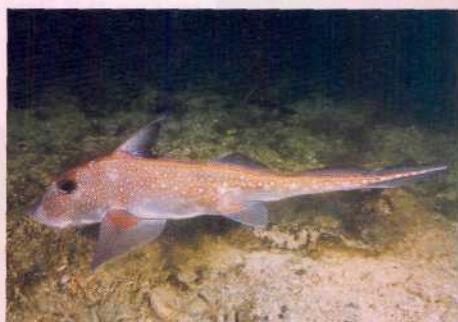

T Figure 34.15 Chondrichthyans.

(a) Blacktip reef shark (*Carcharhinus melanopterus*). Fast swimmers with acute senses, sharks have paired pectoral and pelvic fins.

(b) Southern stingray (*Dasyatis americana*). Most rays are flattened bottom-dwellers that crush molluscs and crustaceans for food. Some rays cruise in open water and scoop food into their gaping mouth.

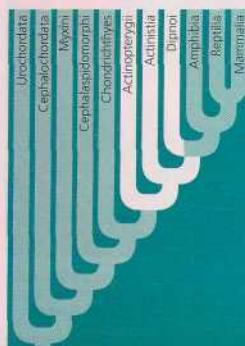

(c) Spotted ratfish (*Hydrolagus colliei*). Ratfishes, or chimaeras, typically live at depths greater than 80 m and feed on shrimps, molluscs, and sea urchins. Some species have a poisonous spine at the front of their dorsal fin.

within the uterus. A few species are **viviparous**; the young develop within the uterus and obtain nourishment prior to birth by receiving nutrients from the mother's blood through a yolk sac placenta, by absorbing a nutritious fluid produced by the uterus, or by eating other eggs. The reproductive tract of the shark empties along with the excretory system and digestive tract into the **cloaca**, a common chamber that has a single opening to the outside.

Although rays are closely related to sharks, they have adopted a very different lifestyle. Most rays are flattened bottom-dwellers that feed by using their jaws to crush molluscs and crustaceans. They use their greatly enlarged pectoral fins like water wings to propel themselves through the water. The tail of many rays is whiplike and, in some species, bears venomous barbs that function in defense.

Chondrichthyans have changed little in over 300 million years. Today, however, they are severely threatened with overfishing. In 2003, researchers reported that shark stocks in the northwest Atlantic declined 75% in 15 years.

Ray-Finned Fishes and Lobe-Fins

The vast majority of vertebrates belong to a clade of gnathostomes called Osteichthyes. Like many other taxonomic names, the name Osteichthyes ("bony fish") was coined long before the advent of phylogenetic systematics. When it was originally defined, the group excluded tetrapods, but we now know that such a taxon would actually be paraphyletic (see Figure 34.2). There-

fore, systematists today include tetrapods along with bony fishes in the clade Osteichthyes. Clearly the name of the group does not accurately describe all of its members.

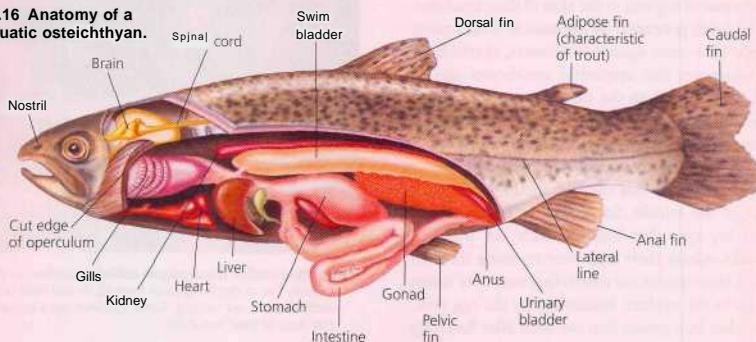

Unlike chondrichthyans, nearly all living osteichthyans have an ossified (bony) endoskeleton with a hard matrix of calcium phosphate. It is not clear when the shift to a bony skeleton took place during gnathostome evolution. It is possible, for example, that the common ancestor of both chondrichthyans and osteichthyans was already highly ossified and that chondrichthyans subsequently lost much of this bone. Until more fossils of early chondrichthyans and osteichthyans are unearthed, the question will remain open.

Aquatic osteichthyans are the vertebrates we informally call fishes. They breathe by drawing water over four or five pairs of gills located in chambers covered by a protective bony flap called the **operculum** (Figure 34.16). Water is drawn into the mouth, through the pharynx, and out between the gills by movement of the operculum and contraction of muscles surrounding the gill chambers.

Most aquatic osteichthyans can control their buoyancy with an air sac known as a **swim bladder**. Movement of gases from the blood to the swim bladder increases buoyancy making the animal rise; a transfer back to the blood causes the animal to sink. Charles Darwin proposed that the lungs of tetrapods evolved from swim bladders, but, strange as it may sound, the opposite seems to be true. Osteichthyans in many early-branching lineages also have lungs, which they use to breathe air as a supplement to gas exchange in their gills. The weight of evidence indicates that lungs arose first and later evolved into swim bladders in some lineages.

The skin of aquatic osteichthyans is often covered by flattened, bony scales that differ in structure from the toothlike scales of sharks. Glands in the skin secrete a slimy mucus over the skin as an adaptation that reduces drag during swimming. Like sharks, aquatic osteichthyans have a lateral line system, which is evident as a row of tiny pits in the skin on either side of the body.

T Figure 34.16 Anatomy of a trout, an aquatic osteichthyan.

Details about the reproduction of aquatic osteichthyans very extensively. Most species are oviparous, reproducing by external fertilization after the female sheds large numbers of small eggs. However, internal fertilization and birthing characterize other species.

Ray-Finned Fishes

Nearly all the aquatic osteichthyans familiar to us are among the ray-finned fishes (class Actinopterygii, from the Greek *aktin*, ray, and *pteryg*, wing or fin). The various species of bass, trout, perch, tuna, and herring are examples (Figure 34.17). The fins, supported mainly by long, flexible rays, are modified for maneuvering, defense, and other functions.

Ray-finned fishes appear to have originated in fresh water and spread to the seas. (Adaptations that solve the osmotic problems associated with the move to salt water are discussed in Chapter 44.) Numerous species of ray-finned fishes returned to fresh water at some point in their evolution. Some of them, including salmon and sea-run trout, replay their evolutionary round-trip from fresh water to seawater and back to fresh water during their life cycle.

Ray-finned fishes serve as a major source of protein for humans, who have harvested them for tens of thousands of years. However, industrial-scale fishing operations now threaten some of the world's biggest fisheries with collapse. Ray-finned fishes also face other pressures from humans, such as the diversion of rivers by dams.

Lobe-Fins

Ray-finned fishes evolved during the Devonian period, along with another major lineage of osteichthyans, the lobe-fins (Sarcopterygii). The key derived character of lobe-fins is the presence of rod-shaped bones surrounded by a thick layer of muscle in their pectoral and pelvic fins. During the Devonian, many lobe-fins lived in brackish waters, such as in coastal wetlands. There they probably used their lobed fins to swim and "walk" underwater across the substrate. Some Devonian lobe-fins were gigantic predators. It is not uncommon to find spike-shaped fossils of Devonian lobe-fin teeth as big as your thumb.

By the end of the Devonian period, lobe-fin diversity was dwindling, and today only three lineages survive. One lineage, the coelacanths (class Actinistia), shifted to the ocean (Figure 34.18). Scientists once thought that coelacanths had become extinct 75 million years ago, but in 1938, fishermen caught a living coelacanth off the Comoros Islands in the western Indian Ocean. Coelacanths were found only in that area until 1999, when a second population was identified in the eastern Indian Ocean, near Indonesia. The Indonesian coelacanth may represent a second species.

The second lineage of living lobe-fins is represented today by three genera of lungfishes (class Dipnii), all of which are

(a) Yellowfin tuna (*Thunnus albacares*), a fast-swimming, schooling fish that is an important commercial fish worldwide

(b) Clownfish (*Amphiprion ocellaris*), a mutualistic symbiont of sea anemones

(c) Sea horse (*Hippocampus ramulosus*), unusual in the animal kingdom in that the male carries the young during their embryonic development

(d) Fine-spotted moray eel (*Gymnothorax dovi*), a predator that ambushes prey from crevices in its coral reef habitat

A Figure 34.17 Ray-finned fishes (class Actinopterygii).

4 Figure 34.18 A coelacanth (*Latimeria*). These lobe-fins live in deep water off the coasts of southern Africa and Indonesia.

found in the Southern Hemisphere. Lungfishes evolved in the ocean but today are found only in fresh water, generally in stagnant ponds and swamps. They surface to gulp air into lungs connected to their pharynx. Lungfishes also have gills, which are the main organs for gas exchange in Australian lungfishes. When ponds shrink during the dry season, some lungfishes can burrow into the mud and aestivate (wait in a state of torpor; see Chapter 40).

The third lineage of lobe-fins that survives today is far more diverse than the coelacanths or lungfishes. During the mid-Devonian, these organisms adapted to life on land and gave rise to terrestrial vertebrates, or tetrapods, including humans. The tetrapod clade is the topic of the next section.

Concept Check 34.4

- What derived characters do sharks and tuna share? What are some characteristics that distinguish them?
- Contrast the habitats of the three surviving lineages of lobe-fins.

For suggested answers, see Appendix A.

Concept 34.5

Tetrapods are gnathostomes that have limbs and feet

One of the most significant events in vertebrate history took place about 360 million years ago, when the fins of some lobe-fins evolved into the limbs and feet of tetrapods. Until then, all vertebrates had shared the same basic fishlike anatomy. Once tetrapods moved onto land, they eventually took on many new forms, from leaping frogs to flying eagles to bipedal humans.

Derived Characters of Tetrapods

The most significant character of tetrapods gives the group its name, which means "four feet" in Greek. In place of pectoral and pelvic fins, tetrapods have limbs that can support their weight on land and feet with digits that allow them to transmit muscle-generated forces to the ground when they walk.

Life on land brought numerous other changes to the tetrapod body plan. The bones of the pelvic girdle, to which the hind legs are attached, are fused to the backbone, permitting forces generated by the hind legs against the ground to be transferred to the rest of the body. Living tetrapods do not have gill slits; during embryonic development, the pharyngeal clefts instead give rise to parts of the ears, glands, and other structures. The ears are adapted to the detection of airborne sounds.

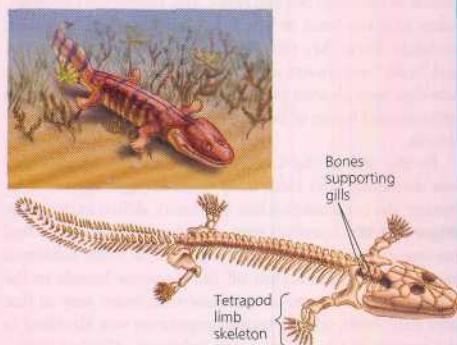

As you will see, some of these characters were dramatically altered or lost in various lineages of tetrapods. For example, in birds the pectoral limbs became wings, while in whales the entire body converged toward a fishlike shape.

The Origin of Tetrapods

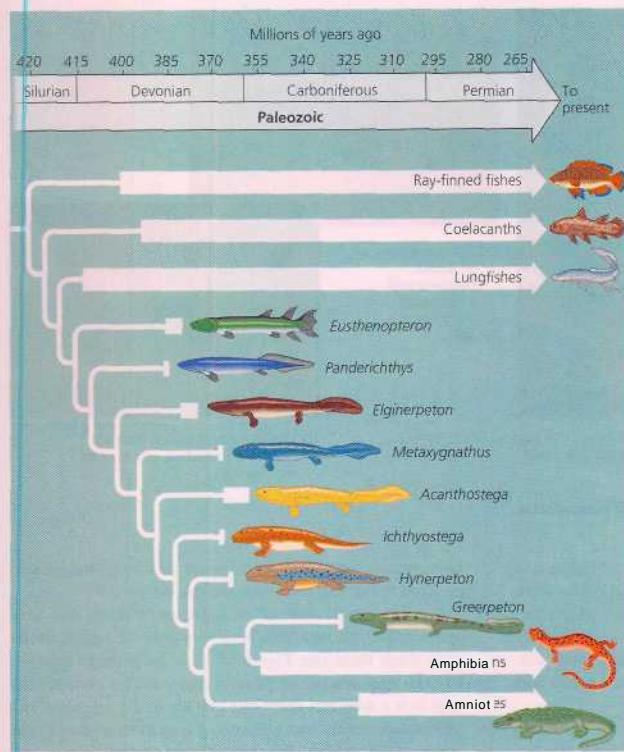

As you have learned, the Devonian coastal wetlands were home to a wide range of lobe-fins. Those that entered particularly shallow, oxygen-poor water could use their lungs to breathe air. Some species probably used their stout fins to help them move across logs or the muddy bottom. Thus, the tetrapod body plan did not evolve "out of nowhere" but was simply a modification of a preexisting body plan.

In one lineage of lobe-fins, the fins became progressively more limb-like while the rest of the body retained adaptations for aquatic life. For example, *Acanthostega*, a close relative of tetrapods that lived in Greenland 365 million years ago, had fully formed legs, ankles, and digits (Figure 34.19). Yet it also retained adaptations for the water. It had bones that supported gills, and it had rays in its tail that supported a delicate fin that propelled it through water. Its pectoral and pelvic girdles were too weak to carry its body on land. *Acanthostega* may have slithered out of the water from time to time, but for the most part it was aquatic.

Extraordinary fossil discoveries over the past 20 years have allowed paleontologists to reconstruct the origin of tetrapods with confidence for the first time (Figure 34.20). A great diversity of tetrapods emerged during the Carboniferous period, and some species reached 2 m in length. Judging from the morphology and locations of their fossils, most of these early tetrapods probably remained tied to the water, a feature they share with some members of a group of living tetrapods called amphibians.

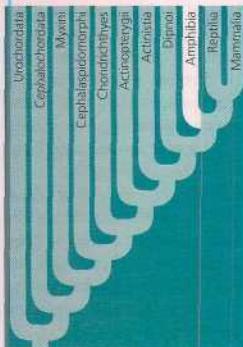

A. Figure 34.19 *Acanthostega*, a Devonian relative of tetrapods. Along with the derived appendages of tetrapods, *Acanthostega* retained primitive aquatic adaptations, such as gills.

▲ Figure 34.20 The origin of tetrapods. The bars on the branches of this diagram place known fossils in time; arrows indicate lineages that extend to today. The drawings of extinct forms are based on fossilized skeletons, but the colors are fanciful.

Vmphibians

Amphibians (class *Amphibia*) are represented today by about 4,800 species of salamanders (order *Urodela*, which means "tailed ones"), frogs (order *Anura*, meaning "tail-less ones"), and caecilians (order *Apoda*, meaning "legless ones")-

There are only about 500 species of urodeles. Some are entirely aquatic, but others live on land as adults or throughout life

(Figure 34.21a). Most salamanders that live on land walk with a side-to-side bending of the body inherited from the early terrestrial tetrapods. Paedomorphism is common among aquatic salamanders; the mudpuppy (*Necturus*), for instance, retains larval features when sexually mature (see Figure 24.23).

Anurans, numbering nearly 4,200 species, are more specialized than urodeles for moving on land (Figure 34.21b). Adult frogs use their powerful hind legs to hop along the terrain. A frog nabs insects by flicking out its long, sticky tongue, which is attached to the front of the mouth. Frogs display a great variety of adaptations that help them avoid being eaten by larger predators. Their skin glands secrete distasteful or even poisonous mucus. Many poisonous species have bright coloration, which predators apparently associate with danger (see Figure 53.6). Other frogs have color patterns that camouflage (see Figure 53.5).

▼ **Figure 34.21 Amphibians.**

(a) Order Urodela. Urodeles (salamanders) retain their tail as adults.

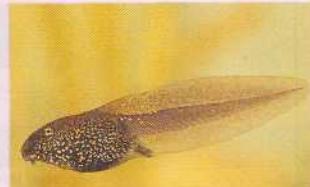

(b) Order Anura. Anurans, such as this poison arrow frog, lack a tail as adults.

(c) Order Apoda. Apodans, or caecilians, are legless, mainly burrowing amphibians.

(a) The male grasps the female, stimulating her to release eggs. The eggs are laid and fertilized in water. They have a jelly coat but lack a shell and would desiccate in air.

(b) The tadpole is an aquatic herbivore with a fishlike tail and internal gills.

(c) During metamorphosis, the gills and tail are resorbed, and walking legs develop.

A Figure 34.22 The "dual life" of a frog (*Rana temporaria*).

Apodans, the caecilians (about 180 species), are legless and nearly blind, and superficially they resemble earthworms (Figure 34.21c). Their absence of legs is a secondary adaptation, as they evolved from a legged ancestor. Caecilians inhabit tropical areas where most species burrow in moist forest soil. A few South American species live in freshwater ponds and streams.

Amphibian means "two lives," a reference to the metamorphosis of many frog species (Figure 34.22). The larval stage of a frog, called a tadpole, is usually an aquatic herbivore with gills, a lateral line system resembling that of aquatic vertebrates, and a long, finned tail. The tadpole initially lacks legs and swims by undulating its tail. During the metamorphosis that leads to the "second life," the tadpole develops legs, lungs, a pair of external eardrums, and a digestive system adapted to a carnivorous diet. At the same time, the gills disappear; the lateral line system also disappears in most species. The young frog crawls onto shore and becomes a terrestrial hunter. In spite of their name, however, many amphibians do not live a dualistic—aquatic and terrestrial—life. There are some strictly aquatic or strictly terrestrial frogs, salamanders, and caecilians. Moreover, salamander and caecilian larvae look much like adults, and typically both the larvae and the adults are carnivorous.

Most amphibians are found in damp habitats such as swamps and rain forests. Even those that are adapted to drier habitats spend much of their time in burrows or under moist leaves, where the humidity is high. Amphibians generally rely heavily on their moist skin for gas exchange with the

environment. Some terrestrial species lack lungs and breathe exclusively through their skin and oral cavity.

Fertilization is external in most amphibians; the male grasps the female and spills his sperm over the eggs as the female sheds them (see Figure 34.22a). Amphibians typically lay their eggs in water or in moist environments on land. The eggs lack a shell and dehydrate quickly in dry air. Some anuran species lay vast numbers of eggs in temporary pools, and mortality is high. In contrast, other species lay relatively few eggs and display various types of parental care. Depending on the species, either males or females may house eggs on their back, in their mouth, or even in their stomach. Certain tropical tree frogs stir their egg masses into moist, foamy nests that resist drying. There are also some ovoviparous and viviparous species that retain the eggs in the female reproductive tract, where embryos can develop without drying out.

Many amphibians exhibit complex and diverse social behaviors, especially during their breeding seasons. Frogs are usually quiet, but the males of many species vocalize to defend their breeding territory or to attract females. In some species, migrations to specific breeding sites may involve vocal communication, celestial navigation, or chemical signaling.

Over the past 25 years, zoologists have documented a rapid and alarming decline in amphibian populations throughout the world. There appear to be several causes, including habitat degradation, the spread of a fungal (chytrid) pathogen, and acid precipitation. The last of these is especially damaging to most amphibians because of their dependence on wet places for completing their life cycles.

Concept Check 34.5

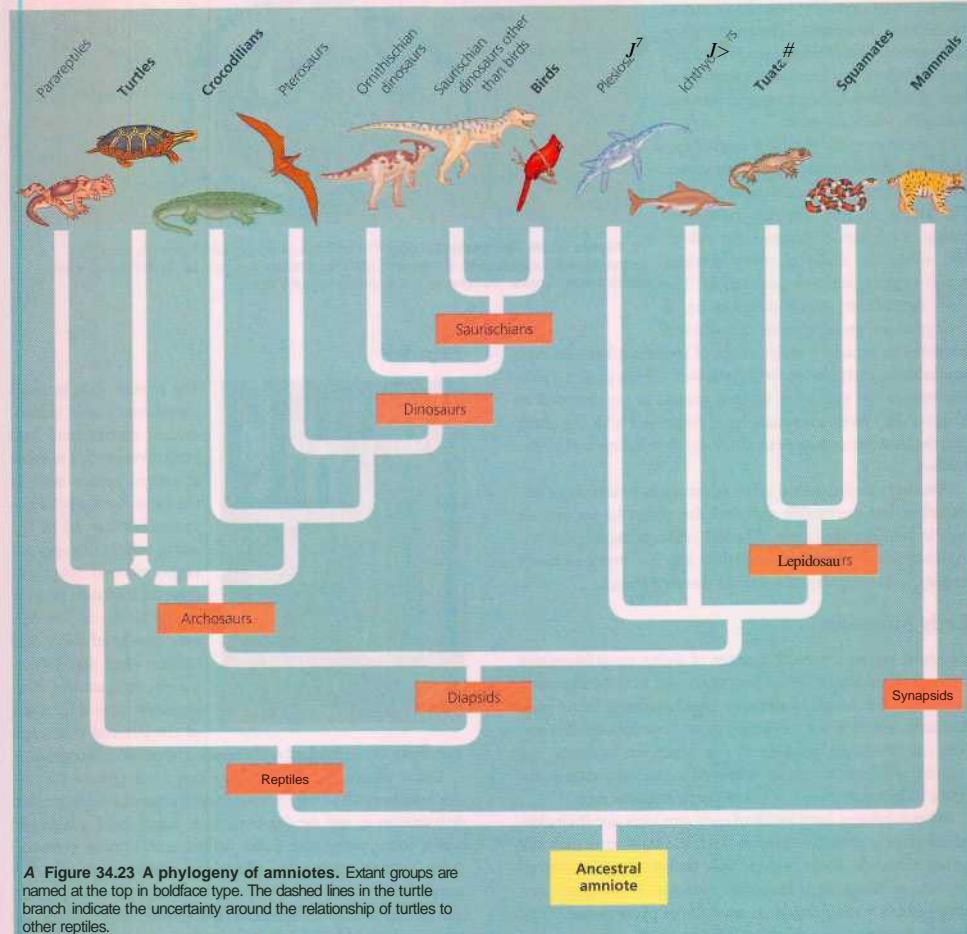

- Was *Acanthostega* a terrestrial tetrapod? Explain your answer.
- Some amphibians never leave the water, whereas others can survive in relatively dry terrestrial environments. Contrast the adaptations that facilitate these two lifestyles.

For suggested answers, see Appendix A.

Concept 34.6

Amniotes are tetrapods that have a terrestrially adapted egg

Amniotes are a group of tetrapods whose living members are the reptiles (including birds) and the mammals (**Figure 34.23**). During their evolution, amniotes acquired a number of new adaptations to life on land.

A Figure 34.23 A phylogeny of amniotes. Extant groups are named at the top in boldface type. The dashed lines in the turtle branch indicate the uncertainty around the relationship of turtles to other reptiles.

Derived Characters of Amniotes

Amniotes are named for the major derived character of the clade, the amniotic egg.

which contains specialized membranes that protect the embryo (Figure 34.24). Called extraembryonic membranes be-

cause they are not part of the body of the embryo itself, these membranes develop **around** the embryo. They function in gas exchange, waste storage, and the transfer of stored nutrients to the embryo. The amniotic egg is named for one of these membranes, the amnion, which encloses a compartment of fluid that bathes the embryo and acts as a hydraulic shock absorber.

In contrast to the shell-less eggs of amphibians, the amniotic eggs of most reptiles and some mammals have a shell. The shells of bird eggs are calcareous (made of calcium carbonate) and inflexible, while the shells of many nonbird reptile eggs are leathery and flexible. The shell significantly slows dehydration of the egg in air, an adaptation that allowed amniotes to occupy a wider range of terrestrial habitats than amphibians, their closest living relatives. (Seeds played a similar role in the evolution of land plants, as you learned in Chapter 29.) Most mammals have dispensed with the shell, and the embryo avoids desiccation by developing within the mother.

Amniotes also acquired other adaptations to terrestrial life, including less permeable skin and the ability to use the rib cage to ventilate the lungs. Whereas earlier tetrapods and living amphibians generally sprawl their legs out, living amniotes display, to varying degrees, a more elevated stance.

Early Amniotes

The most recent common ancestor of living amphibians and amniotes lived about 340 million years ago, in the Carboniferous period. No fossils of amniotic eggs have been found from that time, which is not surprising given how delicate they are. Thus, it is not yet possible to say when the amniotic egg evolved, although it must have existed in the last common ancestor of living amniotes, which all have amniotic eggs.

What is evident from fossils of early amniotes and their closest relatives is that they lived in drier environments than did earlier tetrapods. Some of them were herbivores, as evidenced by their grinding teeth and other features. Herbivorous amniotes began consuming large amounts of plant matter. They, in turn, became prey for large predatory amniotes.

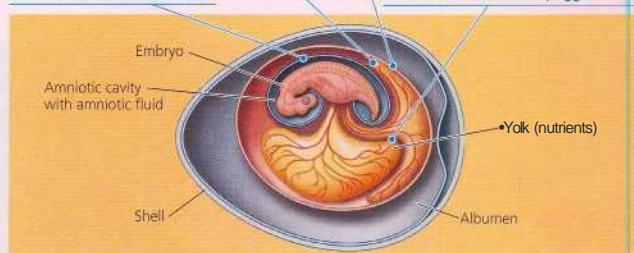

Extraembryonic membranes

Allantois. The allantois is a disposal sac for certain metabolic wastes produced by the embryo. The membrane of the allantois also functions with the chorion as a respiratory organ.

Amnion. The amnion protects cavity that cushions against mechanical shock.

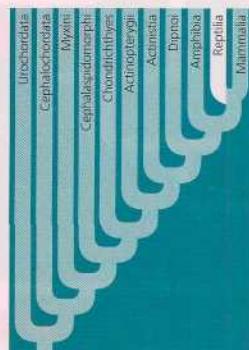

Chorion. The chorion and the membrane of the allantois exchange gases between the embryo and the air. Oxygen and carbon dioxide diffuse freely across the shell.

Yolk sac. The yolk sac contains the yolk, a stockpile of nutrients. Elongated vessels in the yolk sac membrane transport nutrients from the yolk into the embryo. Other nutrients are stored in the albumen ("egg white").

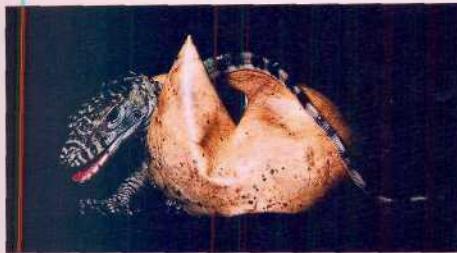

A Figure MM This amniote egg. The embryos of reptiles and mammals form four extraembryonic membranes: the amnion, allantois, chorion, and yolk sac. This drawing shows these extraembryonic membranes in the shelled egg of a reptile.

Reptiles

The reptile clade includes the tuatara, lizards, snakes, turtles, crocodilians, and birds, along with a number of extinct groups such as the large nonflying dimosaurs. Because all of the living reptile lineages are highly derived, none can serve as a straightforward model for the earliest reptiles that lived some 320 million years ago. Nevertheless, comparative studies allow us to infer some of the derived characters that likely distinguished early reptiles from other tetrapods.

Unlike amphibians, reptiles have scales that contain the protein keratin. Scales create a waterproof barrier that helps prevent dehydration in dry air. (In crocodiles, which have adapted to water, more permeable scales, called scutes, have evolved.) Scales prevent reptiles from breathing through their skin like amphibians; most reptiles rely on their lungs alone for gas exchange. Turtles are the exception to this rule; many turtles still use the moist surfaces of their cloaca for gas exchange.

A Figure 34.25 A hatching reptile. This Komodo dragon is breaking out of a parchment-like shell, a common type of shell among living reptiles other than birds.

Most reptiles lay shelled eggs on land (Figure 34.25). Fertilization must occur internally, before the shell is secreted. Many species of snakes and lizards are viviparous; their extraembryonic membranes form a placenta that enables the embryo to obtain nutrients from its mother.

Many reptiles are sometimes said to be "cold-blooded" because they do not use their metabolism extensively to control their body temperature. However, they do regulate their body temperature by using behavioral adaptations. For example, many lizards bask in the sun when the air is cool and seek shade when the air is too warm. A more accurate description of these reptiles is to say that they are ectothermic, which refers to the absorption of external heat as the main source of body heat. (This topic is discussed in more detail in Chapter 40.) By heating directly with solar energy rather than through the metabolic breakdown of food, an ectothermic reptile can survive on less than 10% of the food energy required by a mammal of the same size. The reptile clade is not entirely ectothermic; birds are endothermic, capable of keeping the body warm through metabolism.

The Origin and Evolutionary Radiation of Reptiles

The oldest reptilian fossils, found in rocks from Kansas, date from the end of the Carboniferous period, about 300 million years ago. The first major group of reptiles to emerge were the parareptiles, which were mostly large, stocky, quadrupedal herbivores. Some parareptiles had dermal plates on their skin that may have provided them with defense against predators (mainly synapsids, the ancestors of mammals, which you will learn about later in this chapter). Parareptiles died out by about 200 million years ago, at the end of the Triassic period, some systematists have proposed that parareptiles gave rise to turtles, pointing to the possible homology of parareptile dermal plates and turtle shells. But molecular studies point to different reptilian origins for turtles. The subject remains controversial among experts.

As parareptiles were dwindling, an equally ancient clade of reptiles, the diapsids, was diversifying. One of the most obvious derived characters of diapsids is a pair of holes on each side of the skull, behind the eye socket. The diapsids are composed of two main lineages. One lineage gave rise to the lepidosaurs, which include tuataras, lizards, and snakes. This lineage also produced a number of marine reptiles, including plesiosaurs and ichthyosaurs (see Figure 34.23), some of which rivaled today's whales in length; all of them are extinct. (We'll say more about living lepidosaurs shortly.)

The other diapsid lineage, the archosaurs, produced the crocodilians (which we'll discuss later) and many extinct groups, including the pterosaurs and some dinosaurs. Pterosaurs, which originated in the late Triassic, were the first tetrapods to take to the air. The pterosaur wing was completely different from the wings of birds and bats. It consisted of a bristle-covered membrane stretched between the trunk or hind leg and a very long digit on the foreleg. Well-preserved fossils show the presence of muscles, blood vessels, and nerves in the wing membranes, suggesting that pterosaurs could dynamically adjust their membranes to assist their flight.

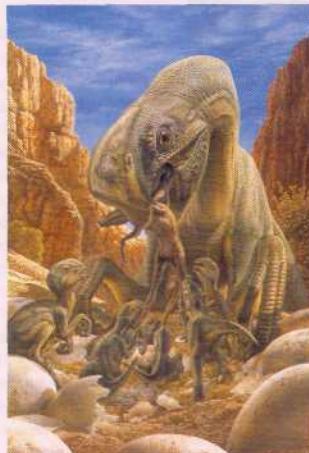

The smallest pterosaurs were no bigger than a gull, and the largest had a wingspan of nearly 11 m. They appear to have converged on many of the ecological roles later played by birds; some were insect-eaters, others grabbed fish out of the ocean, and still others filtered small animals through a long beak. By the end of the Cretaceous period 65 million years ago, pterosaurs had become extinct.

On land, the dinosaurs diversified into a vast range of shapes and sizes, from bipeds the size of a pigeon to 45-m-long quadrupeds with a neck long enough to let them browse the tops of trees. One branch of dinosaurs, the ornithischians, were herbivores; they included many species with elaborate defenses against predators, such as tail clubs and horned crests. The other main branch of dinosaurs, the saurischians, included the long-necked giants and a group called the theropods, which were bipedal carnivores. Theropods included the famous *Tyrannosaurus rex* as well as the ancestors of birds.

There is continuing debate about the metabolism of dinosaurs. Some researchers have pointed out that the Mesozoic climate over much of the dinosaurs' range was relatively warm and consistent, and they have suggested that the low surface-to-volume ratios of large dinosaurs combined with behavioral adaptations such as basking may have been sufficient for an ectotherm to maintain a suitable body temperature. However, some anatomical evidence supports the hypothesis that at least some dinosaurs were endotherms. Furthermore, paleontologists have found fossils of dinosaurs in both Antarctica and the Arctic; although the climate in these areas was milder when dinosaurs existed than it is today, it was cool enough that small dinosaurs may have had difficulty maintaining a high body temperature through ectothermy. The dinosaur that gave rise to birds was *certainly* endothermic, as are all birds.

A Figure 34.26 Dinosaur parental care.
A fossil of a nesting dinosaur and her eggs found in Mongolia sheds light on how dinosaurs cared for their eggs and hatchlings. Known as *Oviraptor*, this dinosaur, which lived 80 million years ago, covered her eggs with her limbs, which may have been feathered.

Traditionally, dinosaurs were considered slow, sluggish creatures. Since the early 1970s, however, fossil discoveries and research have led to the conclusion that many dinosaurs were agile, fast moving, and, in some cases, social. Paleontologists have also discovered signs of parental care among dinosaurs (**Figure 34.26**).

All dinosaurs (except birds) became extinct by the end of the Cretaceous period. However, the fossil record indicates that the number of dinosaur species had begun to decline several million years before the Cretaceous ended. It is unclear whether the extinction of dinosaurs was hastened by the asteroid or comet impact you read about in Chapter 26, as many other terrestrial vertebrates, including most mammals, survived.

Lepidosaurs

One surviving lineage of lepidosaurs is represented by two species of lizard-like reptiles called tuatara (**Figure 34.27a**). Tuatara relatives lived at least 220 million years ago, and they thrived on many continents well into the Cretaceous period, reaching up to a meter in length. Today, however, tuatara are found only on 30 islands off the coast of New Zealand. When humans arrived in New Zealand 750 years ago, the rats that accompanied them devoured tuatara eggs, eventually eliminating the reptiles on the main islands. The tuatara that remain on the outlying islands are about 50 cm long and feed on insects, small lizards, and bird eggs and chicks. They can live to be over 100 years old. Their survival depends on whether their remaining habitats are kept rat-free.

The other major living lineage of lepidosaurs are the squamates (lizards and snakes). Lizards are the most numerous and diverse reptiles (apart from birds) alive today (**Figure 34.27b**).

Most lizards are small; the jaragua lizaril, discovered in the Dominican Republic in 2001, is only 16 mm long—small enough to fit comfortably on a dime. In contrast, the Komodo dragon of Indonesia can reach a length of 3 m. It hunts deer and other large prey, delivering deadly bacteria with its bile. As its wounded prey dies of the infection, the lizard slowly stalks it.

Snakes are legless lepidosaurs that evolved from lizards closely related to the Komodo dragon (**Figure 34.27c**). Today some species of snakes retain vestigial pelvic and limb bones, which provide evidence of their ancestry.

Despite their lack of eggs, snakes are quite proficient at moving on land, most often by producing waves of lateral bending that pass from head to tail. Force exerted by the bends against solid objects pushes the snake forward. Snakes can also move by gripping the ground with their belly scales at several points along the body, while the scales at intervening points are lifted slightly off the ground and pulled forward.

Snakes are carnivorous, and a number of adaptations aid them in hunting and eating prey. They have acute chemical sensors, and though they lack eardrums, they are sensitive to ground vibrations, which helps them detect the movements of prey. Heat-detecting organs between the eyes and nostrils of pit vipers, including rattlesnakes, are sensitive to minute temperature changes, enabling these night hunters to locate warm animals. Poisonous snakes inject their toxin through a pair of sharp, hollow or grooved teeth. The flicking tongue is not poisonous but helps fan odors toward olfactory (smell) organs on the roof of the mouth. Loosely articulated jaws and elastic skin enable most snakes to swallow prey larger than the diameter of the snake itself.

Turtles

Turtles are the most distinctive group of reptiles alive today. All turtles have a boxlike shell made of upper and lower shields that are fused to the vertebrae, clavicles (collarbones) and ribs (**Figure 34.27d**). In most species, the shell is hard, providing excellent defense against predators. The earliest fossils of turtles, dating from about 220 million years ago, have fully developed shells. Without transitional fossils to analyze, the origin of the turtle shell remains a puzzle. As mentioned earlier, some paleontologists have suggested that turtle shells evolved from the dermal plates of parareptiles. But other studies have linked turtles to archosaurs or lepidosaurs.

The earliest turtles could not retract their head into their shell, but mechanisms for doing so evolved independently in two separate branches of turtles. The side-necked turtle

(e) American alligator (*Alligator mississippiensis*)

k Figure 34.27 Extant reptiles (other than birds).

(pleurodires) fold their neck horizontally, while the vertical-necked turtles (cryptodires) fold their neck vertically.

Some turtles have adapted to deserts, and others live almost entirely in ponds and rivers. Still others have returned to the sea. Sea turtles have a reduced shell and enlarged forelimbs that function as flippers. This radiation has produced the largest living turtles, the leatherbacks, which can weigh over 1,500 kg. Feeding on jellies, they dive as deep as 60 m. Leatherbacks and other sea turtles are endangered by fishing boats that accidentally catch them in their nets, as well as by the human development of the beaches where the turtles lay their eggs.

the southeastern United States. Alligators in the United States have made a strong comeback after spending years on the endangered species list.

Birds

There are 8,600 species of birds in the world. Like crocodilians, birds are archosaurs, but almost every feature of their reptilian anatomy has undergone modification in their adaptation to flight.

Derived Characters of Birds

Many of the characters of birds are adaptations that facilitate flight, including weight-saving modifications that make flying more efficient. For example, birds lack a urinary bladder, and the females of most species have only one ovary. The gonads of both females and males are usually small, except during the breeding season, when they increase in size. Living birds are also toothless, an adaptation that trims the weight of the head. The skull is especially light, although a bird's skeleton as a whole is no lighter in relation to body weight than the skeleton of a mammal of similar size.

Alligators and Crocodiles

Alligators and crocodiles (collectively called crocodilians) belong to an archosaur lineage that reaches back to the late Triassic (Figure 34.27e). The earliest members of this lineage were small terrestrial quadrupeds with long, slender legs. Later species became larger and adapted to aquatic habitats, breathing air through their upturned nostrils. Some Mesozoic crocodilians grew as long as 10 m and may have attacked large dinosaurs.

Living crocodilians are confined to the warm regions of Africa, China, Indonesia, India, Australia, South America, and

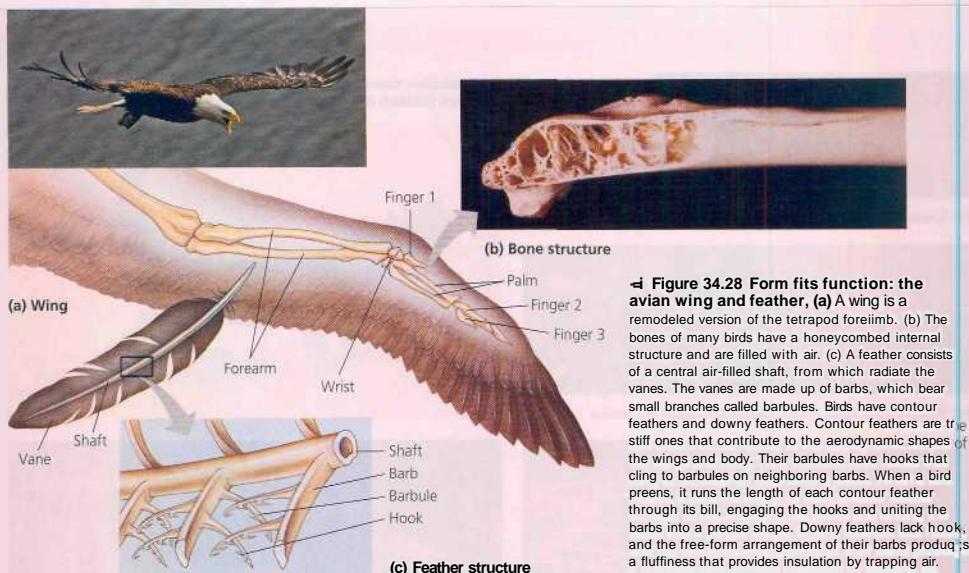

Figure 34.28 Form fits function: the avian wing and feather. (a) A wing is a remodeled version of the tetrapod forelimb. (b) The bones of many birds have a honeycombed internal structure and are filled with air. (c) A feather consists of a central air-filled shaft, from which radiate the vanes. The vanes are made up of barbs, which bear small branches called barbules. Birds have contour feathers and downy feathers. Contour feathers are stiff ones that contribute to the aerodynamic shapes of the wings and body. Their barbules have hooks that cling to barbules on neighboring barbs. When a bird preens, it runs the length of each contour feather through its bill, engaging the hooks and uniting the barbs into a precise shape. Downy feathers lack hook, and the free-form arrangement of their barbs produces a fluffiness that provides insulation by trapping air.

A bird's most obvious adaptations for flight are its wings and feathers (Figure 34.28). Feathers are made of a protein called P-keratin that is also found in the scales of other reptiles. The shape and arrangement of the feathers form the wings into airfoils, which illustrate some of the same principles of aerodynamics as the wings of an airplane. Power for flapping the wings comes from contractions of large pectoral (breast) muscles anchored to a keel on the sternum (breastbone). Some birds, such as eagles and hawks, have wings adapted for soaring on air currents and flap their wings only occasionally (see Figure 34.28); other birds, including hummingbirds, must flap continuously to stay aloft. The fastest birds are the appropriately named swifts, which can fly 170 km/hr.

The evolution of flight provides numerous benefits. It enhances hunting and scavenging; many birds consume flying insects, an abundant, highly nutritious food resource. Flight also provides ready escape from earthbound predators and enables some birds to migrate great distances to exploit different food resources and seasonal breeding areas.

Flying requires a great expenditure of energy from an active metabolism. Birds are endothermic; they use their own metabolic heat to maintain a high, constant body temperature. Feathers and in some species a layer of fat provide insulation that enables birds to retain body heat. An efficient respiratory system and a circulatory system with a four-chambered heart keep tissues well supplied with oxygen and nutrients, supporting a high rate of metabolism. The lungs have tiny tubes leading to and from elastic air sacs that help dissipate heat and reduce the density of the body.

Flight also requires both acute vision and fine muscle control. Birds have excellent eyesight, perhaps the best of all the vertebrates. The visual areas of the brain are well developed, as are the motor areas. The avian brain is proportionately larger than those of amphibians and nonbird reptiles.

Birds generally display very complex behaviors, particularly during breeding season, when they engage in elaborate courtship rituals. Because eggs are shelled when laid, fertilization must be internal. Copulation usually involves contact between the mates' vents, the openings to their cloacas. After eggs are laid, the avian embryo must be kept warm through brooding by the mother, father, or both, depending on the species.

The Origin of Birds

Cladistic analyses of birds and of reptilian fossils strongly suggest that birds belong to the group of bipedal saurischians called theropods. Since the late 1990s, Chinese paleontologists have unearthed a spectacular trove of feathered theropod fossils that are shedding light on the first birds. Several species of dinosaurs closely related to birds had feathers with vanes, and a wider range of species had filamentous feathers. Such findings imply that feathers evolved long before powered flight. Among the possible functions of these early feathers were insulation, camouflage, and courtship display.

Scientists have investigated two possible ways in which powered flight may have evolved in theropods. In one scenario, feathers may have enabled small, ground-running dinosaurs chasing prey or escaping predators to gain extra lift in

▲ Figure 34.29 Artist's reconstruction of *Archaeopteryx*, the earliest known bird. Fossil evidence indicates that *Archaeopteryx* was capable of powered flight but retained many characters of nonbird dinosaurs.

they jumped into the air. In another scenario, some dinosaurs could climb trees and glide, aided by feathers.

By 150 million years ago, feathered theropods had evolved into birds. *Archaeopteryx*, which was discovered in a German limestone quarry in 1861, remains the earliest known bird (figure 34.29). It had feathered wings but retained primitive characters such as teeth, clawed digits in its wings, and a long tail. Most experts agree that *Archaeopteryx* was a weak flyer at best. Fossils of a number of other birds from the Cretaceous period show a gradual loss of certain features of dinosaur anatomy, such as teeth, as well as the acquisition of innovations that are shared by all birds today, including a short tail covered by a fan of feathers.

Living Birds

Clear evidence of Neomithes, the clade that includes the 28 orders of living birds, can be found after the Cretaceous-Paleogene boundary 65.5 million years ago. Most birds can fly, yet there are several orders that include one or more flightless species. The ratites (order Struthioniformes), which consist of the ostrich, rhea, kiwi, cassowary, and emu, are all flightless. In penguins (from the Latin *ratis*, flat-bottomed), the sternal keel is absent, and the pectoral muscles are not greatly enlarged (figure 34.30a). Penguins make up the flightless order Sphenisciformes, but, like flying birds, they have powerful pectoral muscles, which they use in swimming. Certain species of frails, ducks, and pigeons are also flightless.

The demands of flight have rendered the general body form of many flying birds similar to one another, yet experienced

V Figure 34.30 A small sample of living birds.

(a) **Emu.** This ratite lives in Australia.

(b) **Mallards.** Like many bird species, the mallard exhibits pronounced color differences between the sexes.

(c) **Laysan albatrosses.** Like most birds, Laysan albatrosses have specific mating behaviors, such as this courtship ritual.

(d) **Barn swallows.** The barn swallow is a member of the order Passeriformes. Species in this order are called perching birds because the toes of their feet can lock around a branch or wire, enabling the bird to rest in place for long periods.

A Figure 34.31 Diversity of form and function in bird feet.

bird-watchers can distinguish different species by their body profile, flying style, behavior, feather colors, and beak shape (**Figure 34.30b, c, and d**). The beak has proved to be very adaptable during avian evolution, taking on a great variety of shapes suitable for different diets. Foot structure, too, shows considerable variation (**Figure 34.31**). Various birds use their feet for perching on branches, grasping food, defense, swimming or walking, and even courtship (see Figure 24.4e).

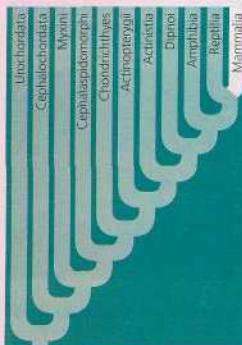

Concept Check 34.6

1. Defend or refute the following statement: The amniotic egg of a reptile is a closed system in which the embryo develops in isolation from the outside environment.
2. Identify four avian adaptations for flight.

For suggested answers, see Appendix A.

Concept 34.7

Mammals are amniotes that have hair and produce milk

Reptiles (including birds) represent one of two great lineages of amniotes. The other lineage is our own, the mammals (class Mammalia). Today, there are more than 5,000 species of mammals on Earth.

Derived Characters of Mammals

Mammary glands, which produce milk for offspring, are a distinctively mam-

malian character. All mammalian mothers nourish their young with milk, a balance of diet rich in fats, sugars, proteins, minerals, and vitamins. Hair, another mammalian characteristic, and a fat layer under the skin help the body retain heat. Like birds, mammals are endothermic, and most have a high metabolic rate. Efficient respiratory and circulatory systems (including a four-chambered heart) support a mammal's metabolism. A sheet of muscle called the diaphragm helps ventilate the lungs.

Mammals generally have a larger brain than other vertebrates of equivalent size, and many species are capable learners. The relatively long duration of parental care extends the time for offspring to learn important survival skills by observing their parents.

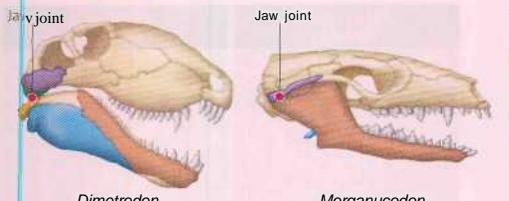

Differentiation of teeth is another important mammalian trait. Whereas the teeth of reptiles are generally conical and uniform in size, the teeth of mammals come in a variety of sizes and shapes adapted for chewing many kinds of food. Humans, for example, have teeth modified for shearing (incisors and canine teeth) and for crushing and grinding (premolars and molars).

Early Evolution of Mammals

Mammals belong to a group of amniotes known as synapsids. Nonmammalian synapsids lacked hair, had a sprawling gait, and laid eggs. A distinctive characteristic of synapsids is the temporal fenestra, a hole behind the eye socket on each side of the skull. Humans retain this feature; your jaw muscles pass through the temporal fenestra and anchor on your temple. The jaw was remodeled during the evolution of mammals from nonmammalian synapsids, and two of the bones that formerly made up the jaw joint were incorporated into the mammalian middle ear (**Figure 34.32**).

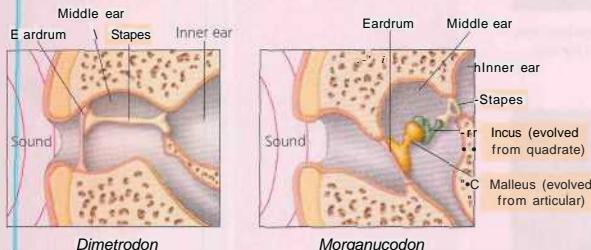

Synapsids evolved into large herbivores and carnivores during the Permian period, and for a time they were the dominant tetrapods. However, the Permian-Triassic extinction took a heavy toll on them, and their diversity fell during the Triassic. Mammal-like synapsids emerged by the end of the Triassic 200 million years ago. While not true mammals, these synapsids had acquired a number of the derived characters that distinguish mammals from other amniotes. They were small and probably hairy, and they likely fed on insects at night. They probably had a higher metabolism than other synapsids, but they still laid eggs.

During the Jurassic period, the first true mammals arose and diversified into a number of lineages, many of which are extinct. Yet throughout the Mesozoic era, nearly all mammals remained about the size of today's shrews. One possible explanation for

| Key |
|-----------|
| Dentary |
| Angular |
| Squamosal |
| Articular |
| Quadratae |

- (a) The lower jaw of *Dimetrodon* is composed of several fused bones; two small bones, the quadrate and articular, form part of the jaw joint. In *Morganucodon*, the lower jaw is reduced to a single bone, the dentary, and the location of the jaw joint has shifted.

- (b) During the evolutionary remodeling of the mammalian skull, the quadrate and articular bones became incorporated into the middle ear as two of the three bones that transmit sound from the eardrum to the inner ear. The steps in this evolutionary remodeling are evident in a succession of fossils.

▲ **Figure 34.32 The evolution of the mammalian jaw and ear bones.** *Dimetrodon* was an early synapsid, a reptile-like lineage that eventually gave rise to the mammals. *Morganucodon* was a mammaliform, a close relative of living mammals that lived 200 million years ago.

their small size is that dinosaurs already occupied ecological niches of large-bodied animals.

During the Mesozoic, the three major lineages of living mammals emerged: monotremes (egg-laying mammals), marsupials (mammals with a pouch), and eutherians (placental mammals). After the extinction of large dinosaurs, pterosaurs, and marine reptiles during the late Cretaceous period, mammals underwent an adaptive radiation, giving rise to large predators and herbivores, as well as flying and aquatic species.

Monotremes

Monotremes are found only in Australia and New Guinea and are represented by one species of platypus and two species of echidnas (spiny anteaters). Monotremes lay eggs, a character that is primitive for amniotes and retained in most reptiles (Figure 34.33). Like all mammals, monotremes have hair and produce milk, but they lack nipples. Milk is secreted by glands on the belly of the mother. After hatching, the baby sucks the milk from the mother's fur.

Marsupials

Opossums, kangaroos, and koalas are examples of marsupials. Both marsupials and eutherians share derived characters not found among monotremes. They have a higher metabolic rate and nipples that provide milk, and they give birth to live young. The embryo develops inside the uterus of the female's reproductive tract. The lining of the uterus and the extraembryonic membranes that arise from the embryo form a placenta, a structure in which nutrients diffuse into the embryo from the mother's blood.

A marsupial is born very early in its development and completes its embryonic development while nursing. In most species, the nursing young are held within a maternal pouch called a marsupium (Figure 34.34a, on the next page). A red kangaroo, for instance, is about the size of a honeybee at its birth, just 33 days after fertilization. Its hind legs are merely buds, but its forelegs are strong enough for it to crawl from the exit of its mother's reproductive tract to a pouch that opens to the front of her body, a journey that lasts a few minutes. In other species, the marsupium opens to the rear of the mother's body; in bandicoots this protects the young as they crawl through the dirt (Figure 34.34b, on the next page.)

▲ **Figure 34.33 Short-beaked echidna (*Tachyglossus aculeatus*), an Australian monotreme.** Monotremes have hair and produce milk, but they lack nipples. Monotremes are the only mammals that lay eggs (inset).

(a) A young brushtail possum. The young of marsupials are born very early in their development. They finish their growth while nursing from a nipple (in their mother's pouch in most species).

(b) Long-nosed bandicoot. Most bandicoots are diggers and burrowers who eat mainly insects but also some small vertebrates and plant material. Their rear-opening pouch helps protect the young from dirt as the mother digs. Other marsupials, such as kangaroos, have a pouch that opens to the front.

A Figure 34.34 Australian marsupials.

Marsupials existed worldwide during the Mesozoic era, but today they are found only in the Australian region and in North and South America. The biogeography of marsupials is an example of the interplay between biological and geologic evolution (see Chapter 26). Alter the breakup of Pangaea, South America and Australia became island continents, and their marsupials diversified in isolation from the eutherians that began an adaptive radiation on the northern continents. Australia has not been in contact with another continent since early in the Cenozoic era, about 65 million years ago. In Australia, convergent evolution has resulted in a diversity of marsupials that resemble eutherians in similar ecological niches in other parts of the world (**Figure 34.35**). Although South America had a diverse marsupial fauna throughout the Paleogene, it

A Figure 34.35 Evolutionary convergence of marsupials and eutherians (placental mammals). (Drawings are not to scale.)

has experienced several migrations of eutherians. One of the most important migrations occurred about 3 million years ago, when North and South America joined at the Panamanian isthmus and extensive two-way traffic of animals took place over the land bridge. Today, only three families of marsupials live outside the Australian region, and only one species, the opossum, is found in North America.

Eutherians (Placental Mammals)

Eutherians are commonly called placental mammals because their placentas are more complex than those of marsupials. Compared to marsupials, eutherians have a longer period of pregnancy. Young eutherians complete their embryonic development within the uterus, joined to their mother by the placenta. The eutherian placenta provides an intimate and long-lasting association between the mother and her developing young.

The living orders of eutherians originated in the late Cretaceous period. **Figure 34.36**, on the next two pages, explores the major eutherian orders and their possible phylogenetic relationships with each other as well as with the monotremes and marsupials.

Primates

The mammalian order Primates includes the lemurs, the tarsiers, the monkeys, and the apes. Humans are members of the primate group.

Derived Characters of Primates. Most primates have hands and feet adapted for grasping, and their digits have flat nails instead of the narrow claws of other mammals. There are other characteristic features of the hands and feet, such as skin ridges on the fingers (which account for human fingerprints). Relative to other mammals, primates have a large brain and short jaws, giving them a flat face. Primates also have relatively well-developed parental care and complex social behavior.

The earliest primates were probably tree-dwellers, and many of the characteristics of primates are adaptations to the demands of living in the trees. Grasping hands and feet allow primates to hang onto tree branches. All modern primates, except humans, have a big toe that is widely separated from the other toes, enabling them to grasp branches with their feet. All primates have a thumb that is relatively mobile and separate from the fingers, but anthropoids (monkeys, apes, and humans) have a fully opposable thumb; that is, they can touch the ventral surface (fingerprint side) of the tip of all four fingers with the ventral surface of the thumb of the same hand. In monkeys and apes, the opposable thumb functions in a grasping "power grip," but in humans, a dis-

tinctive bone structure at the base of the thumb allows it to be used for more precise manipulation. The unique dexterity of humans represents descent with modification from our tree-dwelling ancestors. Arboreal maneuvering also requires excellent eye-hand coordination. The overlapping visual fields of the two eyes enhance depth perception, an obvious advantage when brachiating (traveling by swinging from branch to branch in trees).

Living Primates. There are three main groups of living primates: the lemurs of Madagascar (**Figure 34.37**) and the lorises and pottos of tropical Africa and southern Asia; the tarsiers, which live in Southeast Asia; and the anthropoids, which include monkeys and hominoids and are found worldwide. Lemurs, lorises, and pottos probably resemble early arboreal primates. The oldest known anthropoid fossils, discovered in China in mid-Eocene strata about 45 million years old, indicate that tarsiers are more closely related to anthropoids (**Figure 34.38**, on page 700). You will see in Figure 34.38 that monkeys do not constitute a monophyletic group.

The fossil record indicates that monkeys first appeared in the New World (in South America) during the Oligocene. By that time, South America and Africa had drifted apart. The first monkeys probably evolved in the Old World (in Africa and Asia), and they may have reached South America by rafting on logs or other debris from Africa. What is certain is that New World monkeys and Old World monkeys underwent separate adaptive radiations during their many millions of

type of lemur.

Figure 34.36
Exploring Mammalian Diversity

PHYLOGENETIC RELATIONSHIPS OF MAMMALS

Evidence from numerous fossils and molecular analyses indicates that monotremes diverged from other mammals about 200 million years ago and that marsupials diverged from eutherians (placental mammals) about 180 million years ago. Molecular systematics has

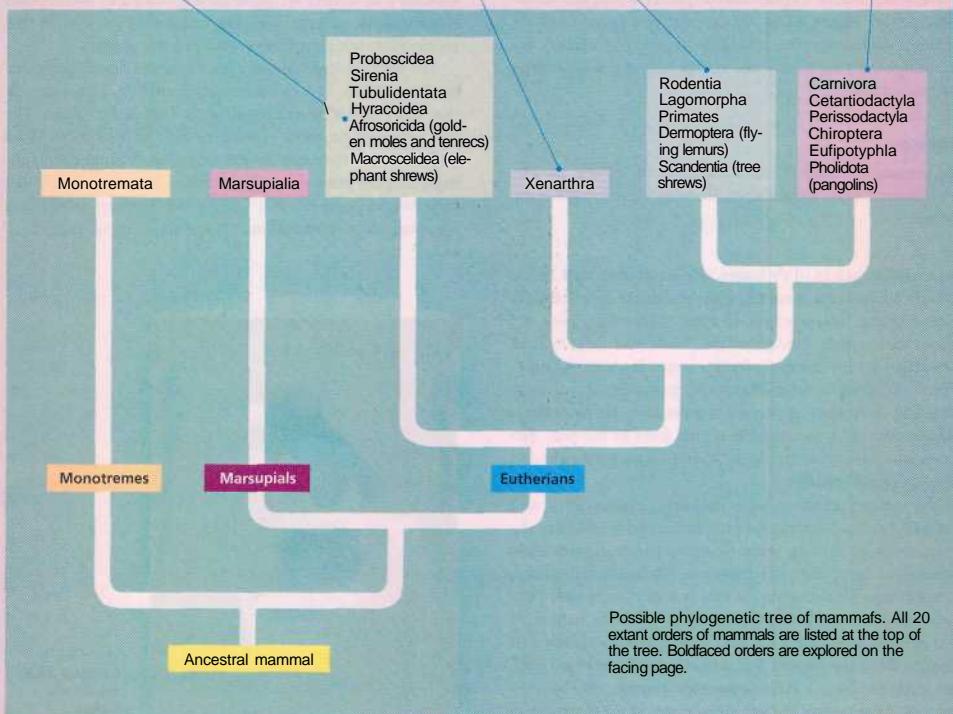

helped to clarify the evolutionary relationships between the eutherian orders, though there is still no broad consensus on a phylogenetic tree. One current hypothesis, represented by the tree shown below, clusters the eutherian orders into four main clades.

This clade of eutherians evolved in Africa when the continent was isolated from other landmasses. It includes Earth's largest living land animal (the African elephant), as well as species that weigh less than 10 g.

All members of this clade, which underwent an adaptive radiation in South America, belong to the order Xenarthra. One species, the nine-banded armadillo, is found in the southern United States.

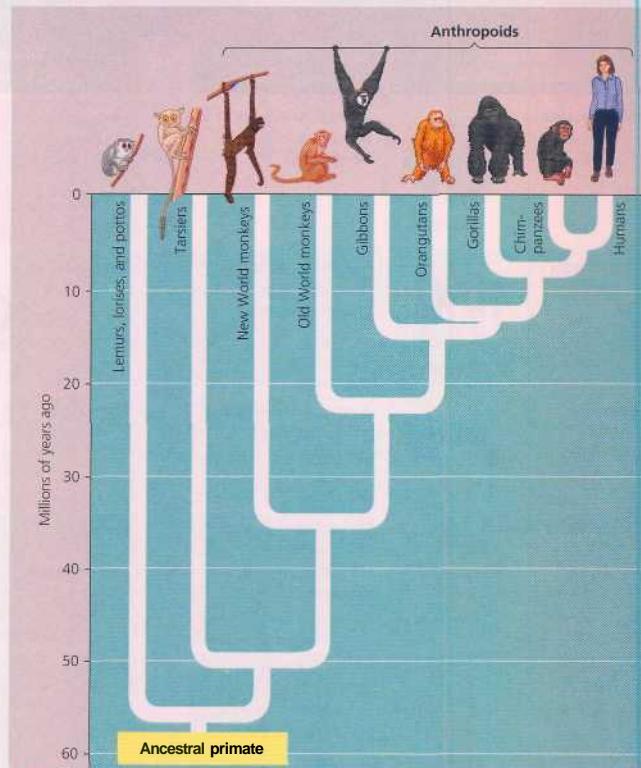

This is the largest eutherian clade. It includes the rodents, which make up the largest mammalian order by far, with about 1,770 species. Humans belong to the order Primates.

This diverse clade includes terrestrial and marine mammals as well as bats, the only flying mammals. A growing body of evidence, including Eocene fossils of whales with feet, supports putting whales in the same order (Cetartiodactyla) as pigs, cows, and hippos.

| ORDERS AND EXAMPLES | MAIN CHARACTERISTICS | ORDERS AND EXAMPLES | MAIN CHARACTERISTICS |
|---|--|---|--|
| Monotremata Platypuses, echidnas |  Echidna Lay eggs; no nipples; young suck milk from fur of mother | Marsupialia Kangaroos, opossums, koalas | Embryo completes development in pouch on mother |
| Proboscidea Elephants |  African elephant Long, muscular trunk; thick, loose skin; upper incisors elongated as tusks | Tubulidentata Aardvark | Teeth consisting of many thin tubes cemented together; eats ants and termites |
| Sirenia • Manatees, dugongs |  Manatee Aquatic; finlike forelimbs and no hind limbs; herbivorous | Hyracoidea Hyraxes | Short legs; stumpy tail; herbivorous; complex, multichambered stomach |
| Xenarthra I Sloths, anteaters, armadillos |  Tamandua Reduced teeth or no teeth; herbivorous (sloths) or carnivorous (anteaters, armadillos) | Rodentia Squirrels, beavers, rats, porcupines, mice | Chisel-like, continuously growing incisors worn down by gnawing, herbivorous |
| Lagomorpha Rabbits, hares, pikas |  Jackrabbit Chisel-like incisors; hind legs longer than forelegs and adapted for running and jumping | Primates Lemurs, monkeys, apes, humans | Opposable thumbs; forward-facing eyes; well-developed cerebral cortex: omnivorous |
| Carnivora Dogs, wolves, bears, cats, weasels, otters, seals, walruses |  Coyote Sharp, pointed canine teeth and molars for shearing; carnivorous | Perissodactyla Horses, zebras, tapirs, rhinoceroses | Hooves with an odd number of toes on each foot; herbivorous |
| Celaciocaudyla Artiodactyls Sheep, pigs, cattle, deer, giraffes |  Bighorn sheep Hooves with an even number of toes on each foot; herbivorous | Chiroptera Bats | Adapted for flight; broad skin fold that extends from elongated fingers to body and legs; carnivorous or herbivorous |
| Cetaceans Whales, dolphins, porpoises |  Pacific white-sided porpoise Aquatic; streamlined body; paddle-like forelimbs and no hind limbs; thick layer of insulating blubber; carnivorous | Eulipotyphla "Core insectivores": some moles, some shrews | Diet consists mainly of insects and other small invertebrates |

► **Figure 34.38 A phylogenetic tree of primates.** The fossil record indicates that anthropoids began diverging from other primates about 50 million years ago. New World monkeys, Old World monkeys, and hominoids (the clade that includes gibbons, orangutans, gorillas, chimpanzees, and humans) have been evolving as separate lineages for over 30 million years. The lineages leading to humans branched off from other hominoids somewhere between 5 and 7 million years ago.

years of separation (**Figure 34.39**). All species of New World monkeys are arboreal, whereas Old World monkeys include ground-dwelling as well as arboreal species. Most monkeys in both groups are diurnal (active during the day) and usually live in bands held together by social behavior.

The other group of anthropoids, the hominoids, consists of primates informally called apes (**Figure 34.40**). This group includes the genera *Hyalohates* (gibbons), *Pongo* (orangutans), *Gorilla* (gorillas), *Pan* (chimpanzees and bonobos), and *Homo* (humans). Hominoids diverged from Old World monkeys about 20–25 million years ago. Today, non-human hominoids are found exclusively in tropical regions of the Old World. With the exception of gibbons, living hominoids are larger than monkeys. All living hominoids have relatively long arms, short legs, and no tail. Although all nonhuman hominoids spend time in trees, only gibbons and orangutans are primarily arboreal. Social organization varies among the genera of hominoids; gorillas and chimpanzees are highly social. Hominoids have a larger brain in proportion to their body size than other primates, and hominoid behavior is more flexible.

• **Figure 34.39 New World monkeys and Old World monkeys.**

(a) New World monkeys, such as spider monkeys (shown here), squirrel monkeys, and capuchins, have a prehensile tail and nostrils that open to the sides.

(b) Old World monkeys lack a prehensile tail, and their nostrils open downward. This group includes macaques (shown here), mandrills, baboons, and rhesus monkeys.

(a) Gibbons, such as this Muller's gibbon, are found only in southeastern Asia. Their very long arms and fingers are adaptations (or brachiation).

(b) Orangutans are shy, solitary apes that live in the rain forests of Sumatra and Borneo. They spend most of their time in trees; note the foot adapted for grasping and the opposable thumb.

(c) Gorillas are the largest apes: some males are almost 2 m tall and weigh about 200 kg. Found only in Africa, these herbivores usually live in groups of up to about 20 individuals.

(d) Chimpanzees live in tropical Africa. They feed and sleep in trees but also spend a great deal of time on the ground. Chimpanzees are intelligent, communicative, and social.

(e) Bonobos are closely related to chimpanzees but are smaller. They survive today only in the African nation of Congo.

A Figure 34.40 Hominoids (apes).

Concept Check 34.7

1. Contrast monotremes, marsupials, and eutherians in terms of how they bear young.
2. Identify at least five derived traits of primates.

For suggested answers, see Appendix A.

Concept 34.8

Humans are bipedal hominoids with a large brain

In our tour of Earth's biodiversity, we come at last to our own species, *Homo sapiens*, which is about 160,000 years old.

When you consider that life has existed on Earth for at least 3.5 billion years, we are clearly evolutionary newcomers.

Derived Characters of Humans

A number of characters distinguish humans from other hominoids. Most obviously, humans stand upright and walk on two legs. Humans have a much larger brain than other hominoids and are capable of language, symbolic thought, and the manufacture and use of complex tools. Humans also have reduced jawbones and jaw muscles, along with a shorter digestive tract. The list of derived human characters at the molecular level is growing as scientists compare the genomes of humans and chimpanzees. Although the two genomes are 99% identical, a disparity of 1% can translate into a large number of differences in a genome that contains 3 billion base pairs.

Bear in mind that such genomic differences—and whatever derived phenotypic characters they code for—separate humans

from other *living* hominoids. But many of these new characters first emerged in our ancestors, long before our own species appeared. We will consider some of these ancestors to see how these traits originated.

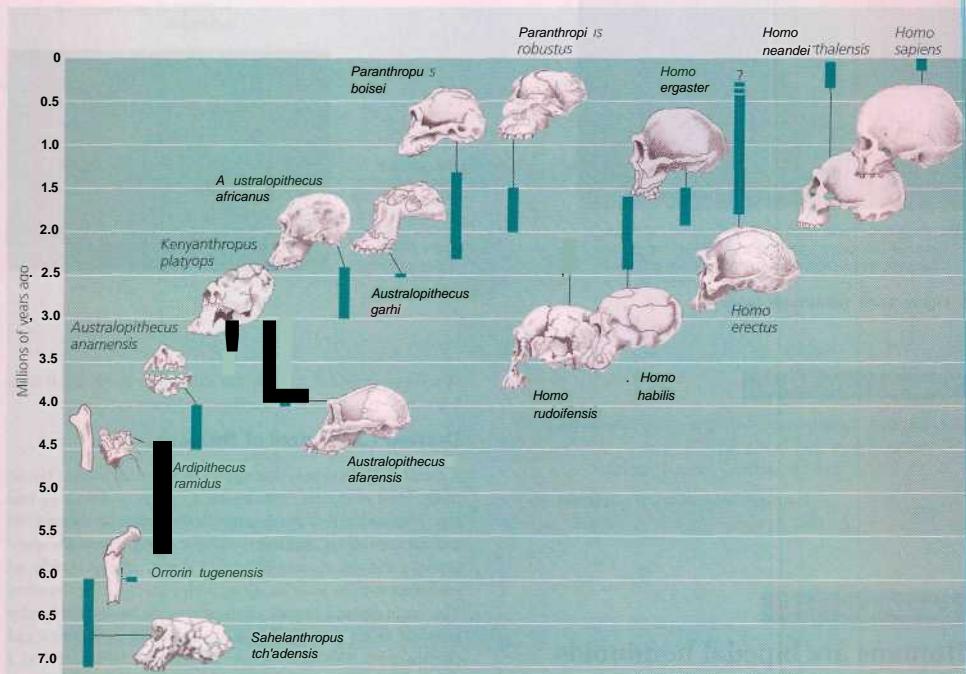

The Earliest Hominids

The study of human origins is known as **paleoanthropology**. Paleoanthropologists have unearthed fossils of approximately 20 species of extinct hominoids that are more closely related to humans than to chimpanzees. These species are known as **hominids** (Figure 34.41). Since 1994, four hominid species dating from more than 4 million years ago have been discovered in the fossil record. The oldest of these hominids, *Sahelanthropus tchadensis*, lived about 7–6 million years ago; its fossils were discovered in 2002.

Sahelanthropus and other early hominids shared some of the derived characters of humans. For example, they had reduced

canine teeth, and some fossils suggest that they had relatively flat faces. They also show signs of having been more upright and bipedal than other hominoids. One clue to their upright stance can be found in the foramen magnum, the hole at the base of the skull through which the spinal cord exits. In chimpanzees, the foramen magnum is relatively far back on the skull, while in early hominids (and in humans), it is located underneath the skull. This derived position allows us to hold our head directly over our body, and apparently early hominids did as well. Leg bones of *Australopithecus bahrelghazali*, a hominid that lived 4.5–4 million years ago, also suggest that early hominids were increasingly bipedal. (We will return to the subject of bipedalism later.)

Note that the characters that distinguish humans from other living hominoids did not all evolve in tight unison. While early hominids were showing signs of bipedalism, their brains remained small—about 400–450 cm³ in volume, compared with an average of 1,300 cm³ for *Homo sapiens*. The earliest hominids also were small (the 4.5-million-year-old

A Figure 34.41 A timeline for some selected hominid species. Most of these fossils come from sites in eastern and southern Africa. Note that at most times in hominid history, two or more hominid species were contemporaries. The names of some of the species are controversial, reflecting phylogenetic debates about the interpretation of skeletal details and biogeography.

Ardipithecus ramidus is estimated to have weighed only 40 kg and had relatively large teeth and a lower jaw that projected beyond the upper part of the face. (Humans, in contrast, have a relatively flat face. Compare your own face with that of the chimpanzee in Figure 34.40d.) Differing rates of evolution in different features is known as **mosaic evolution**.

It's important LO avoid two common misconceptions when considering these early hominids. One is to think of them as chimpanzees. Chimpanzees represent the tip of a separate branch of hominid evolution, and they acquired derived characters of their own after they diverged from their common ancestor with humans.

Another misconception is to imagine that human evolution is a ladder leading directly from an ancestral hominoid to *Homo sapiens*. This error is often illustrated as a parade of fossil hominids that become progressively more like ourselves as they march across the page. If human evolution is a parade, it is a very disorderly one, with many groups breaking away from the march to wander down dead-end alleyways. At times, several hominid species coexisted, but all except one—*the one that gave rise to Homo sapiens*—ended in extinction. Some paleoanthropologists suggest that convergence was common in early hominid evolution. Different lineages of hominids acquired different combinations of derived characters and retained different sets of primitive characters, has even been suggested that some of the fossils claimed to be early hominids, such as *Orrorin tugenensis* (see Figure 4.41) are actually outside the hominid clade altogether. If that's true, they must have independently acquired some hominid-like traits.

Australopiths

The fossil record indicates that hominid diversity increased dramatically between 4 and 2 million years ago. Many of the hominids from this period are collectively called australopiths. Their phylogeny remains unresolved on many points, but as a group, they are almost certainly paraphyletic. *Australopithecus anamensis*, mentioned earlier, links the australopiths to older hominid such as *Ardipithecus ramidus*.

Australopiths got their name from the 1924 discovery in South Africa of *Australopithecus africanus* ("southern ape of Africa"), which lived between 3 and 2.4 million years ago. With the discovery of more fossils, it became clear that *A. africanus* walked fully erect (was bipedal) and had human-like hands and teeth. However, its brain was only about one-third the size of the brain of a present-day human.

In 1974, in the Afar region of Ethiopia, paleoanthropologists discovered a 3.24-million-year-old *Australopithecus* skeleton that was 40% complete. "Lucy," as the fossil was named, was short—only about 1 m tall. Lucy and similar fossils have been considered sufficiently different from *Australopithecus africanus* to be designated as a separate species,

Australopithecus afarensis (for the Afar region). Fossils discovered in the early 1990s show that *A. afarensis* existed as a species for at least 1 million years.

At the risk of oversimplifying, one could say that *A. afarensis* had fewer derived characters of humans above the neck than below. Lucy's head was the size of a softball, indicating a brain size about the same as that of a chimpanzee of Lucy's body size. *A. afarensis* skulls also have a long lowerjaw. Skeletons of *A. afarensis* suggest a capacity for arboreal locomotion, with arms relatively long in proportion to body size (compared to the proportions in humans). However, fragments of the pelvis and skull bones indicate that *A. afarensis* walked on two legs. Fossilized footprints in Laetoli, Tanzania, corroborate the skeletal evidence that hominids living at the time of *A. afarensis* were bipedal (Figure 34.42).

(a) Lucy, a 3.24-million-year-old skeleton, represents the hominid species *Australopithecus afarensis*.

(b) The Laetoli footprints, more than 3.5 million years old, confirm that upright posture evolved quite early in hominid history.

(c) An artist's reconstruction of what *A. afarensis* may have looked like.

A Figure 34.42 Upright posture predates an enlarged brain in human evolution.

Another lineage of australopiths consisted of the "robust" australopiths. These hominids, which included species such as *Paranthropus boisei*, had sturdy skulls with powerful jaws and large teeth, adapted for grinding and chewing hard, tough foods. They contrast with the "gracile" (slender) australopiths, including *A. ajaensis* and *A. africanus*, which had lighter feeding equipment adapted for softer foods.

Combining evidence from the earliest hominids with the much richer fossil record of later australopiths makes it possible to consider hypotheses about important trends in hominid evolution. Let's consider two of these trends: the emergence of bipedalism and tool use.

Bipedalism

Our anthropoid ancestors of 30–35 million years ago were still tree-dwellers. But about 20 million years ago, the Indian Plate collided with Asia and thrust up the Himalayan range (see Figure 26.20). The climate became drier, and the forests of what are now Africa and Asia contracted. The result was an increased area of savanna (grassland) habitat, with fewer trees. For decades, paleoanthropologists have seen a strong connection between the rise of savannas and the rise of bipedal hominids. According to one hypothesis, tree-dwelling hominids could no longer move through the canopy, so natural selection favored adaptations that made moving over open ground more efficient.

Although some elements of this hypothesis survive, the picture now appears somewhat more complex. Although all recently discovered fossils of early hominids show some indications of bipedalism, none of these hominids lived in savannas. Instead, they lived in mixed habitats ranging from forests to open woodlands. An alternative hypothesis is that bipedalism evolved as an adaptation that allowed early hominids to reach low-hanging fruit on trees.

Hominids did not become more bipedal in a simple, linear fashion. Australopiths seem to have had various locomotor styles, and some spent more time on the ground than others. Only about 1.9 million years ago did hominids begin to walk long distances on two legs. These hominids lived in more arid environments, where bipedal walking requires less energy than walking on all fours.

Tool Use

As you read earlier, the manufacture and use of complex tools is a derived behavioral character of humans. Determining the origin of tool use in hominid evolution is one of paleoanthropology's great challenges today. Other hominoids are capable of surprisingly sophisticated tool use. Orangutans, for example, can fashion probes from sticks for retrieving insects from their nests. Chimpanzees are even more adept, using rocks to smash open food and putting leaves on their feet to walk over thorns. It's likely that early hominids were capable of this sort of simple tool use, but

finding fossils of modified sticks and leaves that were used; shoes is practically impossible.

The oldest generally accepted evidence of tool use by hominids are 2.5-million-year-old cut marks on animal bones found in Ethiopia. These marks suggest that hominids ate flesh from the bones of animals using stone tools. Interestingly, the hominids whose fossils were found near the site where the bones were discovered had a relatively small brain. If these hominids, which have been named *Australopithecus garhi*, were indeed the creators of the stone tools used on bones, that would suggest that stone tool use originated before the evolution of large hominid brains.

Early *Homo*

The earliest fossils that paleoanthropologists place in our genus, *Homo*, are those of the species *Homo habilis*. These fossils, ranging in age from about 2.4 to 1.6 million years, show clear signs of certain derived hominid characters above the neck. Compared to the australopiths, *H. habilis* had a shorter jaw and a larger brain volume, about 600–750 cm³. Sharp stone tools have also been found with some fossils of *H. habilis* (the name means "handy man").

Fossils from 1.9 to 1.6 million years ago mark a new stage in hominid evolution. A number of paleoanthropologists recognize these fossils as those of a distinct species, *Homo ergaster*. *Homo ergaster* had a substantially larger brain than *H. habilis* (over 900 cm³), as well as long, slender legs with hip joints well adapted for long-distance walking (Figure 34.43). The fingers were relatively short and straight, suggesting that *H. ergaster* did not climb trees like earlier hominids. *Homo ergaster* has been found in far more arid environments than earlier hominids and has been associated with more sophisticated stone tools. Its smaller teeth also suggest that *H. ergaster* either ate different foods than australopiths (more meat and less plant material) or prepared some of its food before chewing, perhaps by cooking or mashing the food.

Homo ergaster marks an important shift in the relative sizes of the sexes. In primates, a size difference between males and females is a major component of sexual dimorphism (see Chapter 23). On average, male gorillas and orangutans weigh about twice as much as females of their species. In chimpanzees and bonobos, males are only about 1.35 times as heavy as females, on average. In *Australopithecus ajaensis*, males were 1.5 times as heavy as females. But in early *Homo*, sexual dimorphism was significantly reduced, and this trend continued through our own species: Human males average about 1.2 times the weight of females.

The reduced sexual dimorphism may offer some clues to the social systems of extinct hominids. In living primates, extreme sexual dimorphism is associated with intense male-male competition for multiple females. In species that undergo more pair-bonding (including our own), sexual dimorphism is less dramatic. Male and female *H. ergaster* may therefore

< Figure 34.43 Fossil and artist's reconstruction of *Homo ergaster*.

This 1.7-million-year-old fossil from Kenya belongs to a young male *Homo ergaster*. This individual was tall, slender, and fully bipedal, and he had a relatively large brain.

lave engaged in more pair-bonding than earlier hominids did. This shift may have been associated with long-term biparental care of babies. Human babies depend on their parents for food and protection much longer than do the young of chimpanzees and other hominoids.

Fossils now recognized as *Homo ergaster* were originally considered early members of another species, *Homo erectus*, and some paleoanthropologists still hold this position. *Homo erectus* originated in Africa and was the first hominid to migrate out of Africa. The oldest fossils of hominids outside Africa, dating back 1.8 million years, were discovered in 2000 in the former Soviet Republic of Georgia. *Homo erectus* eventually migrated as far as the Indonesian archipelago. Comparisons of *H. erectus* fossils with humans and studies of human DNA indicate that *H. erectus* became extinct sometime after 200,000 years ago.

Neanderthals

In 1856, miners discovered some mysterious human fossils in a cave in the Neander Valley in Germany. The 40,000-year-old fossils belonged to a thick-boned, heavy hominid with a

prominent brow. The hominid was given the name *Homo neanderthalensis*, commonly called a Neanderthal. At one time, many paleoanthropologists considered Neanderthals to be a stage in the evolution of *Homo erectus* into *Homo sapiens*. Now most have abandoned this view. Neanderthals appear to have descended from an earlier species, *Homo kidelbergensis*, which originated in Africa about 600,000 years ago and then spread to Europe. Neanderthals, which appeared in Europe and the Near East by 200,000 years ago, had a brain as large as that of present-day humans and were capable of making hunting tools from stone and wood. But despite their adaptations, Neanderthals apparently became extinct 30,000 years ago, contributing nothing to the gene pool of living humans.

Evidence of the extinction of Neanderthals can be found in their DNA. Scientists extracted fragments of DNA from fossils of four Neanderthals that lived at different times in different localities in Europe. They then compared the Neanderthal DNA with DNA of living humans from Europe, Africa, and Asia. If Neanderthals had given rise to European humans, then both groups should share a common ancestor, with other humans being more distantly related. Instead, the DNA analysis indicates that all of the Neanderthals form a clade, while living Europeans are more closely related to living Africans and Asians.

Homo Sapiens

Evidence from fossils, archaeological relics, and DNA studies is beginning to cohere into a compelling hypothesis about how our own species, *Homo sapiens*, emerged and spread around the world.

It is now clear that the ancestors of humans originated in Africa. Older species (perhaps *H. ergaster* or *H. erectus*) gave rise to newer species, such as *H. heidelbergensis* and ultimately *H. sapiens*. In 2003, researchers working in Ethiopia reported the discovery of 160,000-year-old fossils of *H. sapiens*, the oldest known fossils of our own species (Figure 34.44). These

< Figure 34.44 Oldest known fossil of *Homo sapiens*. This skull differs little from the skulls of living humans.

early humans lacked the heavy browridges of *H. erectus* and Neanderthals and were more slender than other hominids.

The Ethiopian fossils support molecular evidence about the origin of humans. As we noted earlier, DNA analysis indicates that all living humans are more closely related to one another than to Neanderthals. Other studies on human DNA show that Europeans and Asians share a relatively recent common ancestor and that many African lineages branched off more ancient positions on the human family tree. These findings strongly suggest that all living humans have ancestors that originated as *Homo sapiens* in Africa, which is further supported by analysis of mitochondrial DNA and Y chromosomes from members of various human populations.

The oldest fossils of *Homo sapiens* outside Africa date back about 50,000 years. Studies of the human Y chromosome suggest that humans spread beyond Africa in one or more waves, first into Asia and then to Europe and Australia. The date of the first arrival of humans in the New World is still a matter of debate, although the oldest generally accepted evidence puts that date at 55,000 years ago.

New findings continually update our understanding of the context of *H. sapiens*' evolution. For example, in October 2004, Peter Brown, of the University of New England in New South Wales, Australia, Thomas Sutikna, of the Indonesian Centre for Archaeology, and their colleagues reported an astonishing find unearthed in 2003: the skeleton of an adult hominid dating from just 18,000 years ago and representing a previously unknown species, now named *Homo floresiensis*. Discovered in a limestone cave on the Indonesian island of Flores, the individual was much shorter and had a much smaller brain volume than *H. sapiens*—more similar, in fact, to an australopith. However, the skeleton also displays many derived traits, including skull thickness and proportions and teeth shape, that suggest it is descended from the larger *H. erectus*. One intriguing explanation for this species' apparent "shrinkage" is that isolation on the island may have resulted in selection for greatly reduced size. Such dramatic size reduction is well studied in other dwarf mammalian species endemic to islands; these include primitive pygmy elephants found in the same vicinity as the *H. floresiensis* specimen. Compelling questions that may yet be answered from the cache of anthropological and archeological finds on Flores include more clues to the origin of *H. floresiensis*, whether its members used tools, and whether they ever encountered *H. sapiens*, which coexisted in Indonesia during the late Pleistocene.

The rapid expansion of our species (and the replacement of Neanderthals) may have been spurred by the evolution of human cognition as *Homo sapiens* evolved in Africa. Although Neanderthals and other hominids were able to produce sophisticated tools, they showed little creativity and not much capability for symbolic thought, as far as we can tell. In contrast, researchers are beginning to find evidence of more sophisticated thought as *Homo sapiens* evolved. For example, in 2002,

• Figure 34.45 Art, a human hallmark. The engravings on this 77,000-year-old piece of ochre, discovered in South Africa's Blombos Cave, are among the earliest signs of symbolic thought in humans.

researchers reported the discovery in South Africa of 77,000-year-old art—geometric markings made on pieces of ochre (Figure 34.45). And in 2004, archaeologists working in southern and east Africa found 75,000-year-old ostrich eggs and snail shells with holes neatly drilled through them. By 36,000 years ago, humans were producing spectacular cave paintings

Symbolic thought may have emerged along with full-blown human language. Both may have raised the survival and reproductive fitness of humans by allowing them to construct new tools and teach others how to build them. Long-range trade for scarce resources also became possible. As the population of Africa rose, population pressures may have driven humans to migrate into Asia and then Europe. Neanderthals may have been driven to extinction by the combined stresses of the last ice age and competition from newly arrived humans.

Clues to the cognitive transformation of humans can be found in the human genome as well as in archaeological sites, in a gene known as *FOXP2* was identified in 2001 as essential for human language. People who inherit mutated versions of the gene suffer from a range of language impediments and have reduced activity in Broca's area in the brain (see Chapter 48). In 2002, geneticists compared the *FOXP2* gene in humans with the homologous gene in other mammals. They concluded that the gene experienced intense natural selection after the ancestors of humans and chimpanzees diverged. By comparing mutations in flanking regions of the gene, the researchers estimated that this bout of natural selection occurred within the past 200,000 years. Of course, the human capacity for language involves many regions of the brain, and it's almost certain that many other genes are essential for language. But the evolutionary change in *FOXP2* may be the first genetic clue as to how our own species came to play its unique role in the world.

Our discussion of humans brings this unit of chapters on biological diversity to an end. But this organization isn't meant to imply that life consists of a ladder leading from lowly microbes to lofty humanity. Biological diversity is the product of branching phylogeny, not ladderlike "progress," however we choose to

reasure it. The fact that there are more species of ray-finned fishes alive today than all other vertebrates combined is a clear indication that our finned relatives are not outmoded underachievers that failed to get out of the water. The tetrapods—amphibians, reptiles, and mammals—are derived from one lineage of lobe-finned vertebrates. As tetrapods diversified on land, fishes continued their branching evolution in the greatest portion of the biosphere's volume. Similarly, the ubiquitous presence of diverse prokaryotes throughout the biosphere today is a reminder of the enduring ability of these relatively simple organisms to keep up with the times

through adaptive evolution. Biology exalts life's diversity, past and present.

Concept Check 34.8

1. Contrast hominoids with hominids.
2. How do the characteristics of *Homo ergaster* illustrate mosaic evolution?

For suggested answers, see Appendix A.

Chapter 34 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Chordates have a notochord and a dorsal, hollow nerve cord

- **Derived Characters of Chordates** (p. 673) Chordate characters include a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.
- **Tunicates** (pp. 673–674) Tunicates are marine suspension feeders commonly called sea squirts. They lose some of the derived characters of chordates as adults.
- **Lancelets** (p. 674) Lancelets are marine suspension feeders that retain the hallmarks of the chordate body plan as adults.
- **Early Chordate Evolution** (pp. 674–675) The current life history of tunicates probably does not reflect that of the ancestral chordate. Gene expression in lancelets holds clues to the evolution of the vertebrate brain.

Concept 34.2

Craniates are chordates that have a head

- **Derived Characters of Craniates** (p. 676) Craniates have a head, including a skull, a brain, eyes, and other sensory organs. Many structures in craniates develop partly from a novel population of cells, the neural crest.

► **The Origin of Craniates** (p. 676) Craniates evolved at least 530 million years ago, during the Cambrian explosion.

- **Hagfishes** (pp. 676–677) Hagfishes are jawless marine craniates that have a cartilaginous skull and an axial rod of cartilage derived from the notochord. They lack vertebrae.

Concept 34.3

Vertebrates are craniates that have a backbone

- **Derived Characters of Vertebrates** (p. 678) Vertebrates have vertebrae, an elaborate skull, and, in aquatic forms, fin rays.
- **Lampreys** (p. 678) Lampreys are jawless vertebrates that have cartilaginous segments surrounding the notochord and arching partly over the nerve cord.

Concept 34.4

Gnathostomes are vertebrates that have jaws

- **Derived Characters of Gnathostomes** (pp. 679–680) Gnathostomes have jaws, which evolved from skeletal supports of the pharyngeal slits; enhanced sensory systems, including the lateral line system; an extensively mineralized endoskeleton; and paired appendages.
- **Fossil Gnathostomes** (p. 680) Placoderms were close relatives of living gnathostomes. Acanthodians were closely related to osteichthyans.
- **Chondrichthyan** (Sharks, Rays, and Their Relatives) (pp. 680–682) Chondrichthyans, which include sharks and rays, have a cartilaginous skeleton that evolved secondarily from an ancestral mineralized skeleton.
- **Ray-Finned Fishes and Lobe-Fins** (pp. 682–684) Osteichthyans have a skeleton reinforced by calcium phosphate. Aquatic forms have bony gill covers and a swim bladder; some also have lungs. Ray-finned fishes have maneuverable fins supported by long rays. Lobe-fins include coelacanths, lungfishes, and tetrapods. Aquatic lobe-fins have muscular pectoral and pelvic fins.

Concept 34.5

Tetrapods are gnathostomes that have limbs and feet

- **Derived Characters of Tetrapods** (p. 684) Tetrapods have four limbs and feet with digits. They also have other adaptations for life on land, such as ears.
- **The Origin of Tetrapods** (p. 684) Fossil evidence suggests that tetrapod limbs, now mainly used for walking on land, were originally used for paddling in water.
- **Amphibians** (pp. 685–687) Amphibians include salamanders, frogs, and caecilians. Most have moist skin that complements the lungs in gas exchange. Most frogs and some salamanders undergo metamorphosis of an aquatic larva into a terrestrial adult.

Concept 34.6

Amniotes are tetrapods that have a terrestrially adapted egg.

- **Derived Characters of Amniotes** (p. 688) The amniotic egg contains extraembryonic membranes that carry out a variety of functions, including gas exchange and protection. Amniotes also have other terrestrial adaptations, such as relatively impermeable skin.
- **Early Amniotes** (p. 688) Early amniotes appeared in the Carboniferous period. They included large herbivores and predators.
- **Reptiles** (pp. 688–691) Reptiles include tuatara, lizards, snakes, turtles, crocodilians, and birds. Extinct forms included parareptiles, dinosaurs, pterosaurs, and marine reptiles. Most reptiles are ectothermic, although birds are endothermic (as some dinosaurs may have been).
- **Birds** (pp. 691–694) Birds probably descended from a group of small, carnivorous dinosaurs known as theropods. They have a variety of adaptations well suited to a lifestyle involving flight.
Investigation How Does Bone Structure Shed Light on the Origin of Birds?

Concept 34.7

Mammals are amniotes that have hair and produce milk.

- **Derived Characters of Mammals** (p. 694) Hair and mammary glands are two derived characteristics of mammals.
- **Early Evolution of Mammals** (pp. 694–695) Mammals evolved from synapsids in the late Triassic period. Living lineages of mammals originated in the Jurassic but did not undergo a significant adaptive radiation until the beginning of the Paleogene.
- **Monotremes** (p. 695) Monotremes are a small group of egg-laying mammals consisting of echidnas and the platypus.
- **Marsupials** (pp. 695–697) Marsupials include opossums, kangaroos, and koalas. Marsupial young begin their embryonic development attached to a placenta in the mother's uterus but complete development inside a maternal pouch.
- **Eutherians (Placental Mammals)** (pp. 697–701) Eutherians have young that complete their embryonic development attached to a placenta. All primates have hands and (with the exception of humans) feet adapted for gripping. Living primates include lemurs and their relatives, tarsiers, and anthropoids. Anthropoids diverged early into New World and Old World monkeys. Hominoids (gibbons, orangutans, gorillas, chimpanzees, bonobos, and humans) evolved from Old World monkeys.

Activity Characteristics of Chordates

Activity Primate Diversity

Concept 34.8

Humans are bipedal hominoids with a large brain.

- **Derived Characters of Humans** (pp. 701–702) Humans have bipedal locomotion, a shortened jaw, and an enlarged brain.
- **The Earliest Hominids** (pp. 702–703) Hominids originated in Africa at least 6–7 million years ago. Early hominids had a small brain but probably walked upright.
- **Australopithecus** (pp. 703–704) Australopithecus is a paraphyletic assemblage of hominids that lived between 4 and 2 million years ago. Some species walked fully erect and had human-like hands and teeth.

• **Bipedalism** (p. 704) Hominids began to walk long distances on two legs about 1.9 million years ago.

• **Tool Use** (p. 704) The oldest evidence of tool use—cut marks on animal bones—is 2.5 million years old.

• **Early Homo** (pp. 704–706) *Homo ergaster* was the first fully bipedal, large-brained hominid. *Homo erectus* was the first hominid to leave Africa.

• **Neanderthals** (p. 705) Neanderthals lived in Europe and the Near East from 200,000 to 30,000 years ago. They became extinct a few thousand years after the arrival of *Homo sapiens* in Europe.

• **Homo Sapiens** (pp. 705–706) *Homo sapiens* appeared in Africa at least 160,000 years ago and spread to other continents about 50,000 years ago. This spread may have been preceded by changes to the brain that made symbolic thought and other cognitive innovations possible. Research into the origins and contemporaries of *Homo sapiens* is a lively area of research and debate, including the recent discovery of a new species, *Homo Naledi*, dating from the late Pleistocene.

Activity Human Evolution

TESTING YOUR KNOWLEDGE

Evolution Connection

Identify one characteristic that qualifies humans for membership in each of the following clades: eukaryotes, animals, deuterostomes, chordates, vertebrates, gnathostomes, amniotes, mammals, primates

Scientific Inquiry

Scientific inquiry often involves trying to make sense of an interesting observation. One such observation concerns patterns of genetic versus morphological divergence in some vertebrate groups. Amphibians, for example, show great similarity in morphology, yet they are far more genetically diverse than the morphologically diverse birds. A related pattern is evident in chimpanzee-human comparisons: These two species are quite divergent morphologically but are much more similar genetically. Propose one or more hypotheses that might explain these puzzling patterns.

Investigation How Does Bone Structure Shed Light on the Origin of Birds?

Science, Technology, and Society

While human biological evolution is Darwinian, the evolution of human culture could be described as Lamarckian. Explain this distinction after reviewing the ideas of Darwin and Lamarck in Chapter 22.

How to build a successful team-based library

David L. Johnson is president of the University of Wisconsin-Madison Library and the author of *Leading the Library: A Guide for Librarians* (Rowman & Littlefield, 2000).

As a leader, you have the opportunity to make a difference in your organization. You can help your library become a better place to work, a better place to learn, and a better place to serve. You can help your library become a better place to work, a better place to learn, and a better place to serve.

What can you do? Be proactive. Make sure you're using a team

approach to management. Encourage collaboration among staff members. Promote a culture of respect and appreciation for individual differences. Encourage staff members to take ownership of their work. Encourage staff members to take ownership of their work.

Plant Form and Function

AN INTERVIEW WITH **Natasha Raikhel**

From her early work as an invertebrate zoologist at the University of Leningrad to her research today as one of the most prominent American plant biologists, Natasha Raikhel has traveled very far, both geographically and scientifically. Dr. Raikhel is now the Distinguished Professor of Plant Cell Biology at the University of California, Riverside (UCR), where she is also the director of the Center for Plant Cell Biology. In 2003, the American Society for Cell Biology honored Professor Raikhel's achievements with the Women in Cell Biology Senior Career Recognition Award, and in 2004 she received the Stephen Hales Prize of the American Society of Plant Biologists; the award is given to a scientist who has served the science of plant biology in some noteworthy manner. One of Dr. Raikhel's current interests is making systems biology possible by building multidisciplinary research teams. Dr. Raikhel's service to the biology community and her generosity as a mentor to young researchers exemplify the collaborative spirit of the science culture.

How did you begin your science career in what was then the Soviet Union?

Actually, I didn't go directly into science. I was a "musician and was supposed to become a professional pianist. But at some point, I realized that I could not be one of the best pianists, and I didn't like that limitation. I always liked nature, and I was able to study biology at the University of Leningrad. I met my husband when we were both zoology students in Leningrad (now St. Petersburg), where we continued our work at the university through graduate school until we acquired faculty positions. And then we decided to leave the Soviet Union.

What were the circumstances of your emigration?

This was in the late '70s, and as Jews in the Soviet Union, our career opportunities in science were limited, but we were fortunate enough to be allowed to emigrate. After our first son was born in 1975, we wanted him to be exposed to greater opportunities, and that helped us finalize our decision to leave. It was difficult to emigrate from the Soviet Union during that period. But there was a joke at that time that the Carter administration in the United States had a grains-for-jews exchange policy—the more wheat the U.S. sent to the Soviet Union, the more Jews were allowed out. So we were very lucky that we were able to get out of the Soviet Union at a time when many people would have loved to leave.

How did you find your first jobs here?

It was difficult for scientists emigrating from the Soviet Union to find academic jobs because of a lack of references. But again, we were lucky. The research institute (Institute of Cytology) where I worked had a keen interest in modern biology, and the professor in charge invited visiting professors to spend their sabbatical leaves doing research at the institute. A professor, Jerry Paulin, who came with his family from the University of Georgia, had his desk right next to mine in the lab. Our families became friends. At that time, it was very difficult for American visitors in the Soviet Union to get around because they were told, "You cannot go here, you cannot go there." So we helped the Paulins during their visit to Leningrad. Later, when we planned our immigration to the United States, Jerry Paulin was the one professor in the U.S. who knew us and our work as scientists, and he helped us find jobs at the University of Georgia. And so we started all over again as postdoctoral researchers when we came to this country.

In Leningrad, you worked on protozoans—ciliates. But in Georgia, you began your work with plants. What motivated that change?

My interest is at the basic cellular level, and so the switch of organisms was not too difficult. I realized very soon after arriving in the U.S. that it would be hard to get grants for research on free-living protozoans, which do not cause disease. At the time, plant research was really starting to take off in the U.S., and Georgia was one of the key places where plant biology was very modern. I sensed this and wanted to be part of that environment, and so I learned a lot about plants. I also began to reeducate myself to do molecular biology. Molecular approaches in plant biology were just beginning. I didn't have to catch up because I learned along with many people who were also just beginning in molecular biology. So, once again, I was lucky with good timing.

Speaking of good timing, why is this a good time to be in plant biology?

One reason is that we now know a lot about a research organism, the plant *Ambidopsis*. Its genome has been sequenced, and many of its proteins have been identified. Once you understand the functions of these proteins, how the proteins interact, and how pathways in the cell interact, then you can really start to answer questions about how cells function and how the whole plant works. Systems biology becomes possible, and I think this makes plant biology much more exciting.

What will it take to make plant systems biology work?

The essence of systems biology is to be able to model organisms—to be able to predict how various pathways in the organism interact and

how a change in one pathway will affect the whole organism. This requires our approaches to be more quantitative and much, more integrated. We need to infuse plant biology with disciplines such as informatics and engineering, but this is difficult because people are coming from different scientific cultures. Right now, many of us are retraining to understand fields such as bioinformatics, but it will be much better when such multidisciplinary experience becomes the normal environment for training biologists. It is very important that the new generation of plant biologists be very quantitative and comfortable with bioinformatics, and that they are good biologists too. It will take time to create this new generation of scientists. But many people are looking to the community of Arabidopsis researchers to make the systems approach work, because this community is exemplary in terms of openness and sharing among colleagues.

The number of protein-coding genes in *Arabidopsis* rivals that of humans and other complex animals. Did that discovery surprise you?

Not really. Because plants are immobile, they have to be very versatile in their ability to respond to environmental stresses. Plants have to be exquisite to survive because they can't run. This requires a lot of different kinds of proteins, including many that are unique to plants.

Are there important agricultural applications from all this work on *Arabidopsis*?

Yes, because *Arabidopsis* is such a convenient model organism for studying processes that are important in all plants, including crop plants.

For example, resistance to cold and resistance to pathogens are two traits that are very useful in crop plants. But such traits are much easier to analyze in *Arabidopsis*. So, if we first identify certain genes and regulatory pathways that can help *Ajoo-t-Kh-i-sis* resist environmental stress, we can then transfer some of that knowledge to improve crop plants.

What is the focus of your own lab's research?

For a long time, my lab group has worked on the trafficking of molecules through the cell's vesicles and vacuoles. And in the last few years, we've added another project, the synthesis of the cell wall in plants. Vacuoles and cell walls have unique plant-specific functions and are essential for plant life. I therefore am very interested in fully understanding these mechanisms.

In recent years, your influence has extended beyond your own lab to a leadership role in the international community of plant cell biologists. Why do you think this expanded role is important at this stage in your career?

Well, first of all, I want to make it clear that my research with my own lab group is still my number-one priority. But with time, you start to realize that you have experience that enables you to do more for the science community in your field. I got a lot from the community of plant biologists, and now I want to be constructive in giving back to the community. In fact, at a certain point in your career, you have an obligation to give more than you take. For example, I was not looking to become editor-in-chief of the journal *Plant Physiology*, but colleagues convinced me to take the job. This takes a lot of

time now, but the journal is evolving beautifully, which is very rewarding.

As another example of "giving something back," you participate in a program that provides summer research opportunities at UCR for community college students. Is it fun for you to have these students in your lab?

I love to be around these young people because they keep me young. At first, when these students join the lab, they are completely naive about research and just don't know how to get started. But once you put a fire under them and get them excited, it's the most rewarding thing in the world. For example, this past summer, we had a student from San Bernardino Valley College, a community college nearby. He just loved his project, and he will be on a paper that we are writing. He will also be transferring to UCR, and he still works in my lab for many hours each week, even though he's taking lots of courses. This student now wants to become a plant researcher—he's a convert! And that gives me great satisfaction.

With two very busy scientists in the family, how do you and your husband balance the demands of your careers with the responsibilities and enjoyment of family life?

I want young people beginning in science to understand that they will not have to shy away from having a family and having children because of their work. The most wonderful things I have in my life are my two sons. Balancing career and family is not easy, but it's all possible because I have a great husband, and we make decisions and do things together. You can't say, "You stay at home, and that's how we will share." Maybe that does work for some people, but in our case, we both wanted careers in science.

What other advice do you have for students who are interested in becoming scientists?

Because of the way biology is changing, I think students should look for programs that offer interdisciplinary approaches. They should not lock themselves into certain subfields. And they should reach for the stars. You have to be ambitious and work hard, and you have to know what you want, and then don't let anything stop you. You can grow as a scientist here like nowhere else in the world. I think I'm a living example of that. It's a fantastic life!

Plants have to be exquisite to survive because they can't run.

35 Plant Structure, Growth, and Development

▲ Figure 35.1 Fanwort (*Cabomba caroliniana*).

Key Concepts

- 35.1 The plant body has a hierarchy of organs, tissues, and cells
- 35.2 Meristems generate cells for new organs
- 35.3 Primary growth lengthens roots and shoots
- 35.4 Secondary growth adds girth to stems and roots in woody plants
- 35.5 Growth, morphogenesis, and differentiation produce the plant body

Overview

No Two Plants Are Alike

To some people, the plant in **Figure 35.1** is an intrusive aquatic weed that clogs streams, rivers, and lakes. Others consider it an attractive addition to an aquarium. Whatever else the fanwort (*Cabomba caroliniana*) may be, it is a striking example of **plasticity**—an organism's ability to alter or "mold" itself in response to local environmental conditions. The underwater leaves have a feathery appearance, an adaptation that may provide protection from the stress of moving water. In contrast, the surface leaves are pads that aid in flotation. Both leaf types have genetically identical cells, but the dissimilar environments cause different genes involved in leaf formation to be turned on or off. Such extreme developmental plasticity is much more common in plants than in animals and may help compensate for their lack of mobility. As Natasha Raikhel puts it in the interview preceding this chapter, "Plants have to be exquisite to survive because they can't run." Also, since the form of any plant is controlled by environmental as well as genetic factors, no two plants are exactly alike.

In addition to plastic structural responses by individual plants to specific environments, entire species have by nature

selected characteristics of morphology, or external form, that vary little among plants within the species. For example, some species of desert plants, such as cacti, have leaves that are so highly reduced as spines that the stem is actually the primary photosynthetic organ. This reduction in leaf size, and thus in surface area, results in reduced water loss. These leaf adaptations have enhanced survival and productive success in the desert environment.

This chapter focuses on how the body of a plant is formed, setting the stage for the rest of this unit on plant biology. Chapters 29 and 30 described the evolution and characteristics of bryophytes, seedless vascular plants, gymnosperms, and angiosperms. This chapter and Unit Six in general focus mainly on vascular plants—especially angiosperms because flowering plants comprise about 90% of plant species and are the base of nearly every terrestrial food web. As the world's population increases, the need for plants to supply food, fuel fiber, medicine, lumber, and paper has never been greater heightening the importance of understanding how plant grow and develop.

Concept 35.1

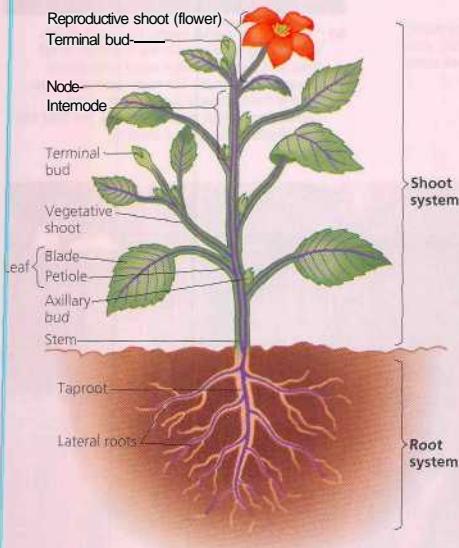

The plant body has a hierarchy of organs, tissues, and cells

Plants, like multicellular animals, have organs composed of different tissues, and these tissues are composed of cells. **tissue** is a group of cells with a common function, structure, or both. An organ consists of several types of tissues that together carry out particular functions. In looking at the hierarchy of plant organs, tissues, and cells, we will focus first on organs as the most readily observable features of plant structure.

Tie Three Basic Plant Organs: Roots, Stems, and Leaves

The basic morphology of vascular plants reflects their evolutionary history as terrestrial organisms that inhabit and draw resources from two very different environments—below-ground and above-ground. Plants must absorb water and minerals from below the ground and CO₂ and light from above the ground. The evolutionary solution to this separation of resources was the development of three basic organs: roots, stems, and leaves. They are organized into a root system and a shoot system, the latter consisting of stems and leaves (Figure 35.2). With few exceptions, angiosperms and other vascular plants rely completely on both systems for survival. Roots are typically nonphotosynthetic and would starve without the organic nutrients imported from the shoot system. Conversely, the shoot system depends on the water and minerals that roots absorb from the soil.

Later in the chapter, we will discuss the transition from vegetative shoots (shoots that are nonreproductive) to reproductive shoots. In angiosperms, the reproductive shoots are flowers, which are composed of leaves that are highly modified for sexual reproduction.

▲ Figure 35.2 An overview of a flowering plant. The plant body is divided into a root system and a shoot system, connected by vascular tissue (purple strands in this diagram) that is continuous throughout the plant. The plant shown is an idealized eudicot.

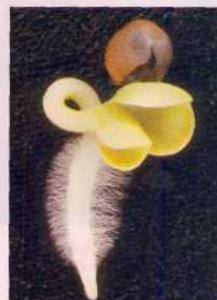

As we take a closer look at roots, stems, and leaves, try to view⁷ these organs from the evolutionary perspective of adaptations to living on land. In identifying some variations in these organs, we will focus mainly on the two major groups of angiosperms: monocots and eudicots (see Figure 30.12).

Roots

A root is an organ that anchors a vascular plant (usually in the soil), absorbs minerals and water, and often stores organic nutrients. Most eudicots and gymnosperms have a taproot system, consisting of one main vertical root (the taproot) that develops from an embryonic root. The taproot gives rise to lateral roots, also called branch roots (see Figure 35.2). In angiosperms, the taproot often stores organic nutrients that the plant consumes during flowering and fruit production. For this reason, root crops such as carrots, turnips, and sugar beets are harvested before they flower. Taproot systems generally penetrate deeply into the ground.

In seedless vascular plants and in most monocots, such as grasses, the embryonic root dies and does not give rise to a main root. Instead, many small roots grow from the stem, with each small root forming its own lateral roots. The result is a fibrous root system—a mat of generally thin roots spreading out below the soil surface, with no root standing out as the main one (see Figure 30.12). Roots arising from the stem are said to be adventitious (from the Latin *adventitius*, extraneous), a term describing any plant part that grows in an unusual location. A fibrous root system is usually shallower than a taproot system. Grass roots are particularly shallow, being concentrated in the upper few centimeters of the soil. Because grass roots hold the topsoil in place, they make excellent ground cover for preventing erosion. Large monocots, such as palms and bamboo, are mainly anchored by sturdy rhizomes, which are horizontal underground stems.

The entire root system helps anchor a plant, but in most plants the absorption of water and minerals occurs primarily near the root tips, where vast numbers of tiny root hairs increase the surface area of the root enormously (Figure 35.3). A

▲ Figure 35.3 Root hairs and root tip. Growing by the thousands just behind each root tip, root hairs increase the surface area for the absorption of water and minerals by the roots.

root hair is an extension of a root epidermal cell (protective cell on a plant surface). Root hairs are not to be confused with lateral roots, which are multicellular organs. Absorption is often enhanced by symbiotic relationships between plant roots and fungi and bacteria, as you will see in Chapters 36 and 37.

T Figure 35.4 Modified roots.

Environmental adaptations may result in roots being modified for a variety of functions. Many modified roots are aerial roots that are above the ground during normal development.

(a) Prop roots. The aerial roots shown here in maize are examples of prop roots, so named because they support tall, top-heavy plants. All roots of a mature maize plant are adventitious after the original roots die. The emerging roots shown here will eventually penetrate the soil.

(b) Storage roots. Many plants, such as sweet potatoes, store food and water in their roots.

(c) "Strangling" aerial roots. The seeds of this strangler fig germinate in the branches of tall trees and send numerous aerial roots to the ground. These snake-like roots gradually wrap around the hosts and objects such as this Cambodian temple ruin. Eventually, the host tree dies of strangulation and shading.

(d) Buttress roots. Aerial roots that look like buttresses support the tall trunks of some tropical trees, such as this ceiba tree in Central America.

Many plants have modified roots. Some of these arise from roots, and others are adventitious, developing from stems and, in rare cases, leaves. Some modified roots provide more support and anchorage, while others store water and nutrients or absorb oxygen or water from the air (Figure 35.4).

(e) Pneumatophores. Also known as air roots, pneumatophores are produced by trees such as mangroves that inhabit tidal swamps. By projecting above the surface, they enable the root system to obtain oxygen, which is lacking in the thick, waterlogged mud.

Stems

A **stem** is an organ consisting of an alternating system of **nodes**, ME points at which leaves are attached, and **internodes**, the stem segments between nodes (see Figure 35.2). In the angle (axil) formed by each leaf and the stem is an **axillary bud**, a structure that has the potential to form a lateral shoot, commonly called a branch. Most axillary buds of a young shoot are dormant (not growing). Thus, elongation of a young shoot is usually concentrated near the shoot apex (tip), which consists of a **terminal bud** with developing leaves and a compact series of nodes and internodes.

The proximity of the terminal bud is partly responsible for inhibiting the growth of axillary buds, a phenomenon called **a deal dominance**. By concentrating resources toward elongation, apical dominance is an evolutionary adaptation that increases the plant's exposure to light. But what if an animal eats the end of the shoot? Or what if, because of obstructions, light is more intense to the side of a plant than directly above it? Under such conditions, axillary buds break dormancy; that is, they start growing. A growing axillary bud gives rise to a lateral shoot, complete with its own terminal bud, leaves, and

axillary buds. Removing the terminal bud usually stimulates the growth of axillary buds, resulting in more lateral shoots. That is why pruning trees and shrubs and "pinching back" houseplants will make them "bushier."

Modified stems with diverse functions have evolved in many plants as environmental adaptations. These modified stems, which include stolons, rhizomes, tubers, and bulbs, are often mistaken for roots (Figure 35.5).

Leaves

The **leaf** is the main photosynthetic organ of most vascular plants, although green stems also perform photosynthesis. Leaves vary extensively in form but generally consist of a flattened **blade** and a stalk, the **petiole**, which joins the leaf to a node of the stem (see Figure 35.2). Among angiosperms, grasses and many other monocots lack petioles; instead, the base of the leaf forms a sheath that envelops the stem. Some monocots, including palm trees, do have petioles.

Monocots and eudicots differ in the arrangement of veins, the vascular tissue of leaves. Most monocots have parallel major veins that run the length of the leaf blade. In contrast,

► **Figure 35.5 Modified stems.**

(a) **Stolons.** Shown here on a strawberry plant, stolons are horizontal stems that grow along the surface. These "runners" enable a plant to reproduce asexually, as plantlets form at nodes along each runner.

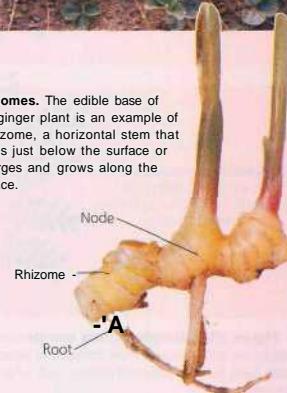

(b) **Bulbs.** Bulbs are vertical, underground shoots consisting mostly of the enlarged bases of leaves that store food. You can see the many layers of modified leaves attached to the short stem by slicing an onion bulb lengthwise.

(c) **Tubers.** Tubers, such as these red potatoes, are enlarged ends of rhizomes specialized for storing food. The "eyes" arranged in a spiral pattern around a potato are clusters of axillary buds that mark the nodes.

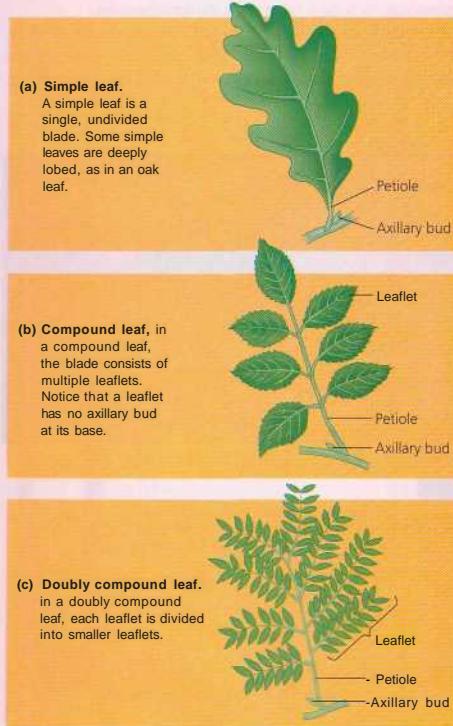

(d) **Rhizomes.** The edible base of this ginger plant is an example of a rhizome, a horizontal stem that grows just below the surface or emerges and grows along the surface.

eudicot leaves generally have a multibranched network of major veins (see Figure 30.12).

In identifying and classifying angiosperms, taxonomists rely mainly on floral morphology, but they also use variations in leaf morphology, such as leaf shape, spatial arrangement of leaves, and the pattern of a leaf's veins. **Figure 35.6** illustrates a difference in leaf shape: simple versus compound leaves. Most very large leaves are compound or doubly compound. This structural adaptation may enable large leaves to withstand strong wind with less tearing and also confine some pathogens that invade the leaf to a single leaflet, rather than allowing them to spread to the entire leaf.

Most leaves are specialized for photosynthesis. However, some plant species have leaves that have become adapted by evolution for other functions, such as support, protection, storage, or reproduction (**Figure 35.7**).

A Figure 35.6 Simple versus compound leaves. You can distinguish simple leaves from compound leaves by looking for axillary buds. Each leaf has only one axillary bud, where the petiole attaches to the stem.

• Figure 35.7 Modified leaves.

(a) Tendrils. The tendrils by which this pea plant clings to a support are modified leaves. After it has "lassoed" a support, a tendril forms a coil that brings the plant closer to the support. Tendrils are typically modified leaves, but some tendrils are modified stems, as in grapevines.

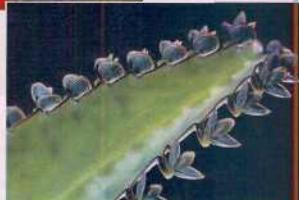

(b) Spines. The spines of cacti, such as this prickly pear, are actually leaves, and photosynthesis is carried out mainly by the fleshy green stems.

(c) Storage leaves. Most succulents, such as this ice plant, have leaves modified for storing water.

(d) Bracts. Red parts of the poinsettia are often mistaken for petals but are actually modified leaves called bracts that surround a group of flowers. Such brightly colored leaves attract pollinators.

(e) Reproductive leaves. The leaves of some succulents, such as *Kalanchoe daigremontiana*, produce adventitious plantlets, which fall off the leaf and take root in the soil.

The Three Tissue Systems: Dermal, Vascular, and Ground

Each plant organ—root, stem, or leaf—has dermal, vascular, and ground tissues. A tissue system consists of one or more tissues organized into a functional unit connecting the organs of a plant. Each tissue system is continuous throughout the entire plant body, but specific characteristics of the tissues and their spatial relationships to one another vary in different organs (Figure 35.8).

The dermal tissue system is the outer protective covering, like our skin, it forms the first line of defense against physical damage and pathogenic organisms. In nonwoody plants, the dermal tissue usually consists of a single layer of tightly packed cells called the epidermis. In woody plants, protective tissues known as periderm replace the epidermis in older regions of stems and roots by a process discussed later in the chapter. In addition to protecting the plant from water loss and disease, the epidermis has specialized characteristics in each organ. For example, the root hairs so important in the absorption of water and minerals are extensions of epidermal cells near root tips. In the epidermis of leaves and most stems, a wax¹ coating called the cuticle helps prevent water loss—an important adaptation

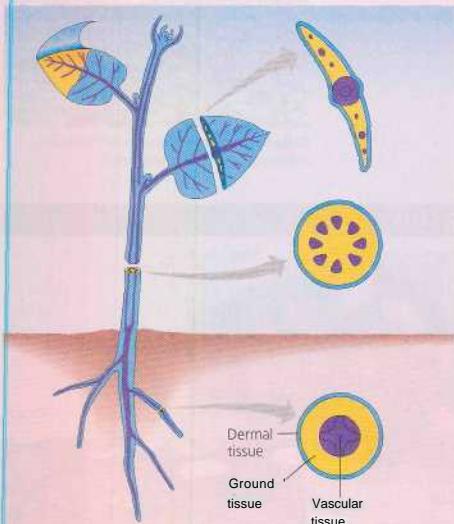

to living on land. Later we will look at specialized leaf cells that regulate CO₂ exchange. Leaf trichomes, which are outgrowths of the epidermis, are yet another example of specialization. For instance, trichomes in aromatic leaves such as mint secrete oils that protect plants from herbivores and disease.

The vascular tissue system carries out long-distance transport of materials between roots and shoots. The two vascular tissues are xylem and phloem. Xylem conveys water and dissolved minerals upward from roots into the shoots. Phloem transports organic nutrients such as sugars from where they are made (usually the leaves) to where they are needed—usually roots and sites of growth, such as developing leaves and fruits. The vascular tissue of a root or stem is collectively called the stele (the Greek word for "pillar"). The arrangement of the stele varies, depending on species and organ. In angiosperms, the stele of the root is in the form of a solid central vascular cylinder. In contrast, the stele of stems and leaves is divided into vascular bundles, strands consisting of xylem and phloem. Both xylem and phloem are composed of a variety of cell types, including cells highly specialized for transport.

Tissues that are neither dermal nor vascular are part of the ground tissue system. Ground tissue that is internal to the vascular tissue is called pith, and ground tissue that is external to the vascular tissue is called cortex. The ground tissue system is more than just filler. It includes various cells specialized for functions such as storage, photosynthesis, and support.

Common Types of Plant Cells

Like any multicellular organism, a plant is characterized by cellular differentiation, the specialization of cells in structure and function. In plant cells, differentiation is sometimes evident within the protoplast, the cell contents exclusive of the cell wall. For example, the protoplasts of some plant cells have chloroplasts, whereas other types of plant cells lack functional chloroplasts. Cell wall modifications also play a role in plant cell differentiation. Figure 35.9, on the next two pages, focuses on some major types of plant cells: parenchyma, collenchyma, sclerenchyma, the water-conducting cells of the xylem, and the sugar-conducting cells of the phloem. Notice the structural adaptations that make specific functions possible. You may wish to review Figures 6.9 and 6.28, which show basic plant cell structure.

▲ **Figure 35.8 The three tissue systems.** The dermal tissue system (blue) covers the entire body of a plant. The vascular tissue system (purple) is also continuous throughout the plant, but is arranged differently in each organ. The ground tissue system (yellow), responsible for most of the plant's metabolic functions, is located between the dermal tissue and the vascular tissue in each organ.

Concept Check 35.1

- How does the vascular tissue system enable leaves and roots to combine functions to support growth and development of the whole plant?
- Describe at least three specializations in plant organs and plant cells that are adaptations to life on land.
- Describe the role of each tissue system in a leaf.

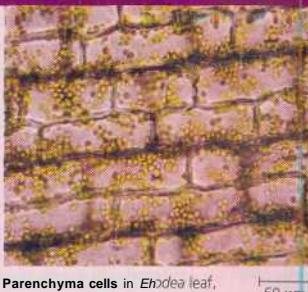

For suggested answers, see Appendix A.

Figure 35.9

Exploring Examples of Differentiated Plant Cells

PARENCHYMA CELLS

Mature **parenchyma cells** have primary walls that are relatively thin and flexible, and most lack secondary walls. (See Figure 6.28 to review primary and secondary layers of cell walls.) The protoplast generally has a large central vacuole. Parenchyma cells are often depicted as "typical" plant cells because they appear to be the least specialized structurally. Parenchyma cells perform most of the metabolic functions of the plant, synthesizing and storing various organic products. For example, photosynthesis occurs within the chloroplasts of parenchyma cells in the leaf. Some parenchyma cells in stems and roots have colorless plastids that store starch. The fleshy tissue of a typical fruit is composed mainly of parenchyma cells. Most parenchyma cells retain the ability to divide and differentiate into other types of plant cells under special conditions—during the repair and replacement of organs after injury to the plant, for example. It is even possible in the laboratory to regenerate an entire plant from a single parenchyma cell.

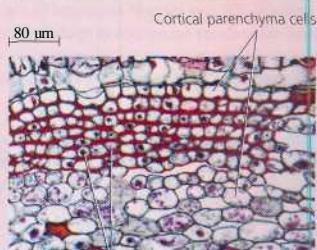

Parenchyma cells in *Erodia* leaf,
with chloroplasts

60 μm

COLLENCHYMA CELLS

Grouped in strands or cylinders, **collenchyma cells** help support young parts of the plant shoot. Collenchyma cells have thicker primary walls than parenchyma cells, though the walls are unevenly thickened. Young stems and petioles often have strands of collenchyma cells just below their epidermis (the "strings" of a celery stalk, for example). Collenchyma cells lack secondary walls, and the hardening agent lignin is absent in their primary walls. Therefore, they provide flexible support without restraining growth. At functional maturity, collenchyma cells are living and flexible, elongating with the stems and leaves they support—**unlike** sclerenchyma cells, which we discuss next.

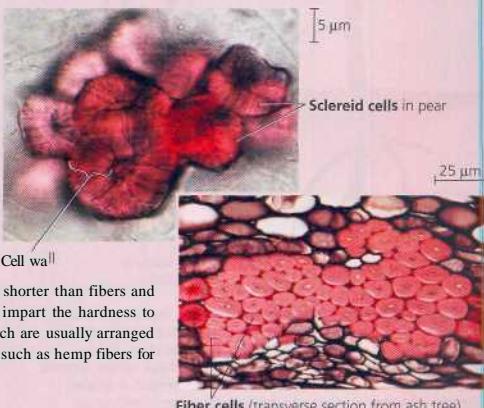

Cortical parenchyma cells
Collenchyma cells (in cortex of *Sambucus*,
elderberry; cell walls stained red)

SCLERENCHYMA CELLS

Also functioning as supporting elements in the plant, but with thick secondary walls usually strengthened by lignin, **sclerenchyma cells** are much more rigid than collenchyma cells. Mature sclerenchyma cells cannot elongate, and they occur in regions of the plant that have stopped growing in length. Sclerenchyma cells are so specialized for support that many are dead at functional maturity, but they produce secondary walls before the protoplast dies. The rigid walls remain as a "skeleton" that supports the plant, in some cases for hundreds of years. In parts of the plant that are still elongating, the secondary walls of immature sclerenchyma are deposited unevenly in spiral or ring patterns. These forms of cell wall thickenings enable the cell wall to stretch like a spring as the cell elongates.

Two types of sclerenchyma cells called **scleoids** and **fibers** are specialized entirely for support and strengthening. Scleoids, which are shorter than fibers and irregular in shape, have very thick, lignified secondary walls. Scleoids impart the hardness to nutshells and seed coats and the gritty texture to pear fruits. Fibers, which are usually arranged in threads, are long, slender, and tapered. Some are used commercially, such as hemp fibers for making rope and flax fibers for weaving into linen.

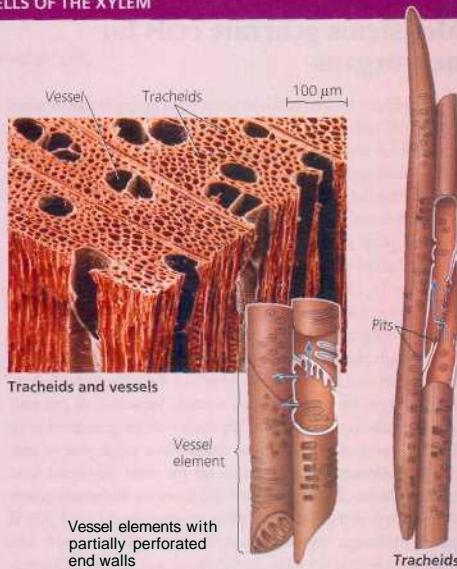

Scleoid cells in pear
Fiber cells (transverse section from ash tree)

WATER-CONDUCTING CELLS OF THE XYLEM

The two types of water-conducting cells, tracheids and vessel elements, are tubular, elongated cells that are dead at functional maturity. Tracheids are found in the xylem of all vascular plants. In addition to tracheids, most angiosperms, as well as a few gymnosperms and a few seedless vascular plants, have vessel elements. When the protoplast of a tracheid or vessel element disintegrates, the cells thickened cell walls remain behind, forming a nonliving conduit through which water can flow. The secondary walls of tracheids and vessel elements are often interrupted by pits, thinner regions where only primary walls are present (see Figure 6.18 to review primary and secondary walls). Water can migrate laterally between neighboring cells through pits.

Tracheids are long, thin cells with tapered ends. Water moves from cell to cell mainly through the pits, where it does not have to cross thick secondary walls. The secondary walls of tracheids are hardened with lignin, which prevents collapse under the tensions of water transport and also provides support.

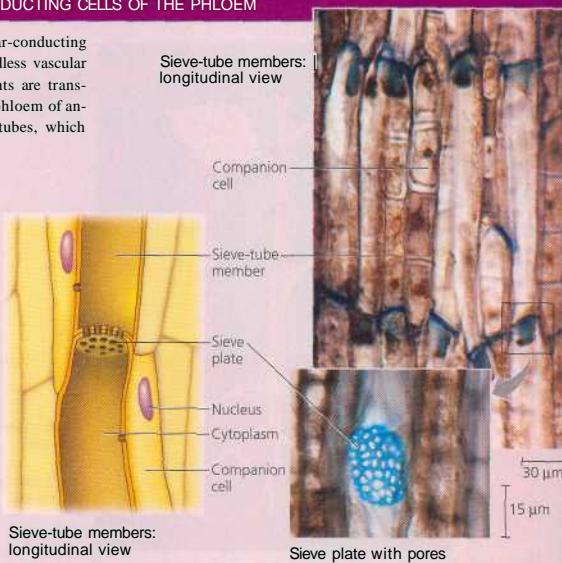

Vessel elements are generally wider, shorter, thinner walled, and less tapered than tracheids. They are aligned end to end, forming long micro-pipes known as vessels. The end walls of vessel elements have perforations, enabling water to flow freely through the vessels.

SUGAR-CONDUCTING CELLS OF THE PHLOEM

Unlike the water-conducting cells of the xylem, the sugar-conducting cells of the phloem are alive at functional maturity. In seedless vascular plants and gymnosperms, sugars and other organic nutrients are transported through long, narrow cells called sieve cells. In the phloem of angiosperms, these nutrients are transported through sieve tubes, which consist of chains of cells called sieve-tube members.

Though alive, sieve-tube members lack such organelles as the nucleus, ribosomes, and a distinct vacuole. This reduction in cell contents enables nutrients to pass more easily through the cell. The end walls between sieve-tube members, called sieve plates, have pores that facilitate the flow of fluid from cell to cell along the sieve tube. Alongside each sieve-tube member is a nonconducting cell called a companion cell, which is connected to the sieve-tube member by numerous channels, the plasmodesmata (see Figure 6.8). The nucleus and ribosomes of the companion cell may serve not only that cell itself but also the adjacent sieve-tube member. In some plants, companion cells in leaves also help load sugars into the sieve-tube members, which then transport the sugars to other parts of the plant.

Concept 35.2

Meristems generate cells for new organs

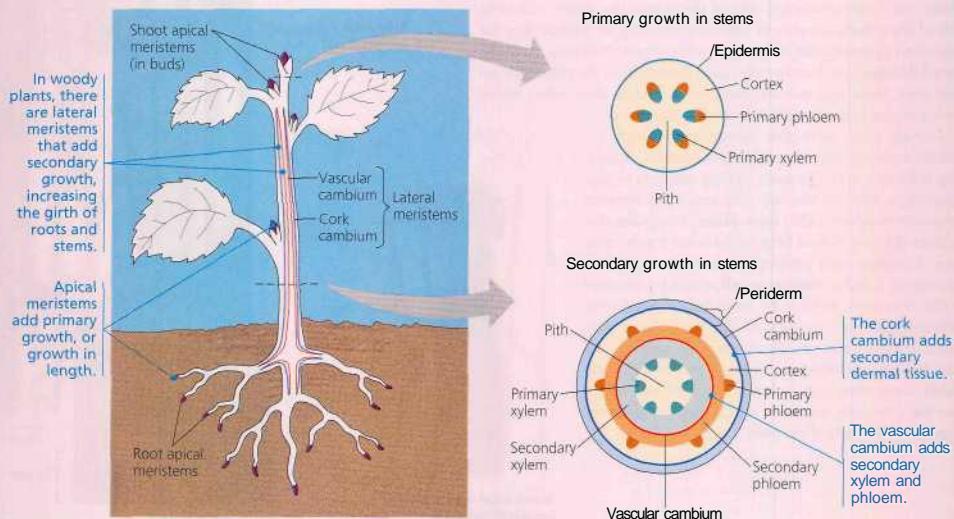

So far, we have looked at the structure and arrangement of plant tissues and cells in mature organs. But how does this organization arise? A major difference between plants and most animals is that plant growth is not limited to an embryonic or juvenile period. Instead, growth occurs throughout the plant's life, a condition known as **indeterminate growth**. At any given time, a typical plant consists of embryonic, developing, and mature organs. Except for periods of dormancy, most plants grow continuously. In contrast, most animals and some plant organs, such as most leaves, undergo **determinate growth**; that is, they cease growing after reaching a certain size.

Although plants continue to grow throughout their lives, they do die, of course. Based on the length of their life cycle, flowering plants can be categorized as annuals, biennials, or perennials. **Annuals** complete their life cycle—from germination to flowering to seed production to death—in a single year or less. Many wildflowers are annuals, as are the most important food crops, including the cereal grains and legumes. **Biennials** generally live two years, often including an intervening cold period (winter) between vegetative growth (first spring/summer) and flowering (second spring/summer). Beets and carrots are biennials.

but are rarely left in the ground long enough to flower. **Perennials** live many years and include trees, shrubs, and some grasses. Some buffalo grass of the North American plains is believed to have been growing for 10,000 years. From seeds that sprouted at the close of the last ice age. When a perennial dies, it is not usually from old age, but from an infection or some environmental trauma, such as fire or severe drought.

Plants are capable of indeterminate growth because they have perpetually embryonic tissues called meristems. There are two main types: apical meristems and lateral meristems. **Apical meristems**, located at the tips of roots and in the buds of shoots, provide additional cells that enable the plant to grow in length, a process known as **primary growth**. Primary growth allows roots to extend throughout the soil and shoots to increase exposure to light and CO₂. In herbaceous (nonwoody) plants, primary growth produces all, or almost all, of the plant body. Woody plants, however, grow in girth in the parts of stems and roots where primary growth has ceased. This growth in thickness, known as **secondary growth**, is caused by the activity of **lateral meristems** called the vascular cambium and cork cambium. These cylinders of dividing cells extend along the length of roots and stems (Figure 35.10). The **vascular cambium** adds layers of vascular tissue called secondary xylem (wood) and secondary phloem. The **cork cambium** replaces the epidermis with periderm, which is thicker and tougher.

The cells within meristems divide relatively frequently, generating additional cells. Some products of this division

A Figure 35.10 An overview of primary and secondary growth.

retain in the meristem and produce more cells, while others differentiate and are incorporated into tissues and organs of the growing plant. Cells that remain as sources of new cells are called initials. The new cells displaced from the meristem, called derivatives, continue to divide until the cells they produce become specialized within developing tissues.

In woody plants, primary and secondary growth occur simultaneously but in different locations. Each growing season, primary growth near the apical meristem produces young extensions of roots and shoots, while lateral meristems produce secondary growth that thickens and strengthens older parts of the plant (**Figure 35.11**). The oldest regions, such as at a tree trunk base, have the most accumulation of tissues produced by secondary growth.

Concept Check 35.2

- Cells in lower layers of your skin divide and replace dead cells sloughed from the surface. Why is it inaccurate to compare such regions of cell division to a plant meristem?
- Contrast the types of growth arising from apical and lateral meristems.

For suggested answers, see Appendix A.

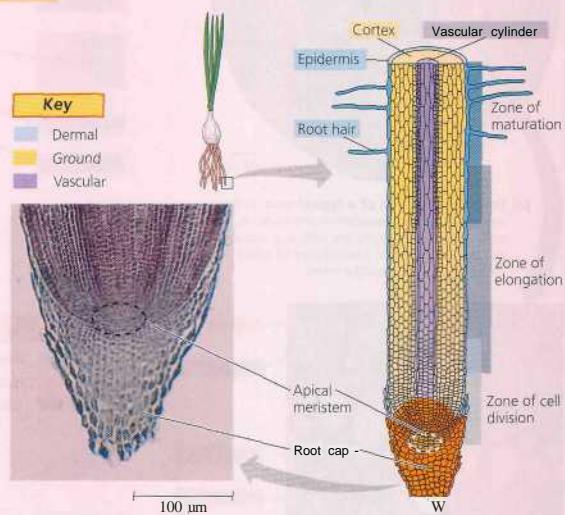

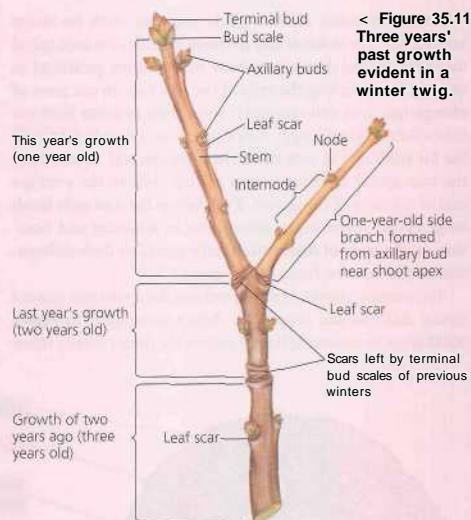

Concept 35.3

I*primary growth lengthens roots and shoots

Primary growth produces the primary plant body, the parts of the root and shoot systems produced by apical meristems. In herbaceous plants, the primary plant body is usually the entire plant. In woody plants, it consists only of the youngest parts, which have not yet become woody. Although apical meristems lengthen both roots and shoots, there are differences in the primary growth of these two systems.

I'primary Growth of Roots

The root tip is covered by a thimble-like root cap, which protects the delicate apical meristem as the root pushes through the abrasive soil during primary growth. The root cap also secretes a polysaccharide slime that lubricates the soil around the root tip. Growth occurs just behind the root tip, in three zones of cells at successive stages of primary growth. Moving away from the root tip, they are the zones of cell division, elongation, and maturation (**figure 35.12**).

A Figure 35.12 Primary growth of a root. The diagram and light micrograph take us into the tip of an onion root. Mitosis is concentrated in the zone of cell division, where the apical meristem and its immediate products are located. The apical meristem also maintains the root cap by generating new cells that replace those that are sloughed off. Most lengthening of the root is concentrated in the zone of elongation. Cells become functionally mature in the zone of maturation. The zones grade into one another without sharp boundaries.

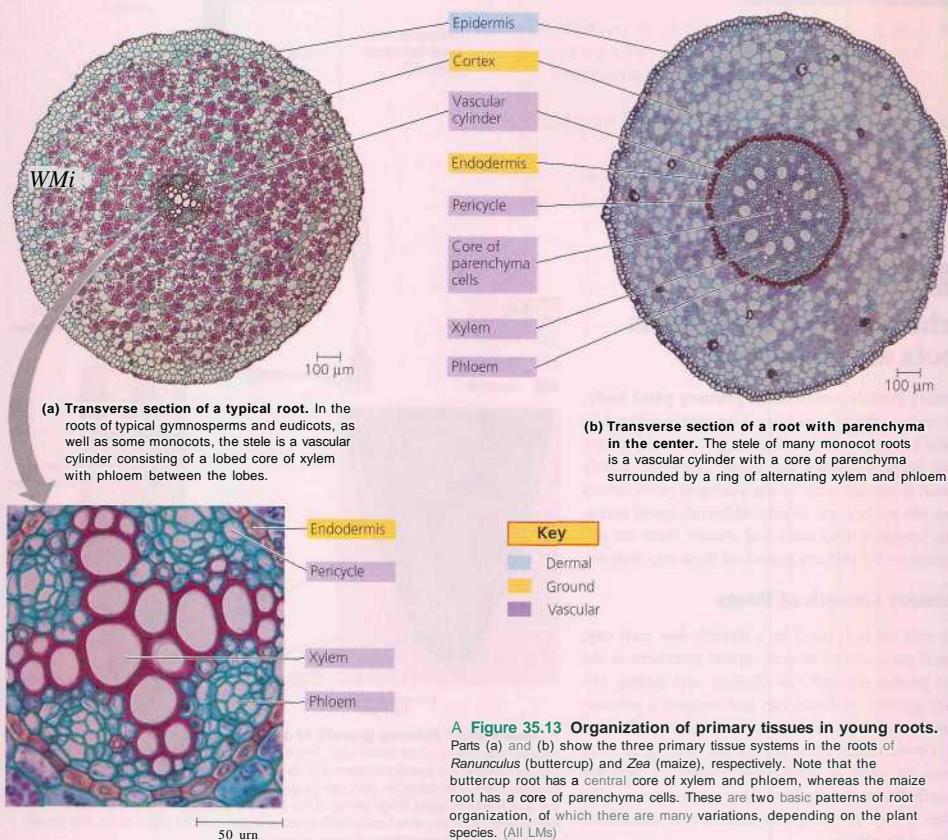

The three zones of cells grade together, with no sharp boundaries. The **zone of cell division** includes the root apical meristem and its derivatives. New root cells are produced in this region, including the cells of the root cap. In the zone of **elongation**, root cells elongate, sometimes to more than ten times their original length. Cell elongation is mainly responsible for pushing the root tip farther into the soil. Meanwhile, the root apical meristem keeps adding cells to the younger end of the zone of elongation. Even before the root cells finish lengthening, many begin specializing in structure and function. In the zone of **maturity**, cells complete their differentiation and become functionally mature.

The primary growth of roots produces the epidermis, ground tissue, and vascular tissue. The light micrographs in **Figure 35.13** show in transverse (cross) section the three primary tissue

systems in the young roots of a eudicot (*Ranunculus*, buttercup) and a monocot (*Zea*, maize). Water and minerals absorbed from the soil must enter through the epidermis, a single layer of cells covering the root. Root hairs enhance this process by greatly increasing the surface area of epidermal cells.

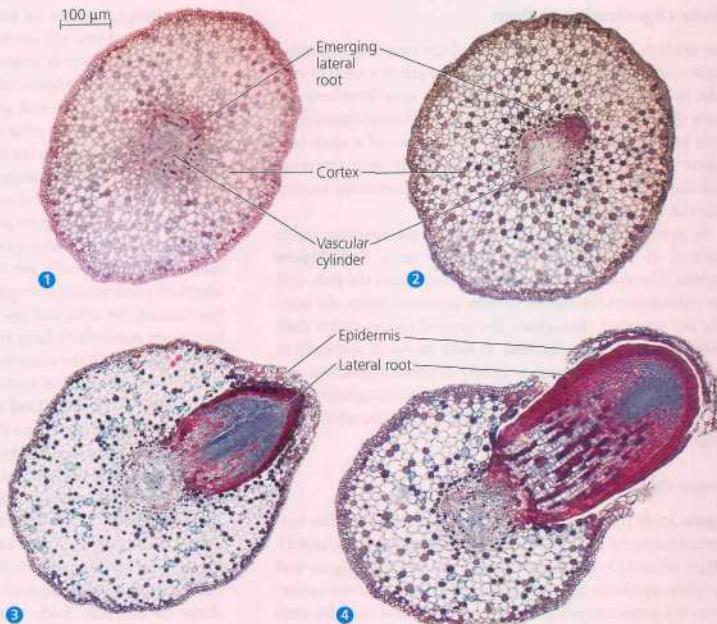

In most roots, the stele is a vascular cylinder, a solid core of xylem and phloem (see Figure 35.13a). The xylem radiates from the center in two or more spokes, with phloem developing in the wedges between the spokes. In many monocot roots, the vascular tissue consists of a central core of parenchyma cells surrounded by alternating rings of xylem and phloem (see Figure 35.13b). The central region is often called pith but should not be confused with stem pith, which is ground tissue.

The ground tissue of roots, consisting mostly of parenchyma cells, fills the cortex, the region between the vascular cylinder

A Figure 35.13 Organization of primary tissues in young roots. Parts (a) and (b) show the three primary tissue systems in the roots of *Ranunculus* (buttercup) and *Zea* (maize), respectively. Note that the buttercup root has a central core of xylem and phloem, whereas the maize root has a core of parenchyma cells. These are two basic patterns of root organization, of which there are many variations, depending on the plant species. (All LMs)

► Figure 35.14 The formation of a lateral root. A lateral root originates in the pericycle, the outermost layer of the vascular cylinder of a root, and grows out through the cortex and epidermis. In this series of micrographs, the view of the original root is a transverse section, while the view of the lateral root is a longitudinal section.

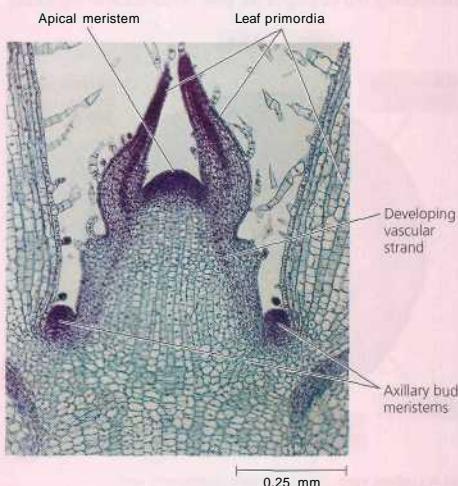

and epidermis. Cells within the ground tissue store organic nutrients, and their plasma membranes absorb minerals from the soil solution. The innermost layer of the cortex is called the endodermis, a cylinder one cell thick that forms the boundary with the vascular cylinder. You will learn in Chapter 36 how the endodermis is a selective barrier regulating passage of substances from the soil solution into the vascular cylinder.

Lateral roots arise from within the pericycle, the outermost cell layer in the vascular cylinder (see Figure 35.13). A lateral root elongates and pushes through the cortex and epidermis until it emerges from the established root (Figure 35.14). It cannot originate near the root's surface because it must remain connected with the vascular cylinder of the established root as part of the continuous vascular tissue system.

Primary Growth of Shoots

A shoot apical meristem is a dome-shaped mass of dividing cells at the tip of the terminal bud (Figure 35.15). Leaves arise as leaf primordia (singular, *primordium*), finger-like projections along the flanks of the apical meristem. Axillary buds develop from islands of meristematic cells left by the apical meristem at the bases of the leaf primordia. Axillary buds can form lateral shoots at some later time (see Figure 35.2).

Within a bud, leaf primordia are crowded close together because internodes are very short. Most of the actual elongation of the shoot occurs by the growth in length of slightly older internodes below the shoot apex. This growth is due to both cell division and cell elongation within the internode. So, like plants, including grasses, elongate all along the shoot because there are meristematic regions called intercalary meristems at the base of each leaf. That is why grass continues to grow after being mowed.

► Figure 35.15 The terminal bud and primary growth of a shoot. Leaf primordia arise from the flanks of the apical dome. This is a longitudinal section of the shoot tip of *Coleus* (LM).

Tissue Organization of Stems

The epidermis covers stems as part of the continuous dermal tissue system. Vascular tissue runs the length of a stem in vascular bundles. Unlike lateral roots, which arise from vascular tissue deep within a root (see Figure 35.14), lateral shoots arise from preexisting axillary buds on the surface of a stem (see Figure 35.15). The vascular bundles of the stem converge with the roots vascular cylinder in a zone of transition located near the soil surface.

In gymnosperms and most eudicots, the vascular tissue consists of vascular bundles arranged in a ring (Figure 35.16a). The xylem in each vascular bundle faces the pith, and the phloem faces the cortex. In most monocot stems, the bundles are scattered throughout the ground tissue, rather than forming a ring (Figure 35.16b). In both monocot and eudicot stems, ground tissue consists mostly of parenchyma, but collenchyma cells just beneath the epidermis strengthen many stems. Sclerenchyma cells, specifically fiber cells within vascular bundles, also provide support.

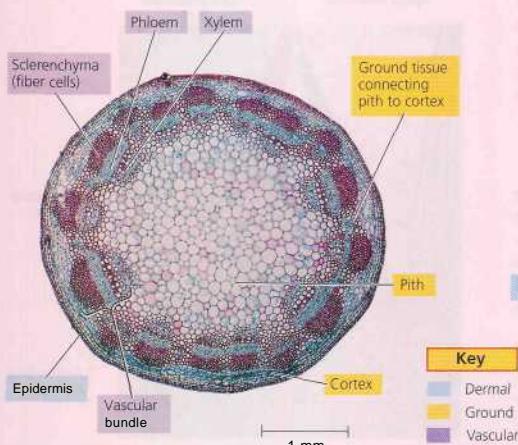

Tissue Organization of Leaves

Figure 35.17 provides an overview of leaf structure. The epidermal barrier is interrupted by the stomata (singular, *stoma*), which allow CO₂ exchange between the surrounding air and the photosynthetic cells inside the leaf. The term *stoma* can refer to the stomatal pore or to the entire stomatal complex consisting of a pore flanked by two guard cells, which regulate the opening and closing of the pore. In addition to regulating

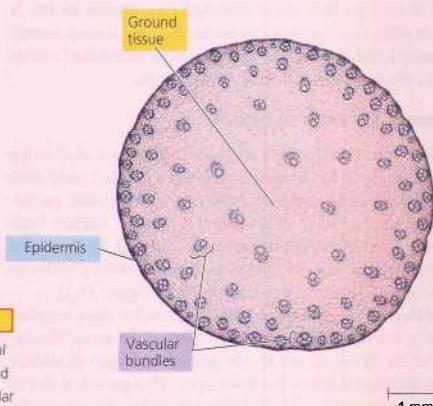

CO₂ exchange, stomata are major avenues for the evaporation / loss of water, as you will see in Chapter 36.

The ground tissue is sandwiched between the upper and lower epidermis, a region called the **mesophyll** (from the Greek *mesos*, middle, and *phyll*, leaf). Mesophyll consists mainly of parenchyma cells specialized for photosynthesis. The leaves of many eudicots have two distinct areas: palisade mesophyll, or palisade parenchyma, consists of one or more layers of elongated cells on the upper part of the leaf. The spongy mesophyll, also called spongy parenchyma, is below the palisade mesophyll. These cells are more loosely arranged, with a labyrinth of air spaces through which CO₂ and oxygen circulate around the cells and up to the palisade region. The air spaces are particularly large in the vicinity of stomata, where gas exchange with the outside air occurs.

The vascular tissue of each leaf is continuous with the vascular tissue of the stem. Leaf traces, connections from vascular bundles in the stem, pass through petioles and into leaves. Veins are the leaf's vascular bundles, which subdivide repeatedly and branch throughout the mesophyll. This network brings xylem and phloem into close contact with the photosynthetic tissue, which obtains water and minerals from the xylem and loads its sugars and other organic products into the phloem for shipment to other parts of the plant. The vascular structure also functions as a skeleton that reinforces the shape of the leaf. Each vein is enclosed by a protective bundle sheath, consisting of one or more cell layers, usually consisting of parenchyma.

Concept 35.4

J Secondary growth adds girth to stems and roots in woody plants

Secondary growth, the growth in thickness produced by lateral meristems, occurs in stems and roots of woody plants, but rarely in leaves. The secondary plant body consists of the tissues produced by the vascular cambium and cork cambium. The vascular cambium adds secondary xylem (wood) and secondary phloem. Cork cambium produces a tough, thick covering consisting mainly of cork cells.

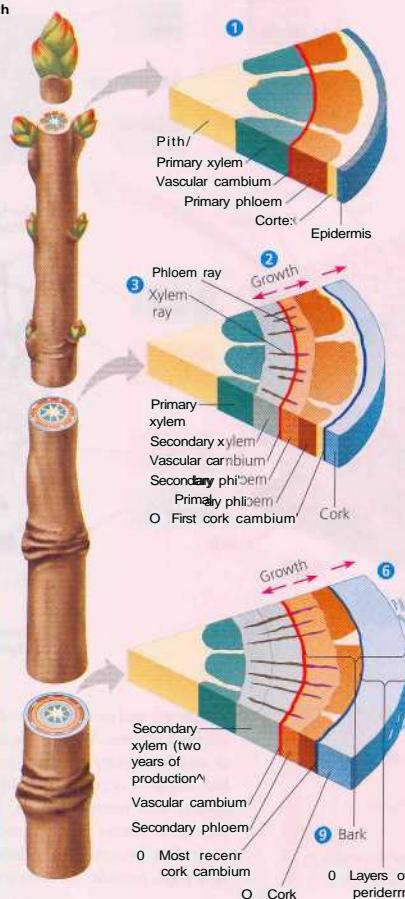

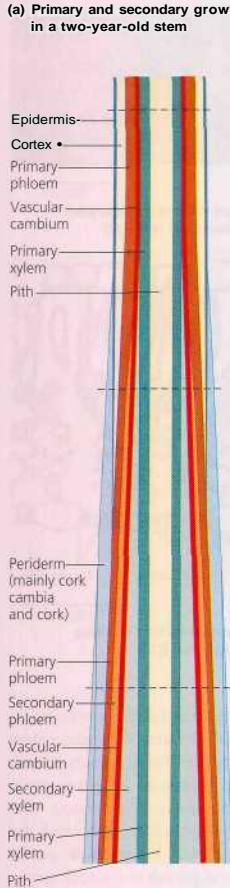

Primary and secondary growth occur simultaneously but in different regions. While an apical meristem elongates a stem or root, secondary growth commences where primary growth has stopped, occurring in older regions of all gymnosperm species and many eudicots, but rarely in monocots. The process is similar in stems and roots, which look much the same after extensive secondary growth. Figure 35.18, on the next page, provides an overview of growth in a woody stem.

The Vascular Cambium and Secondary Vascular Tissue

The vascular cambium is a cylinder of meristematic cells one cell thick. It increases in circumference and also lays down successive layers of secondary xylem to its interior and secondary phloem to its exterior, each layer with a larger diameter than the previous layer (see Figure 35.18). In this way, it is primarily responsible for the thickening of a root or stem.

The vascular cambium develops from undifferentiated cells and parenchyma cells that regain the capacity to divide. In a typical gymnosperm or woody eudicot stem, the vascular cambium forms in a layer between the primary xylem and primary phloem of each vascular bundle and in the ground tissue between the bundles. The meristematic bands within and between the

(a) Primary and secondary growth in a two-year-old stem

Q In the youngest part of the stem, you can see the primary plant body, as formed by the apical meristem during primary growth. The vascular cambium is beginning to telop.

Q As primary growth continues to elongate the stem, the portion of the stem formed earlier the same year has already started secondary growth. This portion increases in girth as fusiform initials of the vascular cambium form secondary xylem to the inside and secondary phloem to the outside.

0 The ray initials of the vascular cambium give rise to the xylem and phloem rays.

0 As the diameter of the vascular cambium increases, the secondary phloem and other tissues external to the cambium cannot keep pace with the expansion because the cells no longer divide. As a result, these tissues, including the epidermis, rupture. A second lateral meristem, the cork cambium, develops from parenchyma cells in the cortex. The cork cambium produces cork cells, which replace the epidermis.

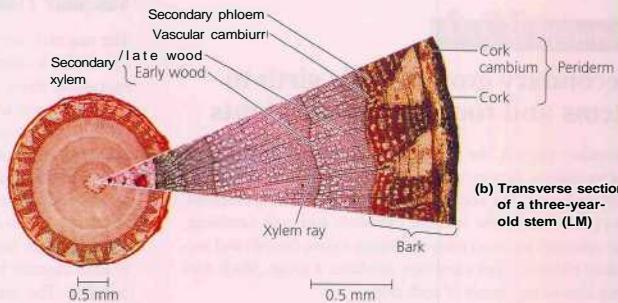

0 In year 2 of secondary growth, the vascular cambium adds to the secondary xylem and phloem, and the cork cambium produces cork.

0 As the diameter of the stem continues to increase, the outermost tissues exterior to the cork cambium rupture and slough off from the stem.

0 Cork cambium re-forms in progressively deeper layers of the cortex. When none of the original cortex is left, the cork cambium develops from parenchyma cells in the secondary phloem.

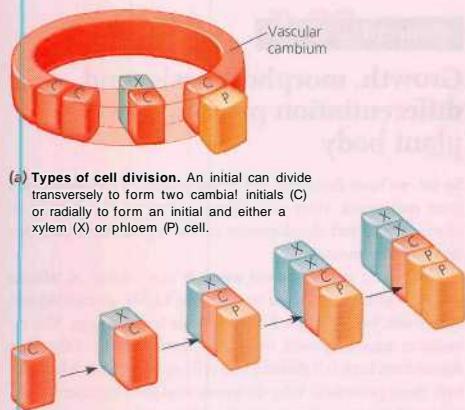

0 Each cork cambium and the tissues it produces form a layer of periderm.

0 Bark consists of all tissues exterior to the vascular cambium.

(b) Transverse section of a three-year-old stem (LM)

A Figure 35.18 Primary and secondary growth of a stem. You can track the progress of secondary growth by examining the sections through sequentially older parts of the stem. (You would observe the same changes if you could follow the youngest region, near the apex, for the next three years.)

(b) Accumulation of secondary growth. Although shown here as alternately adding xylem and phloem, a cambial initial usually produces much more xylem.

▲ **Figure 35.19 Cell division in the vascular cambium.**

vascular bundles unite to become a continuous cylinder of dividing cells. In a typical gymnosperm or woody eudicot root, the vascular cambium forms in segments between the primary phloem, the lobes of primary xylem, and the pericycle, eventually becoming a cylinder.

Viewed in transverse section, the vascular cambium appears as a ring, with interspersed regions of cells called *fusiform initials* and *ray initials*. When these initials divide, they increase the circumference of the cambium itself and add secondary xylem to the inside of the cambium and secondary phloem to the outside (Figure 35.19). *Fusiform initials* produce elongated cells such as the tracheids, vessel elements, and fibers of the xylem, as well as the sieve-tube members, companion cells, parenchyma, and fibers of the phloem. They have tapered (*fusiform*) ends and are oriented parallel to the axis of a stem or root. *Ray initials*, which are shorter and oriented perpendicular to the stem or root axis, produce vascular rays—radial files consisting mainly of parenchyma cells. Vascular rays are living avenues that move water and nutrients between the secondary xylem and secondary phloem. They also store starch and other organic nutrients. The portion of a vascular ray tested in the secondary xylem is known as a *xylem ray*. The portion located in the secondary phloem is called a *phloem ray*.

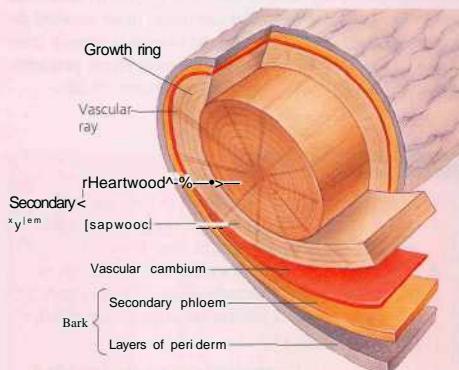

As secondary growth continues over the years, layers of secondary xylem (wood) accumulate, consisting mainly of tracheids, vessel elements, and fibers (see Figure 35.9). Gymnosperms have tracheids, whereas angiosperms have both tracheids and vessel elements. Dead at functional maturity, both types of cells have thick, lignified walls that give wood its hardness and strength. Tracheids and vessel elements that develop

early in the growing season, typically in early spring, are known as *early wood* and usually have relatively large diameters and thin cell walls (see Figure 35.18b). This structure maximizes delivery of water to new, expanding leaves. Tracheids and vessel elements produced later in the growing season, during late summer or early fall, are known as *late wood*. They are thick-walled cells that do not transport as much water but do add more support than do the thinner-walled cells of early wood.

In temperate regions, secondary growth in perennial plants is interrupted each year when the vascular cambium becomes dormant during winter. When growth resumes the next spring, the boundary between the large cells of the new early wood and the smaller cells of the late wood produced during the previous growing season is usually a distinct ring in the transverse sections of most tree trunks and roots. Therefore, a tree's age can be estimated by counting its annual rings. The rings can have varying thicknesses, reflecting the amount of seasonal growth.

As a tree or woody shrub ages, the older layers of secondary xylem no longer transport water and minerals (xylem sap). These layers are called *heartwood* because they are closer to the center of a stem or root (Figure 35.20). The outer layers still transport xylem sap and are therefore known as *sapwood*. That is why a large tree can still survive even if the center of its trunk is hollow. Because each new layer of secondary xylem has a larger circumference, secondary growth enables the xylem to transport more sap each year, supplying an increasing number of leaves. Heartwood is generally darker than sapwood because of resins and other compounds that clog the cell cavities and help protect the core of the tree from fungi and wood-boring insects.

Only the youngest secondary phloem, closest to the vascular cambium, functions in sugar transport. As a stem or root increases in circumference, the older secondary phloem is sloughed off, which is why secondary phloem does not accumulate as extensively as does secondary xylem.

▲ **Figure 35.20 Anatomy of a tree trunk.**

Cork Cambia and the Production of Periderm

During the early stages of secondary growth, the epidermis is pushed outward, causing it to split, dry, and fall off the stem or root. It is replaced by two tissues produced by the first cork cambium, which arises in the outer cortex in stems (see Figure 35.18a) and in the outer layer of the pericycle in roots. One tissue, called *phellogen*, is a thin layer of parenchyma cells that forms to the interior of the cork cambium. The other tissue consists of cork cells that accumulate to the exterior of the cork cambium. As cork cells mature, they deposit a waxy material called *suberin* in their walls and then die. The cork tissue then functions as a barrier that helps protect the stem or root from water loss, physical damage, and pathogens. A cork cambium and the tissues it produces comprise a layer of periderm.

Because cork cells have suberin and are usually compacted together, most of the periderm is impermeable to water and gases, unlike the epidermis. Therefore, in most plants, absorption of water and minerals takes place primarily in the youngest parts of roots, mainly the root hairs. The older parts anchor the plant and transport water and solutes between roots and shoots. Dotted the periderm are small, raised areas called lenticels, in which there is more space between the cork cells, enabling living cells within a woody stem or root to exchange gases with the outside air.

Unlike the vascular cambium, cells of the cork cambium do not continue to divide; thus, there is no increase in its circumference. Instead, the thickening of a stem or root splits the first cork cambium, which loses its meristematic activity and differentiates into cork cells. A new cork cambium forms to the inside, resulting in another layer of periderm. As this process continues, older layers of periderm are sloughed off, as is evident in the cracked, peeling bark of many tree trunks.

Many people think that bark is only the protective outer covering of a woody stem or root. Actually bark includes all tissues external to the vascular cambium. In an outward direction, its main components are the secondary phloem (produced by the vascular cambium), the most recent periderm, and all the older layers of periderm (see Figure 35.20).

Concept 35.5

Growth, morphogenesis, and differentiation produce the plant body

So far, we have described the development of the plant body from meristems. Here we will move from a description of plant growth and development to the mechanisms that underlie these processes.

Consider a typical annual weed. It may consist of billions of cells—some large, some small, some highly specialized and others not, but all derived from a single fertilized egg. The increase in mass, or growth, that occurs during the life of the plant results from both cell division and cell expansion, but what controls these processes? Why do leaves stop growing upon reaching a certain size, whereas apical meristems divide perpetually? Also, note that the billions of cells in our hypothetical weed are not an undifferentiated clump of cells. They are organized into recognizable tissues and organs. Leaves arise from nodes; roots (unless adventitious) do not. Epidermis forms on the exterior of the leaf, and vascular tissue in the interior—never vice versa.

The development of body form and organization is called morphogenesis. Each cell in the plant body contains the same set of genes, exact copies of the genome present in the fertilized egg. Different patterns of gene expression among cells cause the cellular differentiation that creates a diversity of cell types (see Chapter 21). The three developmental processes of growth, morphogenesis, and cellular differentiation act in concert to transform the fertilized egg into a plant.

Molecular Biology: Revolutionizing the Study of Plants

Modern molecular techniques are helping plant biologists explore how growth, morphogenesis, and cellular differentiation give rise to a plant. In the current renaissance in plant biology, new laboratory methods coupled with clever choices of experimental organisms have catalyzed a research explosion. One research focus is *Arabidopsis thaliana*, a little weed of the mustard family that is small enough to allow researchers to cultivate thousands of plants in a few square meters of lab space (Figure 35.21). Its short generation span, about six weeks from germination to flowering, makes *Arabidopsis* an excellent model for genetic studies. Plant biologists also favor the tiny amount of DNA per cell, among the smallest genomes of all known plants. As a result of these attributes, *Arabidopsis* was the first plant to have its entire genome sequenced—a six-year, multinational effort.

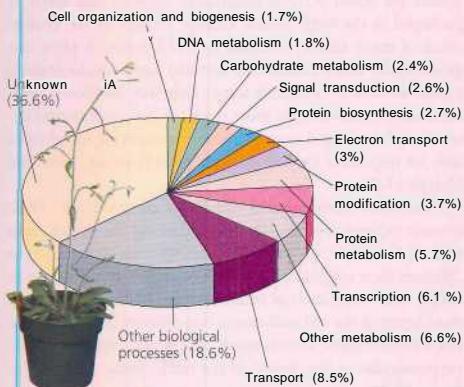

Arabidopsis possesses about 26,000 genes, but many of these are duplicates. There are probably fewer than 15,000 different types of genes, a level of complexity similar to that

Concept Check 35.4

1. A sign is hammered into a tree 2 m from the tree's base. If the tree is 10 m tall and elongates 1 m each year, how high will the sign be after 10 years?
2. A tree can survive even if a tunnel is cut through its center. However, removing a complete ring of bark around the trunk (a process called girdling) will kill the tree. Explain why.

For suggested answers, see Appendix A.

found in the fly *Drosophila*. Knowing what some of the *Arabidopsis* genes do has already expanded our understanding of plant development (see Figure 35.21). To fill the gaps in our knowledge, plant biologists have launched an ambitious quest to determine the function of every one of the plant's genes by the year 2010. Toward this end, they are attempting to create mutants for every gene in the plant's genome. We will discuss

▲ **Figure 35.21** *Arabidopsis thaliana*. Owing to its small size, rapid life cycle, and small genome, *Arabidopsis* was the first plant to have its entire genome sequenced (about 26,000 genes). The pie chart represents the proportion of *Arabidopsis* genes in different functional categories. (Data from TAIR, The *Arabidopsis* Information Resource, 2004)

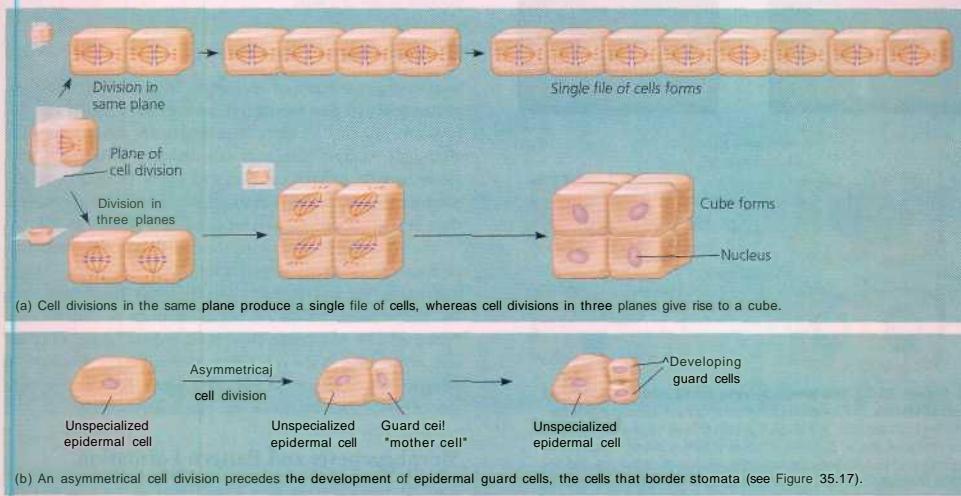

some of these mutants shortly as we take a closer look at the molecular mechanisms that underlie growth, morphogenesis, and cellular differentiation. By identifying each gene's function and tracking every chemical pathway, researchers aim to establish a blueprint for how plants are built, a major goal of systems biology, as discussed by Natasha Raikhel in the interview on pages 710–711. It may one day be possible to create a computer-generated "virtual plant" that enables researchers to visualize which plant genes are activated in different parts of the plant during the entire course of development.

Growth: Cell Division and Cell Expansion

By increasing cell number, cell division in meristems increases the potential for growth. However, it is cell expansion that accounts for the actual increase in plant mass. The process of plant cell division is described more fully in Chapter 12 (see Figure 12.10), and Chapter 39 discusses the process of cell elongation (see Figure 39.8). Here we are more concerned with how these processes contribute to plant form.

The Plane and Symmetry of Cell Division

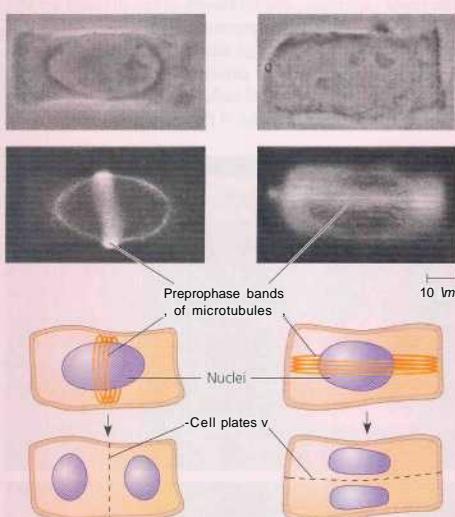

The plane (direction) and symmetry of cell division are immensely important in determining plant form. Imagine a single cell poised to undergo mitosis. If the planes of division of its descendants are parallel to the plane of the first cell division, a single file of cells will be produced (Figure 35.22a). At the other extreme, if the planes vary randomly, a

▲ **Figure 35.22** The plane and symmetry of cell division influence development of form.

disorganized clump of cells results. Meanwhile, even though chromosomes are allocated to daughter cells equally during mitosis, the cytoplasm may divide asymmetrically. Asymmetrical cell division, in which one daughter cell receives more cytoplasm than the other during mitosis, is fairly common in plant cells and usually signals a key event in development. For example, the formation of guard cells typically involves both an asymmetrical cell division and a change in the plane of cell division. An epidermal cell divides asymmetrically to form a large cell that remains an unspecialized epidermal cell and a small cell that becomes the guard cell "mother cell." Guard cells form when this small mother cell divides in a plane perpendicular to the first cell division (Figure 35.22b).

The plane in which a cell divides is determined during late interphase. The first sign of this spatial orientation is a rearrangement of the cytoskeleton. Microtubules in the cytoplasm become concentrated into a ring called the preprophase band (Figure 35.23). The band disappears before metaphase, but it predicts the future plane of cell division. The "imprint" consists of an ordered array of actin microfilaments that remain after the microtubules disperse.

A Figure 35.23 The preprophase band and the plane of cell division. The location of the preprophase band predicts the plane of cell division. Although the cells shown on the left and right are similar in shape, they will divide in different planes. Each cell is represented by two light micrographs, one (top) unstained and the other (bottom) stained with a fluorescent dye that binds specifically to microtubules. The stained microtubules form a "halo" (preprophase band) around the nucleus in the outer cytoplasm.

Orientation of Cell Expansion

Before discussing how cell expansion contributes to plant form, it is useful to consider the difference in cell expansion between plants and animals. Animal cells grow mainly by synthesizing protein-rich cytoplasm, a metabolically expensive process. Growing plant cells also produce additional protein-rich material in their cytoplasm, but water uptake typically accounts for about 90% of expansion. Most of this water is packaged in the large central vacuole formed by the coalescence of many smaller vacuoles as a cell grows. A plant can grow rapidly and economically because water uptake enables a small amount of cytoplasm to go a long way. Bamboo shoots, for instance, can elongate more than 2 m per week. Rapid extension of shoots and roots increases the exposure to light and soil, an important evolutionary adaptation to the immobile lifestyle of plants.

Plant cells rarely expand equally in all directions. Their greatest expansion is usually oriented along the plant's main axis. For example, cells near the root tip may elongate up to 20 times their original length, with relatively little increase in width. The orientation of cellulose microfibrils in the innermost layers of the cell wall causes this differential growth. The microfibrils cannot stretch much, so the cell expands mainly perpendicular to the "grain" of the microfibrils, as shown in Figure 35.24.

As with the plane of cell division, microtubules play a key role in regulating the plane of cell expansion. It is the orientation of microtubules in the cell's outermost cytoplasm that determines the orientation of cellulose microfibrils that are deposited in the cell wall.

Microtubules and Plant Growth

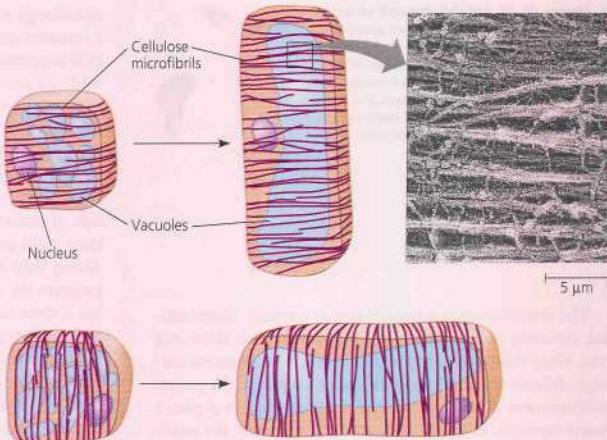

Studies of *jas* mutants of *Arabidopsis* have confirmed the importance of cytoplasmic microtubules in cell division and expansion. The *jas* mutants have unusually squat cells with seemingly random planes of cell division. Their roots and stems have no ordered cell files and layers. Despite these abnormalities, *jass* mutants develop into tiny adult plants, but their organs are compressed longitudinally (Figure 35.25).

The stubby form and disorganized tissue arrangement can be traced to abnormal organization of microtubules. During interphase, the microtubules are randomly positioned, and the preprophase bands do not form prior to mitosis (see Figure 35.23). As a result, there is no orderly "grain" of cellulose microfibrils in the cell wall to determine the direction of elongation (see Figure 35.24). This defect gives rise to cells that expand in all directions and divide haphazardly.

Morphogenesis and Pattern Formation

A plant's body is more than a collection of dividing and expanding cells. Morphogenesis must occur for development to

► Figure 35.24 The orientation of plant cell expansion. Growing plant cells expand mainly through water uptake. In a growing cell, enzymes weaken cross-links in the cell wall, allowing it to expand as water diffuses into the vacuole by osmosis. As shown in these two examples of different orientations, the orientation of cell growth is mainly in the plane perpendicular to the orientation of cellulose microfibrils in the wall. The microfibrils are embedded in a matrix of other (non-cellulose) polysaccharides, some of which form the cross-links visible in the micrograph (TEM). Loosening of the wall occurs when hydrogen ions secreted by the cell activate cell wall enzymes that break the cross-links between polymers in the wall. This reduces restraint on the turgid cell, which can take up more water and expand. Small bubbles, which accumulate most of this water, coalesce and form the cell's central vacuole.

(a) Wild-type seedling

(c) Mature fass mutant

▲ Figure 35.25 The fass mutant of *Arabidopsis* confirms the importance of cytoplasmic microtubules to plant growth. The squat body of the fass mutant results from cell division and cell elongation being randomly oriented instead of orienting in the direction of the normal plant axis.

proceed properly; that is, cells must be organized into multicellular arrangements such as tissues and organs. The development of specific structures in specific locations is called **pattern formation**.

Many developmental biologists postulate that pattern formation is determined by **positional information** in the form of signals that continuously indicate to each cell its location within a developing structure. According to this idea, each cell within a developing organ responds to positional information from neighboring cells by differentiating into a particular cell type. Developmental biologists are accumulating evidence that gradients of specific molecules, generally proteins or mRNAs, provide positional information. For example, a substance diffusing from a shoot apical meristem may "inform" the cells below of their distance from the shoot apex. Cells possibly gauge their radial positions within the developing organ by detecting a second chemical signal that emanates from the outermost cells. The gradients of these two substances would be sufficient for each cell to "get a fix" on its position relative to the longitudinal and radial axes of the developing organ. This idea of diffusible chemical signals is one of the hypotheses that developmental biologists are testing.

One type of positional information is associated with **polarity**, the condition of having structural differences at opposite ends of an organism. Plants typically have an axis, with a root end and a shoot end. Such polarity is most obvious in morphological differences, but it is also manifest in physiological properties, including the unidirectional movement of the hormone auxin (see Chapter 39) and emergence of adventitious roots and shoots from "cuttings." Adventitious roots form within the root end of a stem cutting, and adventitious shoots arise from the shoot end of a root cutting.

Figure 35.26 Establishment of axial polarity. The normal *Arabidopsis* seedling (left) has a shoot end and a root end. In the *gnom* mutant (right), the first division of the zygote was not asymmetrical: as a result, the plant is ball-shaped and lacks leaves and roots. The defect in *gnom* mutants has been traced to an inability to transport the hormone auxin in a polar manner.

The first division of a plant zygote is normally asymmetric, initiating polarization of the plant body into shoot and root. Once this polarity has been induced, it becomes exceedingly difficult to reverse experimentally. Therefore, the proper establishment of axial polarity is a critical step in a plant's morphogenesis. In the *gnom* mutant of *Arabidopsis*, the establishment of polarity is defective. The first cell division of the zygote is abnormal in being symmetrical, and the resulting ball-shaped plant has neither roots nor leaves (Figure 35.26).

Morphogenesis in plants, as in other multicellular organisms, is often under the control of master regulatory genes called homeotic genes that mediate many of the major events in an individual's development, such as the initiation of an organ (see Chapter 21). For example, the protein product of the *KNOTTED-1* homeotic gene, found in many plant species, is important in the development of leaf morphology including the production of compound leaves. If the *KNOTTED-1* gene is overexpressed in tomato plants, the normally compound leaves become "super-compound" (Figure 35.27).

Gene Expression and Control of Cellular Differentiation

What makes cellular differentiation so fascinating is that the cells of a developing organism synthesize different proteins

A Figure 35.27 Overexpression of a homeotic gene in leaf formation. *KNOTTED-1* is a homeotic gene involved in leaf and leaflet formation. Its overexpression in tomato plants results in leaves that are "super-compound" (right) compared with normal leaves (left).

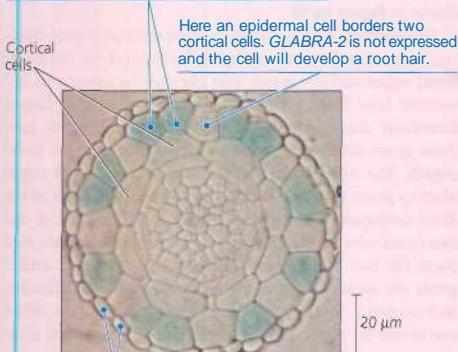

and diverge in structure and function even though they share a common genome. The cloning of whole plants from somatic cells supports the conclusion that the genome of a differentiated cell remains intact (see Figure 21.5). If a mature cell removed from a root or leaf can dedifferentiate in tissue culture and give rise to the diverse cell types of a plant, then it must possess all the genes necessary to make any kind of plant cell. This means that cellular differentiation depends, to a large extent, on the control of gene expression—the regulation of transcription and translation leading to specific proteins. Cells selectively express certain genes at specific times during their differentiation. A guard cell has the genes that program the self-destruction of a vessel element protoplast, but it does not express those genes. A xylem vessel element does express those genes, but only does so at a specific time in its differentiation, after the cell has elongated and has produced its secondary wall. Researchers are beginning to unravel the molecular mechanisms that switch specific genes on and off at critical times during a cell's development (see Chapters 19 and 21).

Cellular differentiation to a large extent depends on positional information—where a particular cell is located relative to other cells. For example, two distinct cell types are formed in the root epidermis of *Arabidopsis*: root hair cells and hairless epidermal cells. Cell fate is associated with the position of the epidermal cells. The immature epidermal cells that are in contact with two underlying cells of the root cortex differentiate into root hair cells, whereas the immature epidermal cells in contact with only one cortical cell differentiate into mature hairless cells. Differential expression of a homeotic gene called *GLABRA-2* (from the Latin *glaber*, bald) is required for appropriate root hair distribution. Researchers have demonstrated this by coupling the *GLABRA-2* gene to a "reporter gene" that causes every cell expressing *GLABRA-2* in the root to turn pale blue following a certain treatment (Figure 35.28). The *GLABRA-2* gene is normally expressed only in epidermal cells that will not develop root hairs. If *GLABRA-2* is rendered dysfunctional by mutation, every root epidermal cell develops a root hair.

Location and a Cell's Developmental Fate

In the process of shaping a rudimentary organ, patterns of cell division and cell expansion affect the differentiation of cells by placing them in specific locations relative to other cells. Thus, positional information underlies all the processes of development: growth, morphogenesis, and differentiation. One approach to studying the relationships among these processes is clonal analysis, in which the cell lineages (clones) derived from each cell in an apical meristem are mapped as organs develop. Researchers can do this by using radiation or chemicals in order to induce somatic mutations that will alter the chromosome number or otherwise tag a cell in some way that distinguishes it from the neighboring cells in the shoot apex. The lineage of

When epidermal cells border a single cortical cell, the homeotic gene (*GLABRA-2*) is selectively expressed, and these cells will remain hairless. (The blue color in this light micrograph indicates cells in which *GLABRA-2* is expressed.)

The ring of cells external to the epidermal layer is composed of root cap cells that will be sloughed off as the root hairs start to differentiate.

▲ Figure 35.28 Control of root hair differentiation by a homeotic gene.

cils derived by mitosis and cell division from the mutant meristematic cell will also be "marked." For example, a single cell in the shoot apical meristem may undergo a mutation that prevents chlorophyll from being produced. This cell and all of its descendants will be "albino," and they will appear as a linear file of colorless cells running down the long axis of the otherwise green shoot.

How early is a cell's developmental fate determined by its position in an embryonic structure? To some extent, the developmental fates of cells in the shoot apex are predictable. For example, clonal mapping has shown that almost all the cells derived from the outermost meristematic cells become part of the dermal tissue. However, we cannot pinpoint which meristematic cells will give rise to specific tissues and organs. Apparently random changes in rates and planes of cell division can reorganize the meristem. For example, the outermost cells usually divide perpendicular to the surface of the shoot apex, adding cells to the surface layer. Occasionally, however, one of the outermost cells divides parallel to the surface of the shoot apex, placing one daughter cell beneath the surface, among cells derived from different lineages. Such exceptions indicate that meristematic cells are not dedicated early to forming specific tissues and organs. Instead, the cell's final position in an emerging organ determines what kind of cell it will become, possibly as a result of positional information.

Shifts in Development: Phase Changes

Multicellular organisms generally pass through developmental phases. In humans, these are infancy, childhood, adolescence, and adulthood, with puberty as the dividing line between the nonreproductive and reproductive phases. Plants also pass through phases, developing from a juvenile phase to an adult vegetative phase to an adult reproductive phase. In animals, these developmental changes take place throughout the entire organism, such as when a larva develops into an adult animal. In plants, in marked contrast, they occur within a single region, the shoot apical meristem. The morphological changes that arise from these transitions in shoot apical meristem activity are called phase changes. During the transition from a juvenile phase to an adult phase, the most obvious morphological changes typically occur in leaf size and shape (Figure 35.29). Once the apical meristem has laid down juvenile

▲ Figure 35.29 Phase change in the shoot system of *Acacia koa*. This native of Hawaii has compound juvenile leaves, consisting of many small leaflets, and mature, sickle-shaped "leaves" (technically, highly modified leaf stalks). This dual foliage reflects a phase change in the development of the apical meristem of each shoot. In the juvenile vegetative phase of an apical meristem, compound leaves develop at each node. In the adult vegetative phase of an apical meristem, sickle-shaped leaves are produced. Once a node forms, the developmental phase—juvenile or adult—is fixed; that is, compound leaves do not mature into sickle-shaped "leaves."

nodes and internodes, they retain that status even after the shoot continues to elongate and the shoot apical meristem has changed to the adult phase. Therefore, any new leaves that develop on branches that emerge from axillary buds at juvenile nodes will also be juvenile, even though the apical meristem may have been laying down mature nodes for years.

Phase changes are examples of plasticity in plant development. The transition from juvenile to adult leaves is only one type of phase change. The transition in the fanwort (see Figure 35.1) from feathery underwater leaves to fan-shaped floating leaves is another example. Next, we will examine a common but nevertheless remarkable phase change—the transition of a vegetative shoot apical meristem into a floral meristem.

Genetic Control of Flowering

Flower formation involves a phase change from vegetative growth to reproductive growth. This transition is triggered by a combination of environmental cues, such as day length, and internal signals, such as hormones. (You will learn more about the control of flowering in Chapter 39.) Unlike vegetative growth, which is indeterminate, reproductive growth is determinate: The production of a flower by a shoot apical meristem stops the primary growth of that shoot. The transition from vegetative growth to flowering is associated with the switching-on of floral meristem identity genes. The protein products of these genes are transcription factors that regulate the genes required for the conversion of the indeterminate vegetative meristems into determinate floral meristems.

When a shoot apical meristem is induced to flower, each leaf primordium that forms will develop into a specific type of floral organ based on its relative position—a stamen, carpel, sepal, or petal (see Figure 30.7 to review basic flower structure). Viewed from above, the floral organs develop in four concentric circles, or whorls: Sepals form the fourth (outermost) whorl; petals form the third; stamens form the second; and carpels form the first (innermost) whorl. Plant biologists have identified several organ identity genes that regulate the development of this characteristic floral pattern. Organ identity genes, also called plant homeotic genes, code for transcription factors. Positional information determines which organ identity genes are expressed in a particular floral organ primordium. The result is development of an emerging leaf into a specific floral organ, such

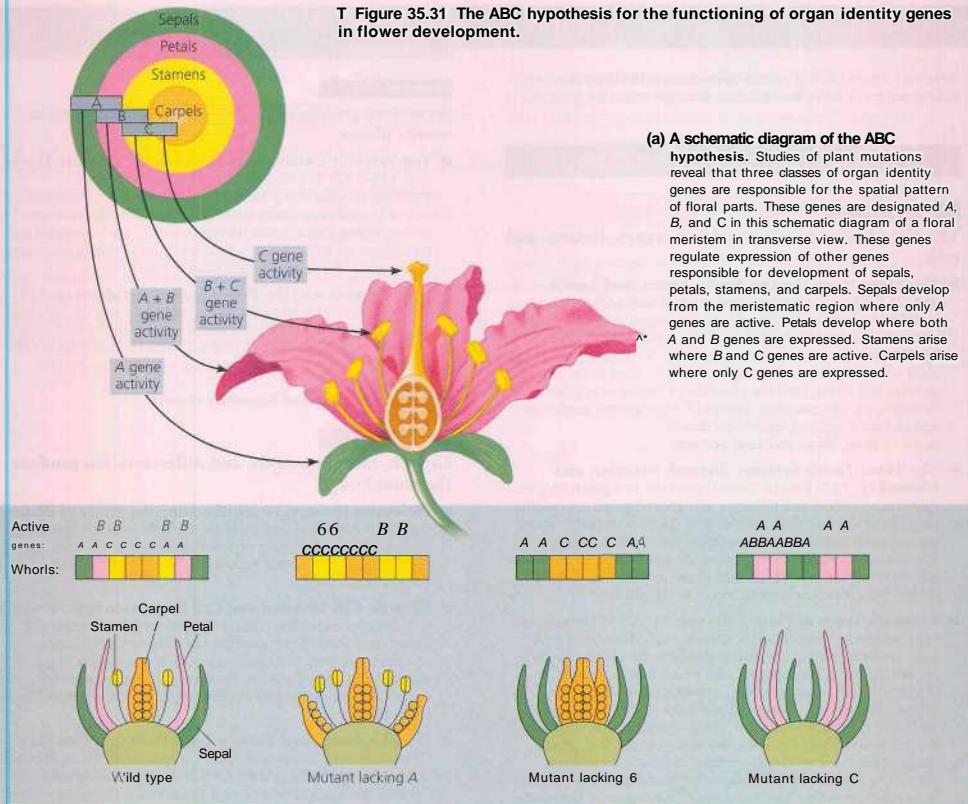

as a petal or a stamen. Just as a mutation in a fruit fly homeotic gene can cause legs to grow in place of antennae, a mutation in a plant organ identity gene can cause abnormal floral development, such as petals growing in place of stamens, as shown in Figure 35.30.

By collecting and studying mutants with abnormal flowers, researchers have identified and cloned three classes of floral organ identity genes, and they are beginning to determine how these genes act. The ABC model of flower formation, diagrammed in Figure 35.31a, identifies how these genes direct the formation of the four types of floral organs. The ABC model proposes that each class of organ identity genes is switched "on" in two specific whorls of the floral meristem. Normally, A genes are switched on in the two outer whorls (sepals and petals); B genes are switched on in the two middle whorls (petals and stamens); and C genes are switched on in the two inner whorls (stamens and carpels). Sepals arise from those parts of the floral meristems in which only A genes are active; petals where A and B genes are active; stamens where B and C genes are active; and carpels where only C genes are active. The ABC model can account for the phenotypes of mutants lacking A, B, or C gene activity, with one addition: Where gene A activity is present, it inhibits C, and vice versa. If either A or C is missing, the other takes its place. Figure 35.31b shows the floral patterns of mutants lacking each of

• **Figure 35.30 Organ identity genes and pattern formation in flower development.**

T Figure 35.31 The ABC hypothesis for the functioning of organ identity genes in flower development.

(I) Side view of organ identity mutant flowers. Combining the model shown in part (a) with the rule that if *A* gene or *C* gene activity is

missing, the other activity spreads through all four whorls, we can explain the phenotypes of mutants lacking a functional *A*, *B*, or *C* organ identity gene.

the three classes of organ identity genes and depicts how the model accounts for the floral phenotypes. By constructing such hypotheses and designing experiments to test them, researchers are tracing the genetic basis of plant development.

In dissecting the plant to examine its parts, as we have done in this chapter, we must remember that the whole plant functions as an integrated organism. In the following chapters, you will learn more about how materials are transported within vascular plants (Chapter 36), how plants obtain nutrients (Chapter 37), how plants reproduce (Chapter 38, focusing on flowering plants), and how the various functions of the plant are coordinated (Chapter 39). Remembering that structure fits function and that plant anatomy and physiology

reflect evolutionary adaptations to the problems of living on land will enhance your understanding of plants.

Concept Check 35.5

- How can two cells in a plant have such vastly different structure even though they possess the same genome?
- Explain how a mutation such as *ass* in *Arabidopsis* results in a stubby plant rather than a normal elongated one.

For suggested answers, see Appendix A.

Chapter 35 Review

SUMMARY OF KEY CONCEPTS

Concept 35.1

The plant body has a hierarchy of organs, tissues, and cells

- **The Three Basic Organs: Roots, Stems, and Leaves**

(pp. 713–716) Roots anchor the plant, absorb and conduct water and minerals, and store food. The shoot system consists of stems, leaves, and (in angiosperms) flowers. Leaves are attached by their petioles to the nodes of the stem, with internodes of the stem separating the nodes. Axillary buds, located in the axils of petioles and stems, have the potential to extend as vegetative or floral shoots. The two main groups of angiosperms, monocots and eudicots, differ in anatomical details.

Activity Root, Stem, and Leaf Sections

- **The Three Tissue Systems: Dermal, Vascular, and Ground** (p. 717) Dermal tissue (epidermis and periderm), vascular tissue (xylem and phloem), and ground tissue are continuous throughout the plant, although in the various plant organs the three tissues differ in arrangement and in some specialized functions. Vascular tissues integrate the parts of the plant. Water and minerals move up from roots in the xylem. Sugar is exported from leaves or storage organs to the phloem.

- **Common Types of Plant Cells** (pp. 717–719) Parenchyma cells, relatively unspecialized cells that retain the ability to divide, perform most of the plant's metabolic functions of synthesis and storage. Collenchyma cells, which have unevenly thickened walls, support young, growing parts of the plant. Sclerenchyma cells—fibers and sclereids—have thick, lignified walls that help support mature, nongrowing parts of the plant. Tracheids and vessel elements, the water-conducting cells of xylem, have thick walls and are dead at functional maturity. Sieve-tube members are the sugar-transporting cells of phloem in angiosperms. Though alive at functional maturity, sieve-tube members depend on the services of neighboring companion cells.

Concept 35.2

Meristems generate cells for new organs

- Apical meristems elongate shoots and roots through primary growth. Lateral meristems add girth to woody plants through secondary growth (pp. 720–721).

Concept 35.3

Primary growth lengthens roots and shoots

- **Primary Growth of Roots** (pp. 721–723) Apical meristems produce cells that continue to divide as meristematic cells. In roots, the apical meristem is located near the tip, where it regenerates the root cap.
- **Primary Growth of Shoots** (pp. 723–725) The apical meristem of a shoot is located in the terminal bud, where it gives rise to a repetition of internodes and leaf-bearing nodes.

Investigation What Are Functions of Monocot Tissues?

Concept 35.4

Secondary growth adds girth to stems and roots in woody plants

- **The Vascular Cambium and Secondary Vascular Tissue** (pp. 725–727) The vascular cambium develops from parenchyma cells into a meristematic cylinder that produces secondary xylem and secondary phloem. Older layers of secondary xylem (heartwood) become inactive, while younger layers (sapwood) still conduct water. Only the youngest secondary phloem is active in conducting organic nutrients.
- **Cork Cambia and the Production of Periderm** (p. 728) The cork cambium gives rise to the secondary plant body's protective covering, or periderm, which consists of the cork cambium plus the layers of cork cells it produces. Bark consists of all the tissues external to the vascular cambium: secondary phloem and periderm.

Activity Primary and Secondary Growth

Concept 35.5

Growth, morphogenesis, and differentiation produce the plant body

- **Molecular Biology: Revolutionizing the Study of Plants** (pp. 728–729) New techniques and model systems, including *Arabidopsis*, are catalyzing explosive progress in our understanding of plants. *Arabidopsis* is the first plant to have had its entire genome sequenced.
- **Growth: Cell Division and Cell Expansion** (pp. 729–730) Cell division and cell expansion are primary determinants of growth and form. A preprophase band determines where a cell plate will form in a dividing cell. The orientation of the cytoskeleton also affects the direction of cell elongation by controlling the orientation of cellulose microfibrils within the cell wall.
- **Morphogenesis and Pattern Formation** (pp. 730–732) Development of tissues and organs in specific locations depends on the ability of cells to detect and respond to positional information, such as information associated with polarity. Homeotic genes often control morphogenesis.
- **Gene Expression and Control of Cellular Differentiation** (p. 732) The challenge of understanding cellular differentiation is explaining how cells with matching genomes diverge into various cell types.
- **Location and a Cell's Developmental Fate** (pp. 732–733) A cell's position in a developing organ determines its pathway of differentiation.
- **Shifts in Development: Phase Changes** (pp. 733–734) Internal or environmental cues may cause a plant to switch from one developmental phase to another—for example, from development of juvenile leaves to development of mature leaves. Such morphological changes are called phase changes.
- **Genetic Control of Flowering** (pp. 734–735) Research on organ identity genes in developing flowers provides an important model system for the study of pattern formation. The ABC model of flower formation identifies how three classes of organ identity genes control formation of sepals, petals, stamens, and carpels.

TESTING YOUR KNOWLEDGE

Evolution Connection

The evolution of plant structure can be explored by looking at alternative growth strategies of related plants that occur in different environments. In this respect, Darwin was one of the earliest observers to note that many herbaceous plant species on continental mainlands have woody, tree-like relatives on remote oceanic islands. In the Hawaiian Islands, for example, one can find tree lobelias and tall, woody violets, groups that occur as small herbs in North America. Suggest an evolutionary hypothesis for this trend: Why is it so common for woody, tree-like forms to evolve from herbaceous ancestors that colonize isolated islands?

scientific Inquiry

Write a paragraph explaining why certain mutants are so useful to researchers who investigate the regulation of plant development. Your paragraph should include at least one specific example.

Investigation What Are Functions of Monocot Tissues?

Science, Technology, and Society

Make a list of the plants and plant products you use in a typical day. How do you use these various plant products? Do you think the number of plants and plant products used in everyday life has increased or decreased in the last century? Do you think the number is likely to increase or decrease in the future? Why?

Investigating Growth

In investigating plant growth, it is important to remember that all living things grow. This growth may be measured in terms of height, weight, or volume. However, growth is not always uniform. For example, a seedling may grow taller in one direction than in another, or it may grow more rapidly in one part than in another. Such differential growth is called curvature. Curvature may be caused by external factors such as light, gravity, or temperature, or it may be caused by internal factors such as hormones or genetic mutations. Curvature is often used to study the effects of environmental factors on plant growth. For example, if a seedling is placed in a dark environment, it will curve toward the light source. This type of curvature is called phototropism. If a seedling is placed in a cold environment, it will curve toward the heat source. This type of curvature is called thermotropism. If a seedling is placed in a dry environment, it will curve toward the water source. This type of curvature is called hydrotropism. If a seedling is placed in a nutrient-poor environment, it will curve toward the nutrient-rich environment. This type of curvature is called chemotropism.

36

Transport in Vascular Plants

A Figure 36.1 Coast redwoods (*Sequoia sempervirens*).

Key Concepts

- 36.1 Physical processes drive the transport of materials in plants over a range of distances
- 36.2 Roots absorb water and minerals from the soil
- 36.3 Water and minerals ascend from roots to shoots through the xylem
- 36.4 Stomata help regulate the rate of transpiration
- 36.5 Organic nutrients are translocated through the phloem

Overview

Pathways for Survival

The algal ancestors of plants absorbed water, minerals, and CO_2 directly from the water in which they were immersed; none of their cells were far from these ingredients. Bryophytes also lack an extensive transport system and are confined to living in very moist environments. For vascular plants, in contrast, the evolutionary journey onto land involved the differentiation of the plant body into roots and shoots. Roots absorb water and minerals from the soil, and shoots absorb light and atmospheric CO_2 for photosynthesis.

Xylem transports water and minerals from roots to shoots. Phloem transports sugars from where they are produced or stored to where they are needed for growth and metabolism. Such transport, which is necessary for a plant to function as a whole, may occur over long distances. For example, the highest leaves of some coast redwoods are more than 100 m (over 300 feet) from the roots (Figure 36.1). What enables a vascular plant to conduct water, minerals, and organic nutrients over such long distances? The mechanisms responsible for internal transport are the subject of this chapter.

Concept 36.1

Physical forces drive the transport of materials in plants over a range of distances

Transport in vascular plants occurs on three scales: (1) transport of water and solutes by individual cells, such as root hairs; (2) short-distance transport of substances from cell to cell at the levels of tissues and organs, such as the loading of sugar from photosynthetic leaf cells into the sieve tubes of the phloem; and (3) long-distance transport within xylem and phloem at the level of the whole plant. A variety of physical processes are involved in these different types of transport. Figure 36.2 provides an overview of long-distance transport in a vascular plant.

Selective Permeability of Membranes: A Review

We covered the transport of solutes and water across biological membranes in detail in Chapter 7. Here we reexamine a few of these transport processes in the specific context of plant cells. The selective permeability of a plant cell's plasma membrane controls the movement of solutes into and out of that cell. Recall from Chapter 7 that solutes tend to diffuse down their gradients and that diffusion across a membrane is called passive transport because it happens without the cell directly using metabolic energy. Active transport is the pumping of solutes across membranes against their electrochemical gradients, the combined effects of the concentration gradient of the solute and the voltage (charge difference) across the membrane. It is called "active" because the cell must expend en-

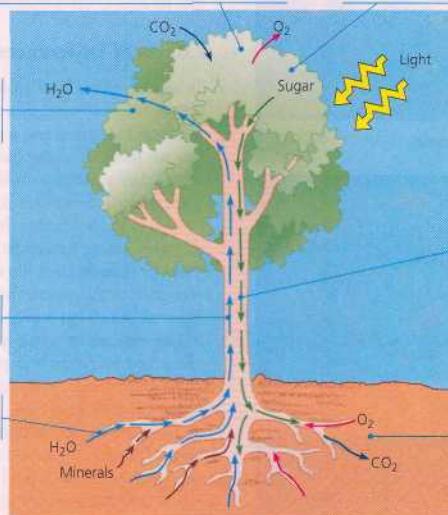

0 Through stomata, leaves take in CO_2 and expel O_2 .
The CO_2 provides carbon for photosynthesis. Some O_2 produced by photosynthesis is used in cellular respiration.

0 Sugars are produced by photosynthesis in the leaves.

3 Transpiration, the loss of water from leaves (mostly through stomata), creates a force within leaves that pulls xylem sap upward.

0 Water and minerals are transported upward from roots to shoots as xylem sap.

0 Roots absorb water and dissolved minerals from the soil.

0 Sugars are transported as phloem sap to roots and other parts of the plant.

0 Roots exchange gases with the air spaces of soil, taking in O_2 and discharging CO_2 . In cellular respiration, O_2 supports the breakdown of sugars.

▲ Figure 36.2 An overview of transport in a vascular plant.

energy, usually in the form of ATP, to transport a solute "uphill"—counter to the net direction in which the solute diffuses.

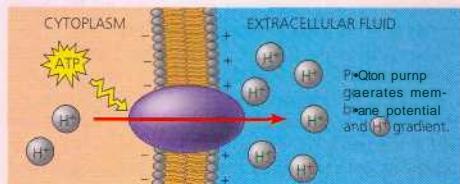

Most solutes cannot cross the lipid bilayer of the membrane; they must pass through **transport proteins** embedded in the membrane. Some transport proteins bind selectively to a solute on one side of the membrane and release the solute on the opposite side. Other transport proteins provide selective channels across the membrane. For example, membranes of most plant cells have potassium channels that allow potassium ions (K^+) to pass, but not other ions, such as sodium (Na^+). Later in this chapter, we will discuss how K^+ channels in guard cells function in the opening and closing of stomata. Some channels are gated, opening or closing in response to certain stimuli.

The Central Role of Proton Pumps

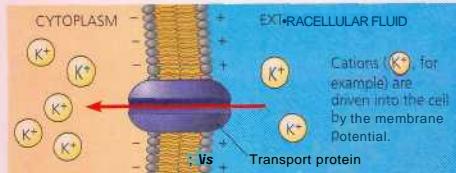

The most important active transport protein in the plasma membranes of plant cells is the **proton pump**, which uses energy from ATP to pump hydrogen ions (H^+) out of the cell. This results in a proton gradient with a higher H^+ concentration outside the cell than inside (Figure 36.3). The gradient is a form of potential (stored) energy because the hydrogen ions tend to diffuse "downhill" back into the cell, and this "flow" of H^+ can be harnessed to do work. And because the proton

pump moves positive charge, in the form of H^+ , out of the cell, the pump also contributes to a voltage known as a membrane potential, a separation of opposite charges across a membrane. Proton pumping makes the inside of a plant cell negative in charge relative to the outside. This voltage is called a membrane potential because the charge separation is a form of potential energy that can be harnessed to perform cellular work.

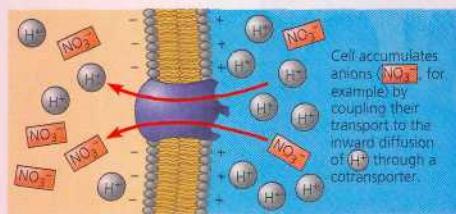

Plant cells use energy stored in the proton gradient and membrane potential to drive the transport of many different solutes. For example, the membrane potential generated by proton pumps contributes to the uptake of K^+ by root cells

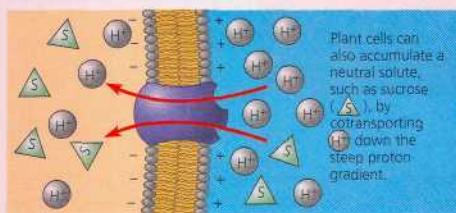

▲ Figure 36.3 Proton pumps provide energy for solute transport. By pumping H^+ out of the cell, proton pumps produce an H^+ gradient and a charge separation called a membrane potential. These two forms of potential energy can be used to drive the transport of solutes.

(a) Membrane potential and cation uptake

(b) Cotransport of anions

(c) Cotransport of a neutral solute

A Figure 36.4 Solute transport in plant cells.

(Figure 36.4a). In the mechanism called cotransport, a transport protein couples the downhill passage of one solute (H^+) to the uphill passage of another (NO_3^- , in the case of **Figure 36.4b**). The "coattail" effect of cotransport is also responsible for the uptake of the sugar sucrose by plant cells (**Figure 36.4c**). A membrane protein cotransports sucrose with the H^+ that is moving down its gradient through the protein.

The role of proton pumps in transport is an application of chemiosmosis (see Figure 9.15). The key feature of chemiosmosis is a transmembrane proton gradient, which links energy-releasing processes to energy-consuming processes in cells. For example, you learned in Chapters 9 and 10 that mitochondria and chloroplasts use proton gradients generated by electron transport chains (which release energy) to drive ATP synthesis (which consumes energy). The ATP synthases that couple H^+ diffusion to ATP synthesis during cellular respiration and photosynthesis work somewhat like the proton pumps in plant cells. But in contrast to ATP synthases, proton

pumps normally run in reverse, using ATP energy to pump H^+ against its gradient. In both cases, proton gradients enable one process to drive another.

Effects of Differences in Water Potential

To survive, plants must balance water uptake and loss. The net uptake or loss of water by a cell occurs by osmosis, the passive transport of water across a membrane (see Figure 7.12). How can we predict the direction of osmosis when a cell is surrounded by a particular solution? In the case of an animal cell, if the plasma membrane is impermeable to the solutes, it is enough to know whether the extracellular solution has a lower or higher solute concentration relative to the cell. Water will move by osmosis from the solution with the lower solute concentration to the solution with the higher solute concentration. But a plant cell has a cell wall, which adds another factor affecting osmosis: physical pressure. The combined effects of solute concentration and physical pressure are incorporated into a measurement that is called water potential, abbreviated by the Greek letter psi (ψ).

Water potential determines the direction of movement of water. The most important thing to remember is that free water, water that is not bound to solutes or surfaces, moves from regions of higher water potential to regions of lower water potential if there is no barrier to its free flow. For example, if a plant cell is immersed in a solution having a higher water potential than the cell, uptake of water will cause the cell to swell. By moving, water can perform work, such as expanding a cell. The "potential" in water potential is water's potential energy—water's capacity to perform work when it moves from a region of higher ψ to a region of lower ψ . Water potential is a specific case of the general tendency of systems to change spontaneously to a state of lowest free energy (see Figure 8.5).

Plant biologists measure ψ in units of pressure called megapascals (abbreviated MPa). Physicists have assigned the value of zero to the water potential of pure water in a container open to the atmosphere ($\psi = 0$ MPa) under standard conditions (at sea level and at room temperature). One MPa is equal to about 10 atmospheres of pressure. (An atmosphere is the pressure exerted at sea level by an imaginary column of air extending through the entire height of the atmosphere—about 1 kg of pressure per square centimeter.) A few examples will give you an idea of the magnitude of a megapascal: Your lungs exert less than 0.1 MPa. A car tire is usually inflated to about 0.2 MPa. Water pressure in home plumbing is about 0.25 MPa. In contrast, most plant cells exist at approximately 1 MPa.

How Solutes and Pressure Affect Water Potential

Both pressure and solute concentration affect water potential, as expressed in the following water potential equation:

where y is the water potential, ψ_s is the solute potential (osmotic potential), and y_p is the pressure potential.

The solute potential (ψ_s) of a solution is proportional to the number of dissolved solute molecules. Solute potential is also called osmotic potential because solutes affect the direction of osmosis. Solutes may be any type of dissolved chemical. By definition, the ψ_s of pure water is 0. But what happens when solutes are added to this pure water? The solutes bind water molecules, reducing the number of free water molecules and lowering the capacity of the water to do work. Thus, adding solutes always lowers the water potential, and the ψ_s of a solution is always negative. A 0.1-molar (0.1 M) solution of a sugar, for example, has a ψ_s of -0.23 MPa .

Pressure potential (y_p) is the physical pressure on a solution. Unlike ψ_s , y_p can be positive or negative. For example, the water in the dead xylem cells of a transpiring plant is often under a negative pressure (tension) of less than -2 MPa . Conversely, much like the air in a balloon, the water in living cells is usually under positive pressure. The cell contents press the plasma membrane against the cell wall, producing what is called turgor pressure.

Quantitative Analysis of Water Potential

Now that we have introduced the water potential equation and its components, let's put it to use. First we will look at water movement in an artificial system. Then we will apply the equation to a living plant cell.

The artificial model represented in **Figure 36.5** shows the movement of water within a U-shaped tube that has a

membrane separating the two arms of the tube. The membrane is permeable to water but not to solutes. What happens if we fill the right arm of the tube with a 0.1 M solution ($\psi_s = -0.23 \text{ MPa}$) and fill the left arm with pure water ($\psi_s = 0$)? In the absence of any physical pressure (that is, when $y_p = 0$), the water potential ψ will be equal to y_s . Thus, the ψ of the left arm of the tube (pure water) will be 0, whereas the ψ of the right arm will be -0.23 MPa . Because water always moves from regions of higher water potential to regions of lower water potential, the net water movement in this case will be from the left arm of the tube to the right arm (**Figure 36.5a**). But if we now apply a physical pressure of $+0.23 \text{ MPa}$ to the solution in the right arm, we raise its water potential from a negative value to 0 MPa ($y = -0.23 + 0.23$). There will now be no net flow of water between this pressurized solution and the compartment of pure water (**Figure 36.5b**). In fact, if we increase y_p to $+0.30 \text{ MPa}$, then the solution has a water potential of $+0.07 \text{ MPa}$ ($\psi = -0.23 + 0.30$), and this solution will actually *lose* water to a compartment containing pure water (**Figure 36.5c**). Finally, imagine using a plunger to pull upward on the pure water instead of pushing downward on the solution. A negative pressure (tension) of -0.30 MPa on the water compartment would be sufficient to draw water from the solution that has a water potential of -0.23 MPa (**Figure 36.5d**). Again, keep in mind the key point; *Water moves in the direction of higher to lower water potential*.

Now let us consider how water potential affects uptake and loss of water by plant cells. First, imagine a flaccid (limp) cell that has a ψ_p of 0. Suppose this flaccid cell is bathed in a solution of higher solute concentration (more negative solute

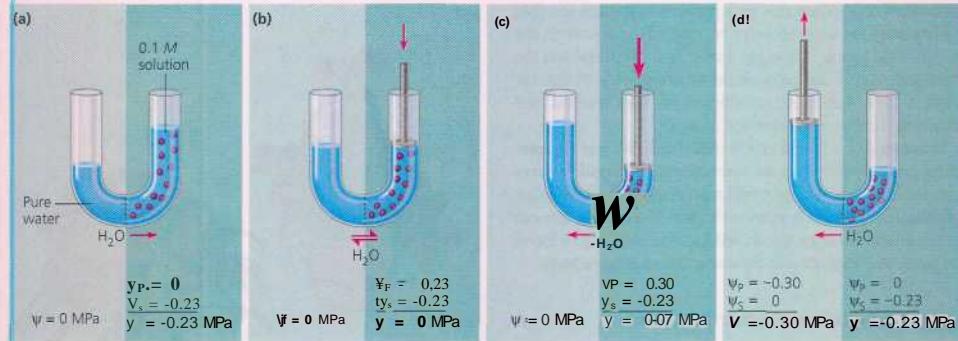

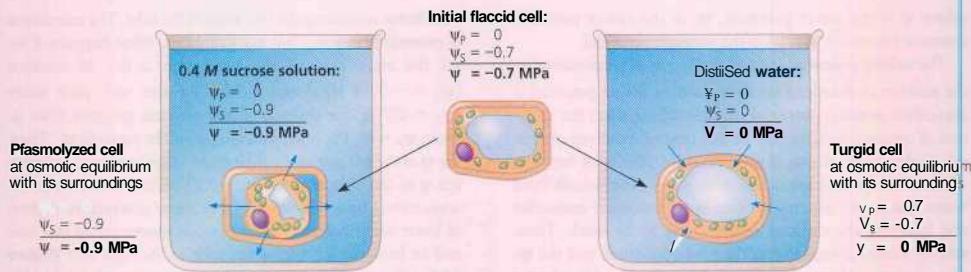

Figure 36.5 Water potential and water movement: an artificial model.

In this U-shaped apparatus, a selectively permeable membrane separates pure water from a 0.1 M solution containing a particular solute that cannot pass freely across the membrane. Water moves across a selectively

permeable membrane from where water potential is higher to where it is lower. The water potential (ψ) of pure water at atmospheric pressure is 0 MPa. If we know the values of pressure potential (y_p) and solute potential (ψ_s), we can calculate water potential: $\psi = y_p + \psi_s$. The values for y

and ψ_s in the left and right arms of the U-tube are given for *initial* conditions, before any net movement of water. (a) The addition of solutes reduces water potential (to a negative value). (b, c) Application of physical pressure increases water potential. (d) A negative pressure (tension) decreases water potential.

(a) **Initial conditions:** cellular $\psi >$ environmental ψ . The cell loses water and plasmolyzes. After plasmolysis is complete, the water potentials of the cell and its surroundings are the same.

(b) **Initial conditions:** cellular $\psi <$ environmental ψ . There is a net uptake of water by osmosis, causing the cell to become turgid. When this tendency for water to enter is offset by the back pressure of the elastic wall, water potentials are equal for the cell and its surroundings. (The volume change of the cell is exaggerated in this diagram.)

A Figure 36.6 Water relations in plant cells. In these experiments, identical cells, initially flaccid, are placed in two different environments. (The protoplasts of flaccid cells are in contact with their walls but lack turgor pressure.) The blue arrows indicate the initial direction of net water movement.

potential) than the cell itself (**Figure 36.6a**). Since the external solution has the lower (more negative) water potential, water will leave the cell by osmosis, and the cell's protoplast will **plasmolyze**, or shrink and pull away from its wall. Now let's place the same flaccid cell in pure water ($\psi = 0$) (**Figure 36.6b**). The cell has a lower water potential than pure water because of the presence of solutes, and water enters the cell by osmosis. The contents of the cell begin to swell and press the plasma membrane against the cell wall, producing a turgor pressure. The partially elastic wall pushes back against the pressurized cell. When this wall pressure is enough to offset the tendency for water to enter because of the solutes in the cell, then ψ_p and ψ_s are equal and $\psi = 0$. This matches the water potential of the extracellular environment—in this example, 0 MPa. A dynamic equilibrium has been reached, and there is no further *net* movement of water.

In contrast to a flaccid cell, a walled cell that has a greater solute concentration than its surroundings is **turgid**, or very firm. Healthy plant cells are turgid most of the time. Their turgor contributes to support in nonwoody parts of the plant. You can see the effects of turgor loss in **wilting**, the drooping of leaves and stems as a result of cells becoming flaccid (**Figure 36.7**).

Aquaporin Proteins and Water Transport

Water potential is the force that moves water across the membranes of plant cells, but how do the water molecules actually cross the membranes? Because water molecules are so small, they move relatively freely across the lipid bilayer, even though the middle zone is hydrophobic (see Figure 7.2). Water transport across biological membranes, however, is too

specific and too rapid to be explained entirely by diffusion through the lipid bilayer. Indeed, water typically crosses vacuolar and plasma membranes through transport proteins called **aquaporins** (see Chapter 7). These selective channels do not affect the water potential gradient or the direction of water flow, but rather the *rate* at which water diffuses down its water potential gradient. Evidence is accumulating that the rate of water movement through these proteins is regulated by phosphorylation of the aquaporin proteins induced by changes in second messengers such as calcium ions (Ca^{2+}).

A Figure 36.7 A watered *Impatiens* plant regains its turgor.

Three Major Compartments of Vacuolated Plant Cells

Transport is also regulated by the compartmental structure of plant cells. Outside the protoplast is a cell wall that helps maintain the cell's shape (see Figure 6.9). However, it is the selectively permeable plasma membrane that directly controls the traffic of molecules into and out of the protoplast. The plasma membrane is a barrier between two major compartments: the cell wall and the cytosol (the part of the cytoplasm contained **within** the plasma membrane but outside the intracellular organelles). Most mature plant cells have a third major compartment, the vacuole, a large organelle that can occupy as much as 30% or more of the protoplast's volume (Figure 36.8a). The **vacuolar membrane**, or **tonoplast**, regulates molecular traffic between the cytosol and the vacular contents, called cell sap. Its proton pumps expel H⁺ from the cytosol into the vacuole. This resulting pH gradient is used to move other ions across the vacuolar membrane by chemiosmosis.

In most plant tissues, the cell walls and cytosol are continuous from cell to cell. Plasmodesmata connect the cytosolic compartments of neighboring cells, thereby forming a continuous pathway for transport of certain molecules between cells. This cytoplasmic continuum is called the **symplast** (figure 36.8b). The continuum of cell walls plus the extracellular spaces is called the **apoplast**. The third cellular compartment, the vacuole, is not shared with neighboring cells.

Functions of the Symplast and Apoplast in Transport

How do water and solutes move from one location to another within plant tissues and organs? For example, what mechanisms transport water and minerals from the root hairs to the vascular cylinder of the root? Such short-distance transport is sometimes called lateral transport because its usual direction is along the radial axis of plant organs, rather than up and down along the length of the plant.

Three routes are available for this transport (see Figure 36.8b). By the first route, substances move out of one cell, across the cell wall, and into the neighboring cell, which may then pass the substances along to the next cell in the pathway by the same mechanism. This transmembrane route requires repeated crossings of plasma membranes as the solutes exit one cell and enter the next.

The second route, via the symplast, the continuum of cytosol within a plant tissue,

requires only one crossing of a plasma membrane. After entering one cell, solutes and water can then move from cell to cell via plasmodesmata.

The third route for short-distance transport within a plant tissue or organ is along the apoplast, the pathway consisting of cell walls and extracellular spaces. Without entering a protoplast, water and solutes can move from one location to another within a root or other organ along the byways provided by the continuum of cell walls.

Bulk Flow in Long-Distance Transport

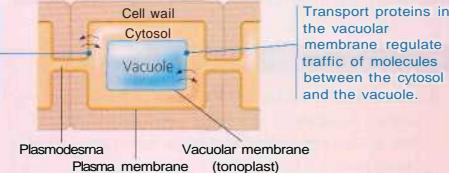

Diffusion in a solution is fairly efficient for transport over distances of cellular dimensions (less than 100 nm), but it is much too slow to function in long-distance transport within a plant. For example, diffusion from one end of a cell to the other takes seconds, but diffusion from the roots to the top of a giant redwood would take decades or more. Long-distance transport occurs through **bulk flow**, the movement of a fluid driven by pressure. In bulk flow, water and solutes move through the tracheids and vessels of the xylem and through the sieve tubes of the phloem. In the phloem, for example, the loading of sugar generates a high positive pressure at one end of a sieve tube, forcing sap to the opposite end of the tube. In xylem, it is actually tension (negative pressure) that drives

Functions of the Symplast and Apoplast in Transport

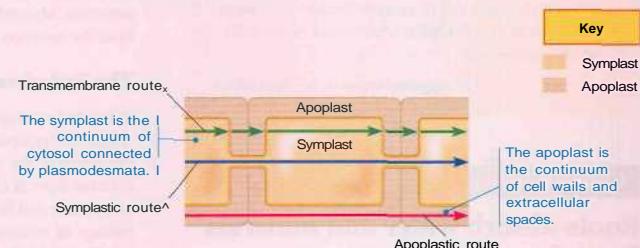

How do water and solutes move from one location to another within plant tissues and organs? For example, what mechanisms transport water and minerals from the root hairs to the vascular cylinder of the root? Such short-distance transport is sometimes called lateral transport because its usual direction is along the radial axis of plant organs, rather than up and down along the length of the plant.

Three routes are available for this transport (see Figure 36.8b). By the first route, substances move out of one cell, across the cell wall, and into the neighboring cell, which may then pass the substances along to the next cell in the pathway by the same mechanism. This transmembrane route requires repeated crossings of plasma membranes as the solutes exit one cell and enter the next.

The second route, via the symplast, the continuum of cytosol within a plant tissue,

(a) Cell compartments. The cell wall, cytosol, and vacuole are the three main compartments of most mature plant cells.

(b) Transport routes between cells. At the tissue level, there are three passages: the transmembrane, symplastic, and apoplastic routes. Substances may transfer from one route to another.

A Figure 36.8 Cell compartments and routes for short-distance transport.

long-distance transport. Transpiration, the evaporation of water from a leaf, reduces pressure in the leaf xylem. This creates a tension that pulls xylem sap upward from the roots.

If you have ever dealt with a partially clogged drain, you know that the volume of flow through a pipe depends on the pipe's internal diameter. Clogs reduce flow because they reduce the effective diameter of the drainpipe. Such household experiences help us understand how the unusual structures of plant cells specialized for bulk flow—the sieve-tube members of the phloem and the tracheids and vessel elements of the xylem—fit their function. Recall from Chapter 35 that the cytoplasm of sieve-tube members is almost devoid of internal organelles and that mature tracheids and vessel elements, being dead cells, have no cytoplasm. Like unplugging a kitchen drain, loss of cytoplasm in a plant's "plumbing" allows for efficient bulk flow through the xylem and phloem. Bulk flow is also enhanced by the perforated end walls of vessel elements and the porous plates connecting sieve-tube members (see Figure 35.9).

Now that we have an overview of the basic mechanisms of transport at the cellular, tissue, and whole-plant levels, we will look more closely at how these mechanisms work together. For example, bulk flow due to a pressure difference is the mechanism of long-distance transport of phloem sap, but it is active transport of sugar at the cellular level that maintains this pressure difference. The four transport functions we will examine in more detail are the absorption of water and minerals by roots, the ascent of xylem sap, the control of transpiration, and the transport of organic nutrients within phloem.

Concept Check 36.1

- Some farmers throughout the world irrigate crops using groundwater, which has a relatively high content of dissolved salts. How might this practice affect water potential in crops?
- If a plant cell immersed in distilled water has a ψ of -0.7 MPa and a ψ of 0 MPa , what is the cell's $\Delta\psi$? If you put the same cell in an open beaker of solution that has a ψ of -0.4 MPa , what would be the cell's $\Delta\psi$ at equilibrium?

For suggested answers, see Appendix A.

Concept 36.2

Roots absorb water and minerals from the soil

Water and mineral salts from the soil enter the plant through the epidermis of roots, cross the root cortex, pass into the vascular cylinder, and then flow up tracheids and vessels to the

shoot system. This section focuses on short-distance transport between cells in the soil-to-xylem pathway. As you read, use [Figure 36.9](#) to reinforce your understanding.

The Roles of Root Hairs, Mycorrhizae, and Cortical Cells

Much of the absorption of water and minerals occurs near root tips, where the epidermis is permeable to water and where root hairs are located. Root hairs, which are extensions of epidermal cells, account for much of the surface area of roots (see Figure 35.12). Soil particles, usually coated with water and dissolved minerals, adhere tightly to the root hairs. The soil solution flows into the hydrophilic walls of epidermal cells and passes freely along the apoplast into the root cortex. This exposes the symplast of all the cells of the cortex to the soil solution, providing a much greater surface area of membrane than the surface area of the epidermis alone.

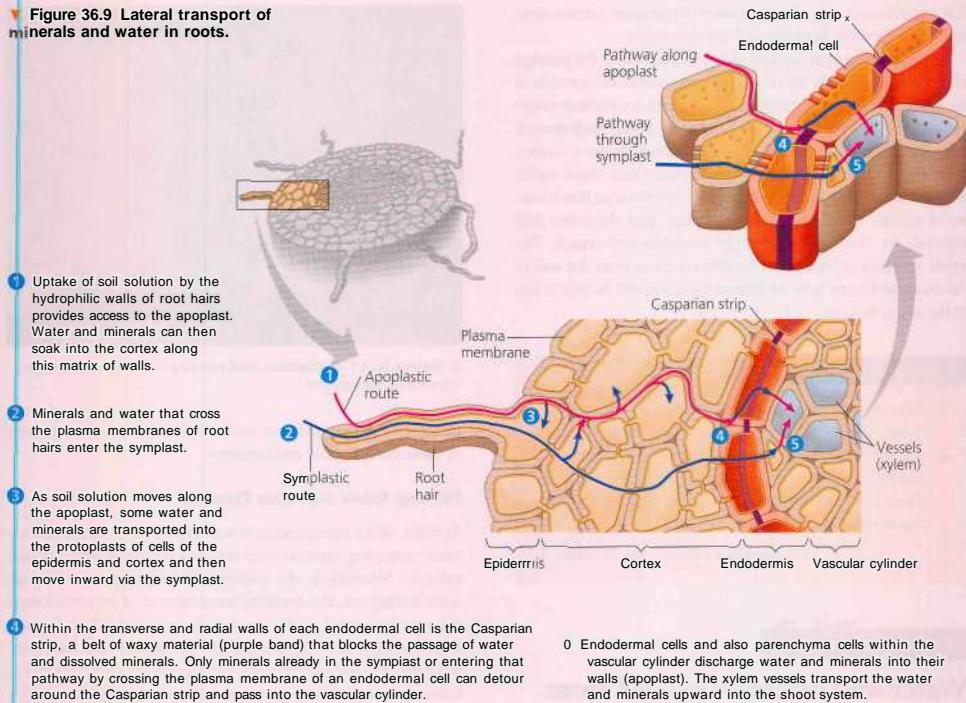

As the soil solution moves along the apoplast into the roots, cells of the epidermis and cortex take up water and certain solutes into the symplast. Although the soil solution is usually very dilute, active transport enables roots to accumulate essential minerals, such as K^+ , to concentrations hundreds of times higher than in the soil.

Most plants form mutually beneficial relationships with fungi, which facilitate the absorption of water and minerals from the soil. Roots and fungi form mycorrhizae, symbiotic structures consisting of plant roots united with fungal hyphae (filaments) ([Figure 36.10](#)). The hyphae absorb water and selected minerals, transferring much of these resources to the host plant. Chapter 37 highlights the role of mycorrhizae in plant nutrition, and Chapter 31 features the fungal partners in these mutualistic relationships. What is important to understand here is that the mycelium (network of hyphae) of the fungus endows mycorrhizae, and thus the plant roots, with an enormous surface area for absorption. As much as 3 m of hyphae can extend from each centimeter along a root's length, reaching a far greater volume of soil than the root alone could penetrate. Mycorrhizae enable even older regions of roots, far from the root tips, to supply water and minerals to the plant.

The Endodermis: A Selective Sentry

Water and minerals that pass from the soil into the root cortex cannot be transported to the rest of the plant until they enter the xylem of the vascular cylinder. The endodermis, the innermost layer of cells in the root cortex, surrounds the vascular cylinder and functions as a last checkpoint for the selective passage of minerals from the cortex into the vascular tissue (see [Figure 36.9](#)). Minerals already in the symplast when they reach the endodermis continue through the plasmodesmata of endodermal cells and pass into the vascular cylinder. These minerals were already screened by the selective membranes they had to cross to enter the symplast in the epidermis or

► Figure 36.9 Lateral transport of minerals and water in roots.

cortex- Those minerals that reach the endodermis via the apoplast encounter a dead end that, blocks their passage into the vascular cylinder: In the transverse and radial walls of each endodermal cell is the Caspary strip, a belt made of suberin, a waxy material impervious to water and dissolved minerals. Thus, water and minerals cannot cross the endodermis and enter vascular tissue via the apoplast. The only way past this barrier is for the water and minerals to cross the plasma membrane of an endodermal cell and enter the vascular cylinder via the symplast.

The endodermis, with its Caspary strip, ensures that no minerals can reach the vascular tissue of the root without crossing a selectively permeable plasma membrane. If minerals do not enter the symplast of cells in the epidermis or cortex, they must enter endodermal cells or be excluded from the vascular tissue. The endodermis also prevents solutes that have been accumulated in the xylem sap from leaking back into the soil solution. The structure of the endodermis and its strategic location in the root fit its function as sentry of the border between the cortex and the vascular cylinder, a function

► Figure 36.10 Mycorrhizae, symbiotic associations of fungi and roots. The white mycelium of the fungus ensheathes these roots of a pine tree. The fungal hyphae provide an extensive surface area for the absorption of water and minerals.

that contributes to the ability of roots to transport certain minerals preferentially from the soil into the xylem.

The last segment in the soil-to-xylem pathway is the passage of water and minerals into the tracheids and vessel elements of the xylem. These water-conducting cells lack protoplasts when mature and are therefore part of the apoplast. Endodermal cells, as well as parenchyma cells within the vascular cylinder, discharge minerals from their protoplasts into their walls. Both diffusion and active transport are involved in this transfer of solutes from symplast to apoplast, and the water and minerals are now free to enter the tracheids and vessels. The water and mineral nutrients we have tracked from the soil to the root xylem can now be transported upward as xylem sap to the shoot system.

Concept Check 36.2

1. Why might a crop develop a severe phosphate deficiency after being sprayed with a fungicide?
2. A scientist adds a water-soluble inhibitor of photosynthesis to the roots of a plant. However, photosynthesis is not affected by addition of the inhibitor in this manner. Why?

For suggested answers, see Appendix A.

Concept 36.3

Water and minerals ascend from roots to shoots through the xylem

Here we will focus on the long-distance transport of xylem sap. The sap flows upward from roots throughout the shoot system to veins that branch throughout each leaf. Leaves depend on this efficient delivery system for their supply of water. Plants lose an astonishing amount of water by transpiration, the loss of water vapor from leaves and other aerial parts of the plant. Consider the example of maize (commonly called corn in the U.S.). A single plant transpires 125 L of water during a growing season. A maize crop growing at a typical density of 75,000 plants per hectare transpires almost 10 million L (10 million kg) of water per hectare every growing season (equivalent to about 1.25 million gallons of water per acre per growing season). Unless the transpired water is replaced by water transported up from the roots, the leaves will wilt and the plants will eventually die. The upward flow of xylem sap also brings mineral nutrients to the shoot system.

Factors Affecting the Ascent of Xylem Sap

Xylem sap rises to heights of more than 100 m in the tallest trees. Is the sap pushed upward from the roots, or is it pulled

A Figure 36.11 Guttation. Root pressure is forcing excess water from this strawberry leaf.

upward by the leaves? Let's evaluate the relative contributions of these two possible mechanisms.

Pushing Xylem Sap: Root Pressure

At night, when transpiration is very low or zero, root cells continue pumping mineral ions into the xylem of the vascular cylinder. Meanwhile, the endodermis helps prevent the ions from leaking out. The resulting accumulation of minerals lowers the water potential within the vascular cylinder. Water flows in from the root cortex, generating root pressure, an upward push of xylem sap. The root pressure sometimes causes more water to enter the leaves than is transpired, resulting in guttation, the exudation of water droplets that can be seen in the morning on tips of grass blades or the leaf margins of some small, herbaceous eudicots (Figure 36.11). Guttation fluid differs from dew, which is condensed moisture produced during transpiration.

In most plants, root pressure is a minor mechanism driving the ascent of xylem sap, at most forcing water upward only a few meters. Many plants do not generate any root pressure. Even in plants that display guttation, root pressure cannot keep pace with transpiration after sunrise. For the most part, xylem sap is not pushed from below by root pressure but pulled upward by the leaves themselves.

Pulling Xylem Sap: The Transpiration-Cohesion-Tension Mechanism

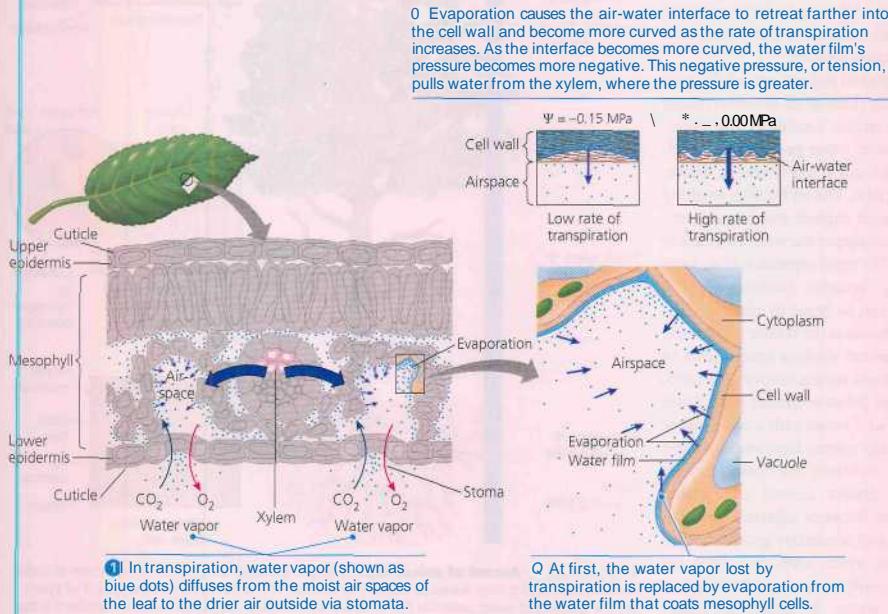

To move material upward, we can apply positive pressure from below or negative pressure from above (as when sucking liquid through a straw). Here we will focus on the process by which water is pulled upward by negative pressure in the xylem. As we investigate this mechanism of transport, we will see that transpiration provides the pull, and the cohesion of water due to hydrogen bonding transmits the upward pull along the entire length of the xylem to the roots.

Transpirational Pull. Stomata, the microscopic pores on the surface of a leaf, lead to a maze of internal airspaces that expose the mesophyll cells to the carbon dioxide they need for photosynthesis. The air in these spaces is saturated with water vapor because it is in contact with the moist walls of the cells. On most days, the air outside the leaf is drier; that is, it has a lower water potential than the air inside the leaf. Therefore, water vapor in the airspaces of a leaf diffuses down its water potential gradient and exits the leaf via the stomata. It is this loss of water vapor from the leaf by diffusion and evaporation that we call transpiration.

But how does loss of water vapor from the leaf translate into a pulling force for upward movement of water through a plant? The leading hypothesis is that negative pressure that causes water to move up through the xylem develops at the air-water interface in mesophyll cell walls. Water is brought to the leaves via the xylem in leaf veins and then is drawn into the mesophyll cells and into their cell walls. This movement depends on adhesion of water to cellulose microfibrils and other hydrophilic components in plant cell walls. At first, water evaporates from a thin water film lining the airspaces surrounding

mesophyll cells. As more water is lost to the air, the air-water interface retreats deeper into the cell wall and becomes more curved (Figure 36.12). As even more molecules evaporate, the degree of curvature and the surface tension of the water molecules increase, and the pressure at the air-water interface becomes increasingly negative. Water molecules from the more hydrated parts of the leaf are then pulled toward this area, reducing the tension. These pulling forces are transferred to the xylem because each water molecule is cohesively bound to the next by hydrogen bonds. Thus, transpirational pull depends on some of the special properties of water that were discussed in Chapter 3: adhesion, cohesion, and surface tension.

The role of negative pressure fits with what you learned earlier about the water potential equation because negative pressure (tension) lowers water potential. Since water moves from where its potential is higher to where it is lower, the increasingly negative pressure at the air-water interface causes xylem cells to lose water to mesophyll cells, which lose water to the airspaces, where it diffuses out through stomata. In short, the negative water potential of leaves provides the "pull" in transpirational pull.

▲ **Figure 36.12 The generation of transpirational pull in a leaf.** The negative pressure at the air-water interface in the leaf is the physical basis of transpirational pull, which draws water out of the xylem.

Cohesion and Adhesion in the Ascent of Xylem Sap. The transpirational pull on xylem sap is transmitted all the way from the leaves to the root tips and even into the soil solution (Figure 36.13). Cohesion and adhesion facilitate this long-distance transport. The cohesion of water due to hydrogen bonding makes it possible to pull a column of sap from above without the water molecules separating. Water molecules exiting the xylem in the leaf tug on adjacent water molecules, and this pull is relayed, molecule by molecule, down the entire column of water in the xylem. The strong adhesion of water molecules (again by hydrogen bonds) to the hydrophilic walls of xylem cells aids in offsetting the downward pull of gravity.

The upward pull on the sap creates tension within the xylem. Pressure will cause an elastic pipe to swell, but tension will pull the walls of the pipe inward. You can actually measure a decrease in the diameter of a tree trunk on a warm day, when transpirational pull puts the xylem under tension. The thick secondary walls prevent vessels from collapsing, much as wire rings maintain the shape of a vacuum hose. The tension produced by transpirational pull lowers water potential in the root xylem to such an extent that water flows passively from the soil, across the root cortex, and into the vascular cylinder.

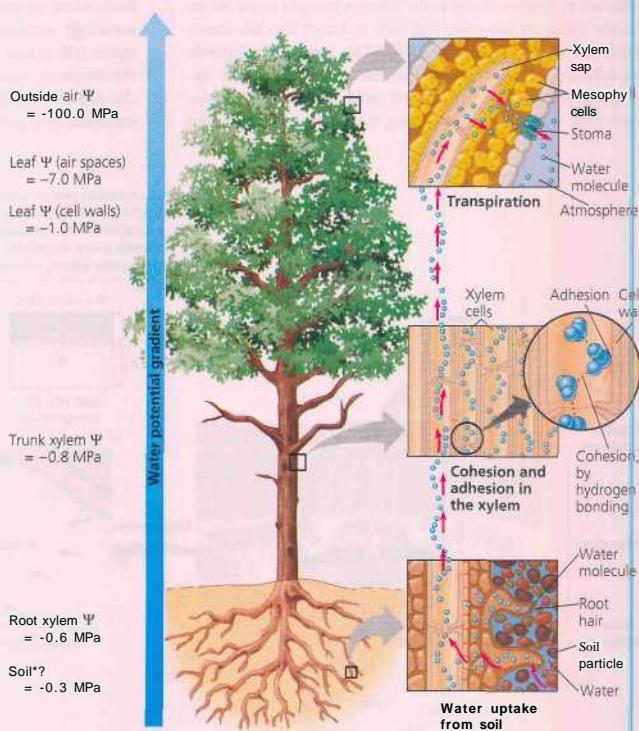

Transpirational pull can extend down to the roots only through an unbroken chain of water molecules. Cavitation, the formation of a water vapor pocket in a vessel, such as when xylem sap freezes in winter, breaks the chain. The air bubbles resulting from cavitation expand and become embolisms, blockages of the water channels of the xylem. The rapid expansion of air bubbles during cavitation produces clicking noises that can be heard by placing sensitive microphones at the surface of the stem.

Root pressure enables small plants to refill embolized vessels in spring. In trees, though, root pressure cannot push water to the top, so a vessel with a water vapor pocket usually cannot function as a water pipe again. However, the chain of molecules can detour around the pocket through pits between adjacent tracheids or vessels, and secondary growth adds a layer of new xylem each year. Only the youngest, outermost secondary xylem transports water. Although no longer functional in water transport, the older secondary xylem does provide support for the tree (see Figure 35.20).

Xylem Sap Ascent by Bulk Flow: A Review

The transpiration-cohesion-tension mechanism that transports xylem sap against gravity is an excellent example of how physical principles apply to biological processes. In the long-distance transport of water from roots to leaves by bulk flow, the movement of fluid is driven by a water potential difference at opposite ends of a conduit. In a plant, the conduits are vessels or chains of tracheids. The water potential difference is generated at the leaf end by transpirational pull, which lowers the water potential (increases tension) at the "upstream" end of the xylem.

On a smaller scale, water potential gradients drive the osmotic movement of water from cell to cell within root and leaf tissue (see Figure 36.13). Differences in both solute concentration and turgor pressure contribute to this short-distance

A Figure 36.13 Ascent of xylem sap. Hydrogen bonding forms an unbroken chain of water molecules extending from leaves all the way to the soil. The force that drives the ascent of xylem sap is a gradient of water potential (Ψ). For the bulk flow over long distance, the Ψ gradient is due mainly to a gradient of the pressure potential (Ψ_p). Transpiration results in the Ψ_p at the leaf end of the xylem being lower than the Ψ_p at the root end. The Ψ values shown at the left are a "snapshot." During daylight, these specific values may vary, but the direction of the water potential gradient remains the same.

transport. In contrast, bulk flow depends only on pressure. Another contrast with osmosis, which moves only water, is that bulk flow moves the whole solution, water plus minerals and any other solutes dissolved in the water.

The plant expends no energy to lift xylem sap by bulk flow. Instead, the absorption of sunlight drives transpiration by causing water to evaporate from the moist walls of mesophyll cells and by lowering the water potential in the air spaces within a leaf. Thus, the ascent of xylem sap is ultimately solar powered.

Concept Check 36.3

- What would be the effect of fertilizing a plant during a drought?
- Plants called epiphytes, including many orchid species, live in the very humid tropics and grow on tree trunks. Epiphytes have no contact with the soil but can absorb water from the air. How is this possible?
- A tip for helping cut flowers last longer without wilting is to cut off the ends of the stems underwater and then transfer the flowers to a vase while water droplets are still present on the cut ends of the stems. Explain why this works.

For suggested answers, see Appendix A.

Concept 36.4

Stomata help regulate the rate of transpiration

Leaves generally have broad surface areas and high surface area-to-volume ratios. The broad surface area is a morphological adaptation that enhances the absorption of light needed to drive photosynthesis. The high surface area-to-volume ratio aids in the uptake of carbon dioxide during photosynthesis as well as in

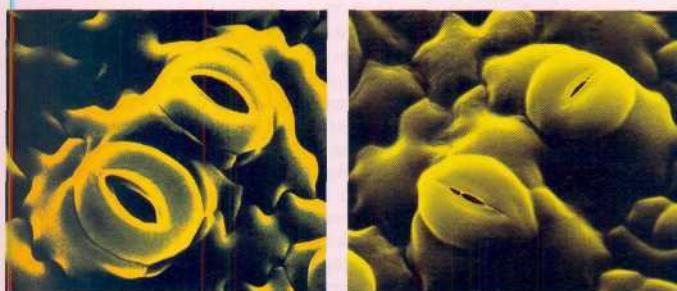

the release of oxygen produced as a by-product of photosynthesis. Upon diffusing through the stomata, CO₂ enters a honeycomb of air spaces formed by the spongy parenchyma cells (see Figure 35.17). Because of the irregular shape of these cells, the internal surface area of the leaf may be 10 to 30 times greater than the external surface area we see when we look at the leaf.

Although broad surface areas and high surface area-to-volume ratios increase photosynthesis, they also have the serious drawback of increasing water loss by way of the stomata. Thus, a plant's tremendous requirement for water is part of the cost of making food by photosynthesis. By opening and closing the stomata, guard cells help balance the plant's requirement to conserve water with its requirement for photosynthesis (Figure 36.14).

Effects of Transpiration on Wilting and Leaf Temperature

A leaf may transpire more than its weight in water each day, and water may move through the xylem at a rate as fast as 75 cm/min, about the speed of the tip of a second hand sweeping around a wall clock. If transpiration continues to pull sufficient water upward to the leaves, they will not wilt. But the rate of transpiration is greatest on a day that is sunny, warm, dry, and windy because these environmental factors increase evaporation. Although plants can adjust to such conditions by regulating the size of the stomatal openings, some evaporative water loss does occur even when the stomata are closed. Under these prolonged drought conditions, the leaves begin to wilt as their cells lose turgor pressure (see Figure 36.7).

Transpiration also results in evaporative cooling, which can lower the temperature of a leaf by as much as 10–15°C compared with the surrounding air. This prevents the leaf from reaching temperatures that could denature various enzymes involved in photosynthesis and other metabolic processes. Cacti and other desert succulents, which have low rates of transpiration, can tolerate high leaf temperatures; in this case, the loss of water due to transpiration is a greater threat than overheating. Evolution of the cactus's biochemistry has facilitated survival in high temperatures.

« Figure 36.14 Open stomata (left) and closed stomata (colorized SEM).

Stomata: Major Pathways for Water Loss

About 90% of the water a plant loses escapes through stomata, though these pores account for only 1–2% of the external leaf surface. The waxy cuticle limits water loss through the remaining surface of the leaf. Each stoma is flanked by a pair of guard cells, which are kidney-shaped in eudicots and dumbbell-shaped in many monocots. Guard cells control the diameter of the stoma by changing shape, thereby widening or narrowing the gap between the two cells (**Figure 36.15a**). The amount of water lost by a leaf depends on the number of stomata and the average size of their apertures.

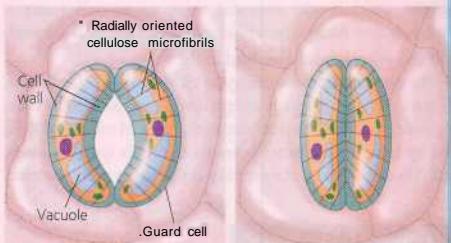

The stomatal density of a leaf, which may be as high as 20,000 per square centimeter, is under both genetic and environmental control. For example, as a result of evolution by natural selection, desert plants have lower stomatal densities than do marsh plants. Stomatal density, however, is also a developmentally plastic feature of many plants. High light intensities and low carbon dioxide levels during leaf development tend to increase stomatal density in many plant species. By measuring the stomatal density of leaf fossils, scientists have been able to gain insight into the levels of atmospheric CO_2 in past climates. A recent British survey found that the stomatal density of many woodland species has decreased since 1927, when a similar survey was made. This survey is consistent with the finding that atmospheric CO_2 levels increased dramatically during the 20th century as a result of the increased burning of fossil fuels.

When guard cells take in water from neighboring cells by osmosis, they become more turgid and bowed. In most angiosperm species, the cell walls of guard cells are uneven in thickness, and the cellulose microfibrils are oriented in a direction that causes the guard cells to buckle outward when they are turgid, as you can see in **Figure 36.15a**. This buckling increases the size of the pore between the guard cells. When the cells lose water and become flaccid, they become less bowed and close the pore.

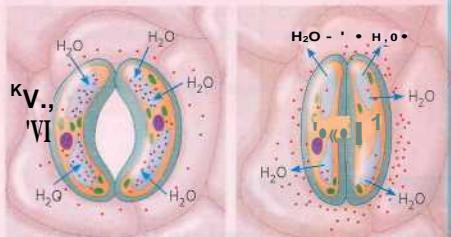

The changes in turgor pressure that open and close stomata result primarily from the reversible uptake and loss of potassium ions (K^+) by the guard cells. Stomata open when guard cells actively accumulate K^+ from neighboring epidermal cells (**Figure 36.15b**). This uptake of solute causes the water potential to become more negative within the guard cells, and the cells become more turgid as water enters by osmosis. Most of the K^+ and water are stored in the vacuole, and thus the vacuolar membrane also plays a role in regulating the water potential of guard cells. Stomatal closing results from an exit of K^+ from guard cells to neighboring cells, which leads to an osmotic loss of water. Regulation of aquaporins may also be involved in the swelling and shrinking of guard cells by varying the permeability of the membranes to water.

The K^+ fluxes across the guard cell membrane are coupled to the generation of membrane potentials by proton pumps.

Cells turgid/Stoma open Cells flaccid/Stoma closed

(a) Changes in guard cell shape and stomatal opening and closing (surface view). Guard cells of a typical angiosperm are illustrated in their turgid (stoma open) and flaccid (stoma closed) states. The pair of guard cells buckle outward when turgid. Cellulose microfibrils in the walls resist stretching and compression in the direction parallel to the microfibrils. Thus, the radial orientation of the microfibrils causes the cells to increase in length more than width when turgor increases. The two guard cells are attached at their tips, so the increase in length causes buckling.

(b) Role of potassium in stomatal opening and closing. The transport of K^+ (potassium ions, symbolized here as red dots) across the plasma membrane and vacuolar membrane causes the turgor changes of guard cells.

A Figure 36.15 The mechanism of stomatal opening and closing.

Stomatal opening correlates with active transport of H^+ out of the guard cell. The resulting voltage (membrane potential) drives K^+ into the cell through specific membrane channels (see Figure 36.4a).

In general, stomata are open during the day and closed at night. This prevents the plant from losing water when it is too dark for photosynthesis. At least three cues contribute to stomatal opening at dawn. First, light itself stimulates guard cells to accumulate K^+ and become turgid. This response is triggered by the illumination of a blue-light receptor in the plasma membrane of guard cells. Activation of these blue-light receptors stimulates the activity of ATP-powered proton pumps in the plasma membrane of the guard cells, in turn promoting the uptake of K^+ .

A second stimulus causing stomata to open is depletion of CO_2 within air spaces of the leaf, which occurs when photosynthesis begins in the mesophyll. A plant will actually open its stomata at night if it is placed in a chamber devoid of CO_2 .

A third cue causing stomatal opening is an internal "clock" in the guard cells. Even if you keep a plant in a dark closet, stomata will continue their daily rhythm of opening and closing*. All eukaryotic organisms have internal clocks that regulate cyclic processes. Cycles that have intervals of approximately 24 hours are called circadian rhythms. You will learn more about circadian rhythms and the biological clocks that control them in Chapter 39.

Environmental stresses can cause stomata to close during the daytime. When the plant suffers a water deficiency, guard cells may lose turgor and close stomata. In addition, a hormone called abscisic acid, which is produced in the roots in response to water deficiency, signals guard cells to close stomata. This response reduces further wilting but also restricts uptake of CO_2 and thereby slows photosynthesis. This is one reason why droughts reduce crop yields.

Guard cells arbitrate the photosynthesis-transpiration compromise on a moment-to-moment basis by integrating a variety of internal and external stimuli. Even the passage of a cloud or a transient shaft of sunlight through a forest canopy can affect the rate of transpiration.

Xerophyte Adaptations That Reduce Transpiration

Plants adapted to arid climates, called xerophytes, have various leaf modifications that reduce the rate of transpiration. Many xerophytes have small, thick leaves, an adaptation that limits water loss by reducing surface area relative to leaf volume. A thick cuticle gives some of these leaves a leathery consistency. Some other xerophyte adaptations are highly reflective leaves and hairy leaves that trap a boundary layer of water. The stomata of xerophytes are concentrated on the lower (shady) leaf surface, and they are often located in depressions that shelter the pores from the dry wind (Figure 36.16). During the driest months, some desert plants shed their leaves. Others, such as cacti, subsist on water the plant stores in fleshy stems during the rainy season.

An elegant adaptation to arid habitats is found in succulents of the family Crassulaceae, in ice plants, and in many other plant families. These plants assimilate CO_2 by an alternative photosynthetic pathway known as CAM, for crassulacean acid metabolism (see Figure 10.20). Mesophyll cells in a CAM plant have enzymes that can incorporate CO_2 into organic acids during the night. During the daytime, the organic acids are broken down to release CO_2 in the same cells, and sugars are synthesized by the conventional (C3) photosynthetic pathway. Because the leaf takes in CO_2 at night, the stomata can close during the day, when transpiration would be greatest.

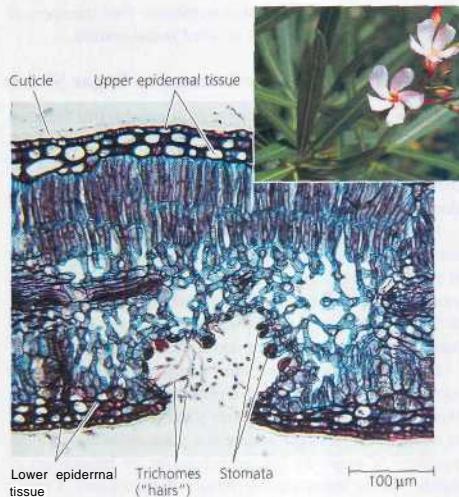

Figure 36.16 STRUCTURAL ADAPTATIONS OF A XEROPHYTE LEAF. Oleander (*Nerium oleander*), shown in the inset, is commonly found in arid climates. The leaves have a thick cuticle and multiple-layered epidermal tissue that reduce water loss. Stomata are recessed in "crypts," an adaptation that reduces the rate of transpiration by protecting the stoma from hot, dry wind. The trichomes ("hairs") also help minimize transpiration by breaking up the flow of air, allowing the chamber of the crypt to have a higher humidity than the surrounding atmosphere (LM).

Concept Check 36.4

1. Some leaf molds, which are fungi that parasitize plants, secrete a chemical that causes guard cells to accumulate potassium ions. How does this adaptation enable the leaf mold to infect the plant?
2. Describe the environmental conditions that would minimize the transpiration-to-photosynthesis ratio for a C₃ plant, such as an oak tree.

For suggested answers, see Appendix A.

Concept 36.5

Organic nutrients are translocated through the phloem

Xylem sap flows from roots to leaves, in a direction opposite to that necessary to transport sugars from leaves to other parts of the plant. It is a second vascular tissue, the phloem, that

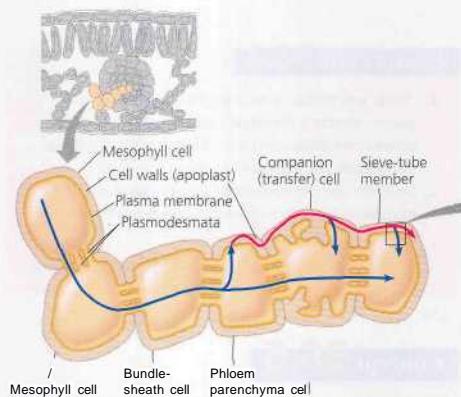

transports the products of photosynthesis. This transport of organic nutrients in the plant is called **translocation**.

Movement from Sugar Sources to Sugar Sinks

In angiosperms, the specialized cells of phloem that function as the conduits for translocation are the sieve-tube members, arranged end to end to form long sieve tubes. Between the cells are sieve plates, structures that allow the flow of sap along the sieve tube (see Figure 35.9).

Phloem sap is an aqueous solution that differs markedly in composition from xylem sap. By far the most prevalent solute in phloem sap is sugar, primarily the disaccharide sucrose in most species. The sucrose concentration may be as high as 30% by weight, giving the sap a syrupy thickness. Phloem sap may also contain minerals, amino acids, and hormones.

In contrast to the unidirectional transport of xylem sap from roots to leaves, the direction that phloem sap travels is variable. However, sieve tubes always carry sugars from a sugar source to a sugar sink. A **sugar source** is a plant organ that is a net producer of sugar, by photosynthesis or by breakdown of starch. Mature leaves are the primary sugar sources. A **sugar sink** is an organ that is a net consumer or storer of sugar. Growing roots, buds, stems, and fruits are sugar sinks. A storage organ, such as a tuber or a bulb, may be a source or a sink, depending on the season. When stockpiling carbohydrates in the summer, it is a sugar sink. After breaking dormancy in the spring, it is a source as its starch is broken down to sugar, which is carried to the growing tips of the plant.

- (a) Sucrose manufactured in mesophyll cells can travel via the symplast (blue arrows) to sieve-tube members. In some species, sucrose exits the symplast (red arrow) near sieve tubes and is actively accumulated from the apoplast by sieve-tube members and their companion cells.

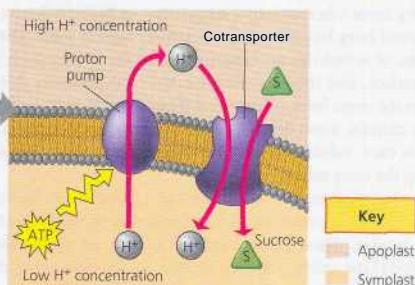

A **Figure 36.17** Loading of sucrose into phloem.

A sugar sink usually receives sugar from the nearest source. Upper leaves on a branch may send sugar to the growing shoot tip, whereas lower leaves export sugar to roots. A growing plant may monopolize sugar sources around it. For each sieve tube, the direction of transport depends on the locations of the source and sink connected by that tube. Therefore, neighboring tubes may carry sap in opposite directions. Direction of flow may also vary by season or developmental stage of the plant.

Sugar must be loaded into sieve-tube members before being exported to sinks. In some species, it moves from mesophyll cells to sieve-tube members via the symplast, passing through plasmodesmata. In other species, it moves by symplastic and apoplastic pathways (Figure 36.17a). In maize leaves, for example, sucrose diffuses through the symplast from chloroplast-containing mesophyll cells into small veins. Much of it then moves into the apoplast and is accumulated by nearby sieve-tube members, either directly or through companion cells, in some plants, companion cells have many ingrowths of their walls, enhancing transfer of solutes between apoplast and symplast. Such modified cells are called transfer cells (see Figure 29.5).

In maize and many other plants, phloem loading requires active transport because sucrose concentrations in sieve-tube members are two to three times higher than in mesophyll. Proton pumping and cotransport of sucrose and H⁺ enable the cells to accumulate sucrose (Figure 36.17b).

Phloem unloads sucrose at the sink end of a sieve tube. The process varies by plant species and type of organ. However, the concentration of free sugar in the sink is always lower than in the sieve tube because the unloaded sugar is either consumed during growth and metabolism of the sink cells or converted into insoluble polymers such as starch. As a result of this sugar concentration gradient, sugar molecules diffuse from the phloem into the sink tissues, and water follows by osmosis.

- (b) A chemiosmotic mechanism is responsible for the active transport of sucrose into companion cells and sieve-tube members. Proton pumps generate an H⁺ gradient, which drives sucrose accumulation with the help of a cotransport protein that couples sucrose transport to the diffusion of H⁺ back into the cell.

Pressure Flow: The Mechanism of Translocation in Angiosperms

Phloem sap flows from source to sink at rates as great as 1 m/hr, much too fast to be accounted for by either diffusion or cytoplasmic streaming. In studying angiosperms, researchers have concluded that sap moves through a sieve tube by bulk flow driven by positive pressure (thus the synonym *pressure flow*), as shown in **Figure 36.18**. The building of pressure at the source end and reduction of that pressure at the sink end cause water to flow from source to sink, carrying the sugar along. Xylem recycles the water from sink to source.

The pressure flow hypothesis explains why phloem sap always flows from source to sink. Experiments such as the one described in **Figure 36.19** build a strong case for pressure flow as the mechanism of translocation in angiosperms. It is not yet known if this model applies to other vascular plants.

We have seen examples of sugar transport on three levels: at the cellular level across plasma membranes (sucrose accumulation by active transport in phloem); short-distance transport within organs (sucrose migration from mesophyll to phloem via the symplast and apoplast); and long-distance transport between organs (bulk flow in sieve tubes). Understanding these

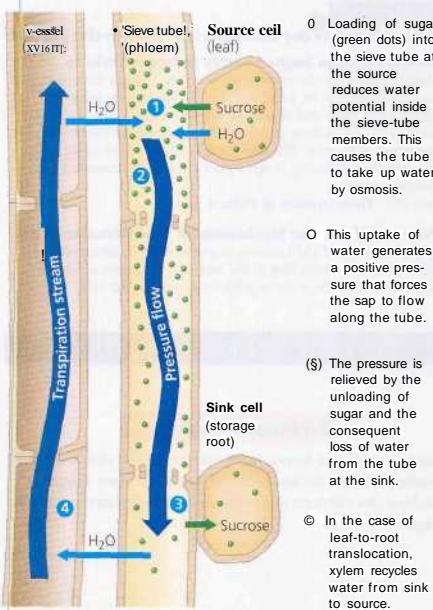

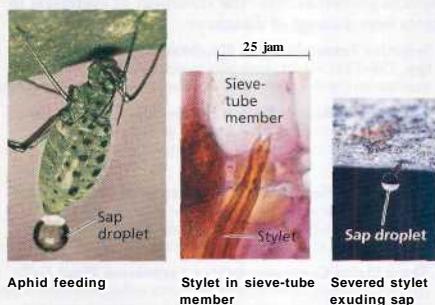

Figure 36.18 Pressure flow in a sieve tube.

Figure 36.19 *Why does phloem sap flow from source to sink?*

EXPERIMENT

To test the pressure flow hypothesis, researchers used aphids that feed on phloem sap. An aphid probes with a hypodermic-like mouthpart called a stylet that penetrates a sieve-tube member. As sieve-tube pressure force-feeds aphids, they can be severed from their stylets, which serve as taps exuding sap for hours. Researchers measured the flow and sugar concentration of sap from stylets at different points between a source and sink.

RESULTS

The closer the stylet was to a sugar source, the faster the sap flowed and the higher was its sugar concentration.

CONCLUSION

The results of such experiments support the pressure flow hypothesis.

processes is central to agricultural advancement. Modeling studies in ideal growing conditions indicate that it is not photosynthesis that limits yield, but rather the ability to transport sugars. Thus, genetic engineering of higher-yielding crop plants may depend on a better understanding of factors that limit bulk flow of sugars. This is just one example of how basic plant research connects to agricultural technology.

Concept Check 36.5

1. Compare and contrast the forces that move phloem sap versus the forces that move xylem sap over long distance.
2. Potatoes break down starch into sugar at low temperature. (This is a problem for the potato chip industry because the sugar in chilled potatoes turns dark brown during processing.) What effect would cooling the soil around an expanding potato tuber have on sugar import into it?

For suggested answers, see Appendix A.

Chapter 36 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 36.1

Physical processes drive the transport of materials in plants over a range of distances

- **Selective Permeability of Membranes: A Review** (pp. 738–739) Specific transport proteins enable plant cells to maintain an internal environment different from their surroundings.
- **The Central Role of Proton Pumps** (pp. 739–740) The membrane potential and H⁺ gradient generated by proton pumps is harnessed to drive the transport of a variety of solutes.
- **Effects of Differences in Water Potential** (pp. 740–742) Solutes decrease water potential, while pressure increases water potential. Water flows by osmosis from a region with higher water potential to a region with a lower potential.
- **Three Major Compartments of Vacuolated Plant Cells** (p. 743) The plasma membrane regulates transport between the cytosol and cell wall, while the vacuolar membrane regulates transport between the cytosol and vacuole.
- **Functions of the Symplast and Apoplast in Transport** (p. 743) The symplast is the continuum of cytosol linked by plasmodesmata. The apoplast is the continuum of cell walls and the extracellular spaces.
- **Bulk Flow in Long-Distance Transport** (pp. 743–744) Transport of xylem and phloem sap is due to pressure differences at opposite ends of conduits—xylem vessels and sieve tubes.

Concept 36.2

Roots absorb water and minerals from the soil

- **The Roles of Root Hairs, Mycorrhizae, and Cortical Cells** (p. 744) Root hairs are the most important avenues of absorption near root tips, but mycorrhizae, symbiotic associations of fungi and roots, are responsible for most absorption by the whole root system. Once soil solution enters the root, the extensive surface area of cortical cell membranes enhances uptake of water and selected minerals.
- **The Endodermis: A Selective Sentry** (pp. 744–746) Water can cross the cortex via the symplast or apoplast, but minerals that reach the endodermis via the apoplast must finally cross the selective membranes of endodermal cells. The waxy Caspary strip of the endodermal wall blocks apoplastic transfer of minerals from the cortex to the vascular cylinder.

Concept 36.3

Water and minerals ascend from roots to shoots through the xylem

- **Factors Affecting the Ascent of Xylem Sap** (pp. 746–748) Loss of water vapor (transpiration) lowers water potential in the leaf by producing a negative pressure (tension). This low water potential draws water from the xylem. Cohesion and adhesion of the water transmit the pulling force down to the roots.

- **Xylem Sap Ascent by Bulk Flow: A Review** (pp. 748–749) The movement of xylem sap against gravity is maintained by transpiration.

Activity *Transport of Xylem Sap*

Concept 36.4

Stomata help regulate the rate of transpiration

- **Effects of Transpiration on Wilting and Leaf Temperature** (p. 749) Plants lose an astonishing amount of water as a result of transpiration. If this lost water is not replaced by water absorption from the roots, the plant will gradually lose water and wilt. Because evaporative cooling is reduced, wilted plants may become overheated.
- **Stomata: Major Pathways for Water Loss** (pp. 750–751) Stomata support photosynthesis by allowing CO₂ and O₂ exchange between the leaf and atmosphere, but these pores are also the main avenues for transpirational loss of water from the plant. Turgor changes in guard cells, which depend on K⁺ and water transport into and out of the cells, regulate the size of stomatal openings.

Investigation *How Is the Rate of Transpiration Calculated?*

- **Xerophyte Adaptations That Reduce Transpiration** (p. 751) Protection of stomata within leaf indentations and other structural adaptations enable certain plants to survive in arid environments.

Concept 36.5

Organic nutrients are translocated through the phloem

- **Movement from Sugar Sources to Sugar Sinks** (p. 752) Mature leaves are the main sugar sources, though storage organs such as bulbs can be sugar sources during certain seasons. Developing roots and shoot tips are some examples of sugar sinks. Phloem loading and unloading depend on the active transport of sucrose. The sucrose is cotransported along with H⁺, which is diffusing down a gradient that is generated by proton pumps.
- Activity *Translocation of Phloem Sap*
- **Pressure Flow: The Mechanism of Translocation in Angiosperms** (p. 753) Loading of sugar at the source end of a sieve tube and unloading at the sink end maintain a pressure difference that keeps the sap flowing through the tube.

TESTING YOUR KNOWLEDGE

Evolution Connection

Analysis of preserved leaves shows that the density of stomata per unit area of leaf has decreased over the past 200 years. Suggest a hypothesis that connects this evolutionary trend to environmental change.

Scientific Inquiry

Barrel cacti (*Ferocactus*) of the Sonoran Desert do not grow straight up, but tilt southward at about a 45° angle. Suggest a hypothesis for the function of this evolutionary adaptation. How could you test your hypothesis?

Investigation How Is the Rate of Transpiration Calculated?

Science, Technology, and Society

Water use is a serious social and environmental issue in the arid southwestern United States. In recent years, there has been growing criticism of water-intensive ornamental landscapes like lawns and golf greens. These areas are maintained artificially by diverting water from rivers and streams or pumping from ancient subterranean aquifers. Is this form of water use something society should limit or even eliminate in such areas? Or should property owners be free to landscape as they choose? Defend your side in this debate.

37

Plant Nutrition

A Figure 37.1 Root and shoot systems of a pea seedling.

Key Concepts

- 37.1 Plants require certain chemical elements to complete their life cycle
- 37.2 Soil quality is a major determinant of plant distribution and growth
- 37.3 Nitrogen is often the mineral that has the greatest effect on plant growth
- 37.4 Plant nutritional adaptations often involve relationships with other organisms

Overview

A Nutritional Network

Every organism continuously exchanges energy and materials with its environment. At the level of the ecosystem, plants and other photosynthetic autotrophs perform the key step of transforming inorganic compounds into organic compounds. Autotrophic, however, does not mean autonomous. Plants need light as the energy source for photosynthesis. In order to synthesize organic matter, plants also require raw materials in the form of inorganic nutrients: water, minerals, and carbon dioxide. For a typical plant, water and minerals come from the soil, while carbon dioxide comes from the air. The branching root system and the shoot system of a vascular plant (Figure 37.1) ensure extensive networking with both of these reservoirs of inorganic nutrients.

In Chapter 36, you studied the mechanisms by which vascular plants transport water, minerals, and organic nutrients. Here you will learn more about nutritional requirements and examine some nutritional adaptations that have evolved in plants, often in relationship with other organisms.

Concept 37.1

Plants require certain chemical elements to complete their life cycle

Watch a large plant grow from a tiny seed, and you cannot help wondering where all the mass comes from. Aristotle thought that soil provided the substance for plant growth because plants seemed to spring from the ground. He believed that leaves of flowering plants simply shaded developing fruit. In the 17th century, Jan Baptista van Helmont performed an experiment to test the hypothesis that plants grow by consuming soil. He planted a small willow in a pot that contained 90.9 kg of soil. After five years, the willow had grown into a tree weighing 76.8 kg, but only 0.06 kg of soil had disappeared from the pot. He concluded that the willow had grown mainly from the water he had added regularly. A century later, an English physiologist named Stephen Hales postulated that plants are nourished mostly by air.

There is some truth to all three hypotheses because soil, water, and air all contribute to plant growth (Figure 37.2). Plants extract mineral nutrients, essential chemical elements, from the soil in the form of inorganic ions. Plants acquire nitrogen, for example, in the form of nitrate ions (NO_3^-). However, mineral nutrients add little to the plants overall mass. Typically, 80–90% of a plant is water, and plants grow mainly by accumulating water in the central vacuoles of their cells. Water is also a nutrient that supplies most of the hydrogen atoms and some of the oxygen atoms incorporated into organic compounds by photosynthesis (see Figure 10.4). Still, only a small fraction of the water that enters a plant contributes atoms to organic molecules. For example, it has been estimated that more than 90% of

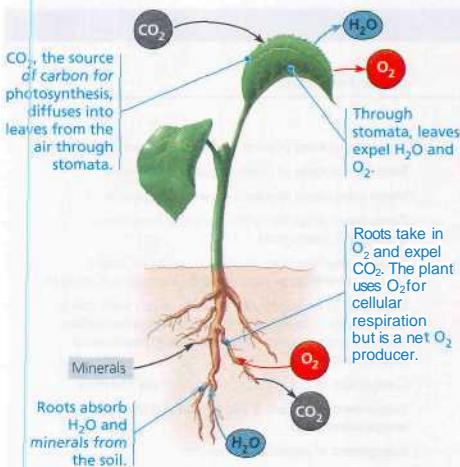

Figure 37.2 The uptake of nutrients by a plant:

a review. From CO₂, O₂, H₂O, and minerals, the plant produces all of its own organic material. See also Figure 36.2.

The water absorbed by maize plants is lost by transpiration. The water retained by a plant serves three main functions: It acts as a so vent, provides most of the volume for cell elongation, and helps maintain the form of soft tissue by keeping cells turgid. By weight, the bulk of a plant's organic material is derived not from water or soil minerals, but from the CO₂ that is assimilated from the air.

We can measure water content by comparing the weight of plant material before and after it is dried. We can then analyze the chemical composition of the dry residue. Organic substances account for about 96% of the dry weight, with inorganic substances making up the remaining 4%. Most of the organic material is carbohydrate, including the cellulose of cell walls. Thus, the components of carbohydrates—carbon, oxygen, and hydrogen—are the most abundant elements in the dry weight of a plant. Because some organic molecules contain nitrogen, sulfur, or phosphorus, these elements are also relatively abundant in plants.

Macronutrients and Micronutrients

More than 50 chemical elements have been identified among the inorganic substances in plants, but not all of these elements are essential. A chemical element is considered an essential element if it is required for a plant to complete a life cycle and produce another generation. In studying the chemical composition of plants, we must distinguish elements that are essential from those that are merely present in the plant. To some extent, the chemical elements in a plant reflect the soil composition.

Plants growing on mine tailings, for instance, may contain gold or silver, but these minerals have no nutritional function.

To determine which chemical elements are essential elements, researchers use hydroponic culture, in which plants are grown without soil by using mineral solutions (Figure 37.3). Such studies have helped identify 17 essential elements that are needed by all plants (Table 37.1, on the next page).

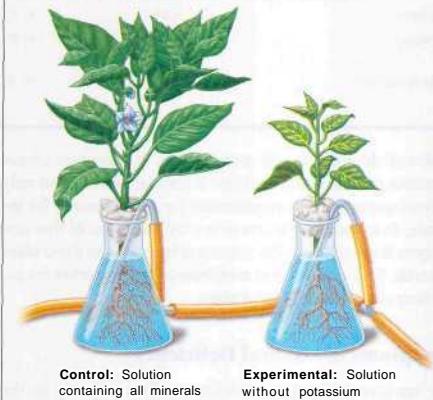

Nine of the essential elements are called macronutrients because plants require them in relatively large amounts. Six of these are the major components of organic compounds forming the structure of a plant: carbon, oxygen, hydrogen, nitrogen, phosphorus, and sulfur. The other three macronutrients are potassium, calcium, and magnesium.

The remaining eight essential elements are known as micronutrients because plants need them in very small amounts. They are chlorine, iron, manganese, boron, zinc, copper, nickel, and molybdenum. Micronutrients function in plants mainly as cofactors, non-protein helpers in enzymatic reactions (see Chapter 8). Iron, for example, is a metallic component of cytochromes, the proteins in the electron transport

Figure 37.3
Research Method Hydroponic Culture

APPLICATION In hydroponic culture, plants are grown in mineral solutions without soil. One use of hydroponic culture is to identify essential elements in plants.

TECHNIQUE Plant roots are bathed in aerated solutions of known mineral composition. Aerating the water provides the roots with oxygen for cellular respiration. A particular mineral, such as potassium, can be omitted to test whether it is essential.

RESULTS If the omitted mineral is essential, mineral deficiency symptoms occur, such as stunted growth and discolored leaves. Deficiencies of different elements may have different symptoms, which can aid in diagnosing mineral deficiencies in soil.

Table 37.1 Essential Elements in Plants

| Element | Form Available to Plants | % Mass in Dry Tissue | Major Functions |
|-----------------------|---|----------------------|--|
| Macronutrients | | | |
| Carbon | CO ₂ | 45% | Major component of plant's organic compounds |
| Oxygen | CO ₂ | 45% | Major component of plant's organic compounds |
| Hydrogen | H ₂ O | 6% | Major component of plant's organic compounds |
| Nitrogen | NO ₃ ⁻ , NH ₃ , NH ₄ ⁺ | 1.5% | Component of nucleic acids, proteins, hormones, chlorophyll, coenzymes |
| Potassium | K ⁺ | 1.0% | Cofactor that functions in protein synthesis; major solute functioning in water balance; operation of stomata |
| Calcium | Ca ²⁺ | 0.5% | Important in formation and stability of cell walls and in maintenance of membrane structure and permeability; activates some enzymes; regulates many responses of cells to stimuli |
| Magnesium | Mg ²⁺ | 0.2% | Component of chlorophyll; activates many enzymes |
| Phosphorus | H ₂ PO ₄ ³⁻ , HPO ₄ ²⁻ | 0.2% | Component of nucleic acids, phospholipids, ATP, several coenzymes |
| Sulfur | SO ₄ ²⁻ | 0.1% | Component of proteins, coenzymes |
| Micronutrients | | | |
| Chlorine | Cl ⁻ | 0.01% | Required for water-splitting step of photosynthesis; functions in water balance |
| Iron | Fe ³⁺ , Fe ²⁺ | 0.01% | Component of cytochromes; activates some enzymes |
| Manganese | Mn ²⁺ | 0.005% | Active in formation of amino acids; activates some enzymes; required for water-splitting step of photosynthesis |
| Boron | H ₂ BO ₃ ⁻ | 0.002% | Cofactor in chlorophyll synthesis; may be involved in carbohydrate transport and nucleic acid synthesis; role in cell wall function |
| Zinc | Zn ²⁺ | 0.002% | Active in formation of chlorophyll; activates some enzymes |
| Copper | Cu ⁺ , Cu ²⁺ | < 0.001% | Component of many redox and lignin-biosynthetic enzymes |
| Nickel | Ni ²⁺ | < 0.001% | Cofactor for an enzyme functioning in nitrogen metabolism |
| Molybdenum | MoO ₄ ²⁻ | < 0.0001% | Essential for symbiotic relationship with nitrogen-fixing bacteria; cofactor that functions in nitrate reduction |

chains of chloroplasts and mitochondria. It is because micronutrients generally play catalytic roles that plants need only minute quantities. The requirement for molybdenum, for instance, is so modest that there is only one atom of this rare element for every 60 million atoms of hydrogen in dried plant material. Yet a deficiency of molybdenum or any other micronutrient can weaken or kill a plant.

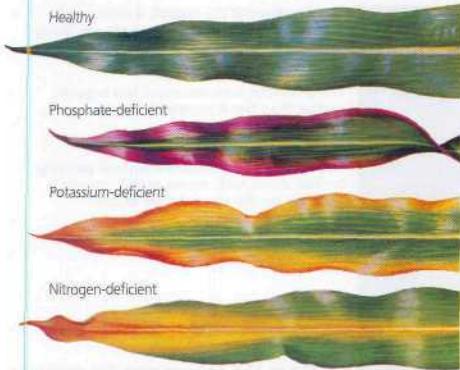

Symptoms of Mineral Deficiency

The symptoms of a mineral deficiency depend partly on the nutrients function. For example, a deficiency of magnesium, a component of chlorophyll, causes yellowing of the leaves, known as chlorosis. In some cases, the relationship between a mineral deficiency and its symptoms is less direct. For instance, iron deficiency can cause chlorosis even though chloro-

phyll contains no iron, because iron ions are required as a cofactor in one of the enzymatic steps of chlorophyll synthesis.

Mineral deficiency symptoms depend not only on the role of the nutrient but also on its mobility within the plant. If a nutrient moves about freely, symptoms will show up first in older organs because young, growing tissues have more "drawing power" for nutrients in short supply. For example, magnesium is relatively mobile and is shunted preferentially to young leaves. Therefore, a plant starved for magnesium will show signs of chlorosis first in its older leaves. The mechanism for preferential routing is the source-to-sink translocation in phloem as minerals move along with the sugars to the growing tissues (see Figure 36.18). In contrast, a deficiency of a mineral that is relatively immobile will affect young parts of the plant first. Older tissues may have adequate amounts, which they are able to retain during periods of short supply. For example, iron does not mole-

Healthy

• **Figure 37.4** The most common mineral deficiencies, as seen in maize leaves. Phosphate-deficient plants have reddish purple margins, particularly in young leaves. Potassium-deficient plants exhibit "firing," or drying, along tips and margins of older leaves. Nitrogen deficiency is evident in a yellowing that starts at the tip and moves along the center (midrib) of older leaves.

freely within a plant, and an iron deficiency will cause yellowing of young leaves before any effect on older leaves is visible.

Deficiencies of nitrogen, phosphorus, and potassium are most common. Shortages of micronutrients are less common and tend to occur in certain geographic regions because of differences in soil composition. The symptoms of a mineral deficiency are often distinctive enough for a plant physiologist or farmer to diagnose its cause (**Figure 37.4**). One way to confirm a diagnosis is to analyze the mineral content of the plant and soil. The amount of a micronutrient needed to correct a deficiency is usually quite small. For example, a zinc deficiency in fruit trees can usually be cured by hammering a few zinc nails into each tree trunk. Moderation is important because overdoses of many nutrients can be toxic to plants. Hydroponic culture can ensure optimal mineral nutrition by using nutrient solutions that can be precisely regulated. However, this method is not used widely in agriculture because it is relatively expensive compared with growing crops in soil.

Concept 37.2

Soil quality is a major determinant of plant distribution and growth

Along with climate, the major factors determining whether particular plants can grow well in a certain location are the texture and composition of the soil. Texture is the soil's general structure, referring to the relative amounts of various sizes of soil particles. Composition refers to the soil's organic and inorganic chemical components. Plants that grow naturally in a certain type of soil are adapted to its texture and composition and can absorb water and extract essential mineral nutrients. In turn, plants affect the soil, as you will soon see. The soil-plant interface is a critical part of the chemical cycles that sustain terrestrial ecosystems.

Texture and Composition of Soils

Soil has its origin in the weathering of solid rock. The freezing of water that has seeped into crevices can mechanically fracture rocks. Acids dissolved in the water can also help break rocks down chemically. When organisms are able to invade the rock, they accelerate breakdown by chemical and mechanical means. Some organisms, for example, secrete acids that dissolve the rock. Roots that grow in fissures lead to mechanical fracturing. The eventual result of all this activity is topsoil, a mixture of particles derived from rock, living organisms, and humus, the remains of partially decayed organic material. The topsoil and other distinct soil layers, or horizons, are often visible in vertical profile where there is a road cut or deep hole (**Figure 37.5**, on the next page). The topsoil, also known as the A horizon, is the richest in organic material and is therefore most important for plant growth.

The texture of topsoil depends on the sizes of its particles, which are classified in a range from coarse sand to microscopic clay particles. The most fertile soils are usually loams, made up of roughly equal amounts of sand, silt (particles of intermediate size), and clay. Loamy soils have enough fine particles to provide a large surface area for retaining minerals and water, which adhere to the particles. But loams also have enough coarse particles to provide air spaces containing oxygen that can be used by roots for cellular respiration. If soil does not drain adequately, roots suffocate because the air spaces are replaced by water; the roots may also be attacked by molds that favor soaked soil. These are common hazards for houseplants that are overwatered in pots with poor drainage.

Soil composition includes organic components as well as minerals. Topsoil is home to an astonishing number and variety of organisms. A teaspoon of topsoil has about 5 billion

IConcept Check 37.1

1. Explain how Table 37.1 can be used to support Hales' hypothesis, yet does not refute van Helmont's hypothesis.
2. Are some essential elements more important than others? Explain.
3. Can a single leaf be used to diagnose all of a plant's mineral deficiencies? Explain.

For suggested answers, see Appendix A.

The A horizon is the topsoil, a mixture of broken-down rock of various textures, living organisms, and decaying organic matter.

The B horizon contains much less organic matter than the A horizon and is less weathered.

The C horizon, composed mainly of partially broken-down rock, serves as the "parent" material for the upper layers of soil.

< Figure 37.5 Soil horizons. This researcher is photographing a vertical profile of three soil layers, or horizons.

bacteria that cohabit with various fungi, algae and other protists, insects, earthworms, nematodes, and roots of plants. The activities of all these organisms affect the soil's physical and chemical properties. Earthworms, for instance, turn over and aerate the soil by their burrowing and add mucus that holds fine soil particles together. Meanwhile, the metabolism of bacteria alters the mineral composition of the soil. Plant roots can also affect soil composition and texture. For instance, they can affect soil pH by releasing organic acids, and they reinforce the soil against erosion.

Humus, an important component of topsoil, consists of decomposing organic material formed by the action of bacteria and fungi on dead organisms, feces, fallen leaves, and other organic refuse. Humus prevents clay from packing together and builds a crumbly soil that retains water but is still porous enough for the adequate aeration of roots. Humus is also a reservoir of mineral nutrients that are returned gradually to the soil as microorganisms decompose the organic matter.

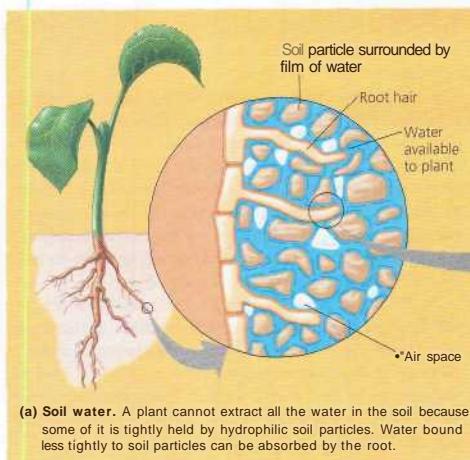

After a heavy rainfall, water drains away from the larger spaces of the soil, but smaller spaces retain water because of its attraction to the negatively charged surfaces of clay and other soil particles. Some water adheres so tightly to soil particles that it cannot be extracted by plants. The film of water bound less tightly to the particles is the water generally available to plants (**Figure 37.6a**). It is not pure water but a soil solution containing dissolved minerals in the form of ions. Roots absorb this soil solution.

To be available to roots, mineral ions must be released from the soil particles into the soil solution. Negatively charged ions (anions)—such as nitrate (NO_3^-), phosphate (H_2PO_4^-), and sulfate (SO_4^{2-})—are not bound tightly to

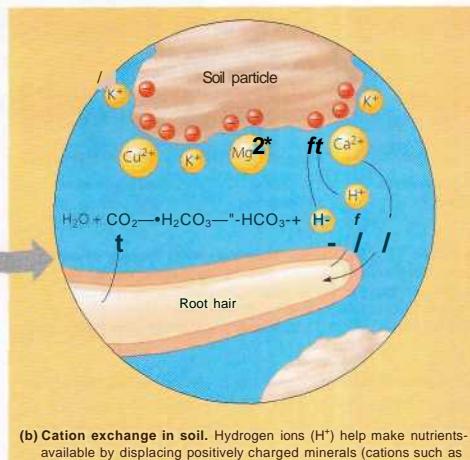

the negatively charged soil particles and are therefore easily released. However, during heavy rain or irrigation, they are leached (drained) quickly into the groundwater, making them less available for uptake by roots. Positively charged ions (cations)—such as potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+})—are less likely to be leached because they bind closely to soil particle surfaces. Mineral cations become available for absorption when they enter the soil solution after being displaced from soil particles by cations in the form of H^+ . This process, called cation exchange, is stimulated by the roots, which add H^+ to the soil solution (**Figure 37.6b**).

Soil Conservation and Sustainable Agriculture

It may take centuries for a soil to become fertile through the breakdown of rock and the accumulation of organic materials, but human mismanagement can destroy that fertility within a few years. Soil mismanagement has been a recurring problem in human history. For example, the Dust Bowl was an ecological and human disaster that took place in the southwestern Great Plains region of the United States in the 1930s. Before the arrival of farmers, the region was covered by hardy grasses that held the soil in place in spite of the long recurrent droughts and torrential rains characteristic of the region. However, in the late 1800s and early 1900s, many homesteaders settled in the region, planting wheat and raising cattle. These land uses left the topsoil exposed to erosion by winds that often sweep over the area. Bad luck in the form of a few years of drought made the problem worse. Much of the topsoil was blown away, rendering millions of hectares of

(a) Soil water. A plant cannot extract all the water in the soil because some of it is tightly held by hydrophilic soil particles. Water bound less tightly to soil particles can be absorbed by the root.

(b) Cation exchange in soil. Hydrogen ions (H^+) help make nutrients available by displacing positively charged minerals (cations such as Ca^{2+}) that were bound tightly to the surface of negatively charged soil particles. Plants contribute H^+ by secreting it from root hairs and also by cellular respiration, which releases CO_2 into the soil solution, where it reacts with H_2O to form carbonic acid (H_2CO_3). Dissociation of this acid adds H^+ to the soil solution.

▲ **Figure 37.6** The availability of soil water and minerals.

farmland useless and forcing hundreds of thousands of people to abandon homes and land, a plight immortalized in John Steinbeck's *The Grapes of Wrath*. Better soil conservation practices could have preserved soil fertility and sustained agricultural productivity.

To understand soil conservation, we must first remember that agriculture can only be sustained by human intervention. In forests, grasslands, and other natural ecosystems, mineral nutrients are usually recycled by the decomposition of dead organic material in the soil. In contrast, when farmers harvest a crop, essential elements are diverted from the chemical cycles going on in that location. In general, agriculture depletes the mineral content of the soil. To grow 1,000 kg of wheat grain, the soil gives up 20 kg of nitrogen, 4 kg of phosphorus, and 4.5 kg of potassium. Each year, the soil fertility diminishes unless fertilizers replace lost minerals such as nitrogen, phosphorus, and potassium. Many crops also use far more water than the vegetation that once grew naturally on that land, forcing farmers to irrigate. Prudent fertilization, thoughtful irrigation, and the prevention of erosion are three of the most important goals of soil conservation. Complementing soil conservation is soil reclamation, the goal of returning agricultural productivity to exhausted or damaged soil. More than 30% of the world's farmland suffers from low productivity stemming from poor

soil conditions such as chemical contamination, mineral deficiencies, acidity, salinity and poor drainage.

Fertilisers

Prehistoric farmers may have started fertilizing their fields after noticing that grass grew faster and greener where animals had defecated. In developed nations today, most farmers use commercially produced fertilizers containing minerals that are either mined or prepared by industrial processes. These fertilizers are usually enriched in nitrogen, phosphorus, and potassium, the macro nutrients most commonly deficient in farm and garden soils. Fertilizers are labeled with a three-number code called the N-P-K ratio, indicating the content of these minerals. A fertilizer marked "15-10-5," for instance, is 15% nitrogen (as ammonium or nitrate), 10% phosphorus (as phosphoric acid), and 5% potassium (as the mineral potash).

Manure, fishmeal, and compost are called "organic" fertilizers because they are of biological origin and contain decomposing organic material. Before plants can use organic material, however, it must be decomposed into the inorganic nutrients that roots can absorb. Whether from organic fertilizer or a chemical factory, the minerals a plant extracts are in the same form, but organic fertilizers release minerals gradually whereas minerals in

A Figure 37.7 Deficiency warnings from "smart" plants.

Some plants have been genetically modified to signal an impending nutrient deficiency before irreparable damage or stunting occurs. For example, after laboratory treatments, the research plant *Arabidopsis* develops a blue color in response to an imminent phosphate deficiency.

commercial fertilizers are immediately available but may not be retained by the soil for long. Excess minerals not absorbed by roots are usually wasted because they are often leached from the soil by rainwater or irrigation. To make matters worse, mineral runoff may pollute groundwater, streams, and lakes.

Agricultural researchers are developing ways to maintain crop yields while reducing fertilizer use. One approach is to genetically engineer "smart" plants that inform the grower when a nutrient deficiency is imminent—but *before* damage has occurred (**Figure 37.7**). One type of smart plant takes advantage of a promoter (a DNA sequence that indicates where to begin transcription) that more readily binds RNA polymerase (the enzyme that drives transcription) when the phosphorus content of plant tissues begins to decline. This promoter is linked to a reporter gene that leads to the production of a blue pigment in the leaf cells. When leaves of these smart plants develop a blue tinge, the farmer knows it is time to add phosphate-containing fertilizer.

To fertilize judiciously, a farmer must note the soil pH because it affects cation exchange and the chemical form of minerals. Although an essential element may be abundant, plants may be starving for that element because it is bound too tightly to clay particles or is in a chemical form the plant cannot absorb. Managing soil pH is tricky; a change in H⁺ concentration may make one mineral more available but make another less available. At pH 8, for instance, the plant can absorb calcium, but iron is almost completely unavailable. The soil pH should be matched to a crop's mineral needs. If the soil is too alkaline, adding sulfate will lower the pH. Soil that is too acidic can be adjusted by liming (adding calcium carbonate or calcium hydroxide).

A major problem with acidic soils, particularly in tropical areas, is that aluminum dissolves at low pH and becomes toxic to roots. Some plants cope with high aluminum levels by secreting organic amons that bind the aluminum and render it harmless.

Irrigation

Water is most often the limiting factor in plant growth. **Irrigation** can transform a desert into a garden, but farming in arid regions is a huge drain on water resources. Many rivers in the southwestern United States have been reduced to trickles by diversion of water for irrigation. Another problem is that irrigation in an arid region can gradually make the soil so salty that it may become completely infertile. Salts dissolved in irrigation water accumulate in the soil as the water evaporates, making the water potential of the soil solution more negative, thereby reducing water uptake by lowering the water-potential gradient from soil to roots (see Chapter 36).

As the world population grows, more and more acres of arid land are being cultivated. New irrigation methods may reduce the risks of running out of water or losing farmland to salinization (salt accumulation). Drip irrigation is used for many crops in the western United States, resulting in less evaporation. In another approach, plant breeders are developing plant varieties that require less water.

Erosion

Topsoil from thousands of acres of farmland is lost to water and wind erosion each year in the United States alone. Certain precautions, such as planting rows of trees as windbreaks, terracing hillside crops, and cultivating in a contour pattern, can prevent loss of topsoil (**Figure 37.8**). Crops such as alfalfa and wheat provide good ground cover and protect the soil better than maize and other crops that are usually planted in more widely spaced rows.

If managed properly, soil is a renewable resource in which farmers can grow food for many generations. The goal of soil management is **sustainable agriculture**, a commitment embracing a variety of farming methods that are conservation-minded, environmentally safe, and profitable.

Figure 37.8 Contour tillage. These crops in Wisconsin are planted in rows that go around—rather than up and down—the hills. Contour tillage helps slow the runoff of water and erosion of topsoil after heavy rains.

Sod Reclamation

Some areas are unfit for agriculture because of contamination of soil or groundwater with toxic heavy metals or organic pollutants. Traditionally, soil reclamation has focused on non-biological technologies, such as removal and storage of contaminated soil in landfills, but these techniques are very costly and often disrupt the landscape. A new method known as phytoremediation is a biological, nondestructive technology that seeks to reclaim contaminated areas cheaply by using the remarkable ability of some plants to extract soil pollutants and concentrate them in portions of the plant that can be easily removed for safe disposal. For example, alpine pennycress (*Thlaspi caerulescens*) can accumulate zinc in its shoots at concentrations 300 times higher than most plants can tolerate. Such plants show promise for cleaning up areas contaminated by smelters, mining operations, or nuclear testing. Phytoremediation is part of the more general technology of bioremediation, which includes the use of prokaryotes and sometimes protists to detoxify polluted sites (see Chapters 27 and 55).

Concept 37.3

Nitrogen is often the mineral that has the greatest effect on plant growth

Of all the mineral nutrients, nitrogen contributes the most to plant growth and crop yields. Plants require nitrogen as a component of proteins, nucleic acids, chlorophyll, and other important organic molecules.

Soil Bacteria and Nitrogen Availability

It is ironic that plants can suffer nitrogen deficiencies, for the atmosphere is nearly 80% nitrogen. However, this atmospheric nitrogen is gaseous N_2 , a form plants cannot use. For plants to absorb nitrogen, it must first be converted to ammonium (NH_4^+) or nitrate (NO_3^-).

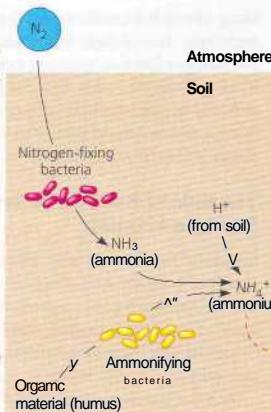

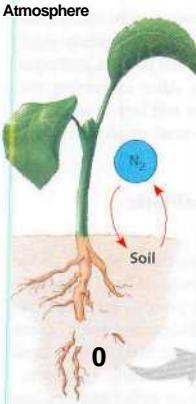

In contrast to other minerals, the NH_4^+ and NO_3^- in soil are not derived from the breakdown of rock. Over the short term, the main source of these minerals is the decomposition of humus by microbes, including ammonifying bacteria (Figure 37.9). Through decomposition, the nitrogen in proteins and other organic compounds is repackaged in inorganic compounds that are recycled when absorbed as minerals by roots. Some nitrogen is lost when soil microbes called denitrifying bacteria convert NO_3^- to N_2 , which diffuses from the soil into the atmosphere. However, other bacteria called

2. "Explain how the phrase "too much of a good thing" can apply to watering and fertilizing plants.

For suggested answers, see Appendix A.

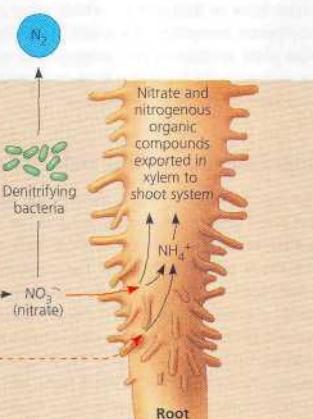

Atmosphere

4 Figure 37.9 The role of soil bacteria in the nitrogen nutrition of plants.

Ammonium is made available to plants by two types of soil bacteria: those that fix atmospheric N_2 (nitrogen-fixing bacteria) and those that

decompose organic material (ammonifying bacteria). Although plants absorb some ammonium from the soil, they absorb mainly nitrate, which is produced from ammonium by nitrifying bacteria. Plants reduce nitrate back to

ammonium before incorporating the nitrogen into organic compounds. Xylem transports nitrogen from roots to shoots in the form of nitrate, amino acids, and various other organic compounds, depending on the species.

nitrogen-fixing bacteria restock nitrogenous minerals in the soil by converting N₂ from the atmosphere to NH₃ (ammonia), in a metabolic process called nitrogen fixation. The complex cycling of nitrogen in ecosystems is traced in detail in Chapter 54. Here we focus on nitrogen fixation and the other steps that lead directly to nitrogen assimilation by plants.

All life on Earth depends on nitrogen fixation, a process performed only by some bacterial species. Several of these species live freely in the soil, while others live in plant roots in symbiotic relationships. (You will learn more about these relationships in the next section.) The conversion of atmospheric nitrogen (N₂) to ammonia (NH₃) is a complicated, multistep process, but we can simplify nitrogen fixation by just indicating the reactants and products:

The enzyme complex nitrogenase catalyzes the entire reaction sequence, which reduces N₂ to NH₃ by adding electrons along with FT. Notice that nitrogen fixation is very expensive in terms of metabolic energy, costing the bacteria eight ATP molecules for each ammonia molecule synthesized. Nitrogen-fixing bacteria are therefore most abundant in soils rich in organic material, which provides fuel for cellular respiration to produce the AT&R.

In the soil solution, ammonia picks up another hydrogen ion to form an ammonium ion (NH₄⁺), which plants can absorb. However, plants acquire their nitrogen mainly in the form of nitrate (NO₃⁻), which is produced in the soil by nitrifying bacteria that oxidize ammonium (see Figure 37.9). After nitrate is absorbed by the roots, a plant enzyme can reduce the nitrate back to ammonium, which other enzymes can then incorporate into amino acids and other organic compounds. Most plant species export nitrogen from roots to shoots, via the xylem, in the form of nitrate or organic compounds that have been synthesized in the roots.

Improving the Protein Yield of Crops

The incorporation of fixed nitrogen by plants into proteins and other organic substances has a major impact on human welfare because the most common form of malnutrition in humans is protein deficiency. The majority of people in the world, particularly in developing countries, have a predominantly vegetarian diet and thus depend mainly on plants for protein. Unfortunately many plants have a low protein content, and those proteins may be deficient in one or more amino acids that humans need from their diet (see Figure 41.10). Improving the quality and quantity of proteins in crops is a major goal of agricultural research.

Plant breeding has resulted in new varieties of maize, wheat, and rice that are enriched in protein. However, many of these "super" varieties have an extraordinary demand for nitrogen, usually supplied in commercial fertilizer. Like

biological nitrogen fixation, industrial production of ammonia and nitrate from atmospheric nitrogen consumes a lot of energy. A chemical factory making fertilizer consumes large quantities of fossil fuels. The countries that most need high-protein crops are usually the ones least able to pay the fuel bill. In the future, new catalysts based on the mechanism by which nitrogenase fixes nitrogen may make commercial fertilizer production less costly. Several years ago, biochemists determined the structure of nitrogenase in *Rhizobium*, a genus of nitrogen-fixing bacteria, providing a model for chemical engineers to design catalysts by imitating nature. Another strategy that could potentially increase protein yields of crops is to improve the productivity of symbiotic nitrogen fixation, a process examined in the next section.

Concept Check 37.3

- Explain why nitrogen-fixing bacteria are essential to human welfare.

For suggested answer, see Appendix A.

Concept 37.4

Plant nutritional adaptations often involve relationships with other organisms

Many plants have nutritional adaptations that involve other organisms. Two of these relationships are mutualistic: symbiotic nitrogen fixation, involving roots and bacteria, and mycorrhizae, involving roots and fungi. After examining these mutually beneficial relationships, we will look at adaptations that are one-sided and relatively unusual: epiphytes, parasitic plants, and carnivorous plants.

The Role of Bacteria in Symbiotic Nitrogen Fixation

Symbiotic relationships with nitrogen-fixing bacteria provide some plant species with a built-in source of fixed nitrogen for assimilation into organic compounds. From an agricultural perspective, the most important and efficient symbioses between nitrogen-fixing bacteria and plants occur in the legume family, including peas, beans, soybeans, peanuts, alfalfa, and clover.

Along a legume's roots are swellings called nodules composed of plant cells that have been "infected" by nitrogen-fixing *Rhizobium* ("root living") bacteria (Figure 37.10a). Inside the nodule, *Rhizobium* bacteria assume a form called bacteroids, which are contained within vesicles formed by the root cell (Figure 37.10b). *Rhizobium* bacteria can fix atmospheric N₂.

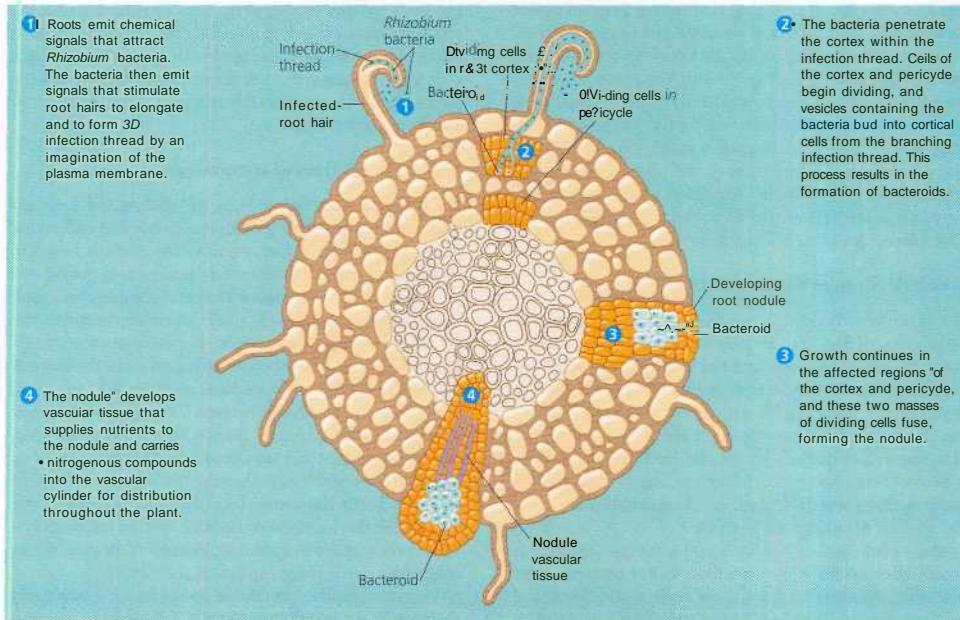

(a) Pea plant root. The bumps on this pea plant root are nodules containing *Rhizobium* bacteria. The bacteria fix nitrogen and obtain photosynthetic products supplied by the plant.

(b) Bacteroids in a soybean root nodule. In this TEM, a cell from a root nodule of soybean is filled with bacteroids in vesicles. The cells on the left are uninfected.

▲ Figure 37.10 Root nodules on legumes.

▲ Figure 37.11 Development of a soybean root nodule.

and supply it as ammonium, a form readily used by the plant (see Figure 37.9). *Legume-Rhizobium* symbioses generate more useful nitrogen for plants than all industrial fertilizers, and the symbiosis provides the right amounts of nitrogen at the right time at virtually no cost to the farmer. In addition to supplying the legume with nitrogen, symbiotic nitrogen fixation significantly reduces spending on fertilizers for subsequent crops.

The location of the bacteroids inside living, nonphotosynthetic cells favors nitrogen fixation, which requires an anaerobic environment. Lignified external layers may also limit gas exchange. Some root nodules are reddish, owing to a molecule called leghemoglobin (leg- for "legume"), an iron-containing protein that binds reversibly to oxygen (like the hemoglobin of human red blood cells). This protein is an oxygen "buffer," keeping the concentration of free O₂ low and regulating the oxygen supply for the intense respiration that the bacteria require to produce ATP for nitrogen fixation.

Each legume is associated with a particular strain of *Rhizobium*. Figure 37.11 describes how a root nodule develops after bacteria enter through what is called an infection thread. The symbiotic relationship between a legume and nitrogen-fixing bacteria is mutualistic because the bacteria supply the plant

with fixed nitrogen while the plant provides the bacteria with carbohydrates and other organic compounds. Most of the ammonium produced by symbiotic nitrogen fixation is used by the nodules to make amino acids, which are then transported to the shoot via the xylem.

The Molecular Biology of Root Nodule Formation

How does a legume species recognize a certain strain of *Rhizobium* among the many bacterial strains in the soil? And how does an encounter with that specific *Rhizobium* lead to development of a nodule? These two questions have led researchers to uncover a chemical dialogue between the bacteria and the root. Each partner responds to the chemical signals from the other by expressing certain genes whose products contribute to nodule formation.

The plant initiates the communication when its roots secrete molecules called flavonoids, which enter *Rhizobium* cells living near the roots. The signal's specificity arises from variations in flavonoid structure, with a particular legume species secreting a flavonoid that only a certain *Rhizobium* strain detects and absorbs. The plant's signal activates a gene-regulating protein in the bacterium, which switches on a cluster of bacterial genes called *nod*, for "nodulation" genes. These *nod* genes produce enzymes that catalyze production of species-specific molecules called Nod factors. Secreted by the bacterial cells, the Nod factors signal the root to initiate the infection process that enables the *Rhizobium* to enter the root and to begin forming the root nodule. The plant's responses require activation of genes called early nodulin genes by a signal transduction pathway involving Ca^{2+} as second messengers (see Chapter 11). By understanding the molecular biology underlying the formation of root nodules, researchers hope to learn how to induce *Rhizobium* uptake and nodule formation in crop plants that do not normally form such nitrogen-fixing symbiotic relationships.

Symbiotic Nitrogen Fixation and Agriculture

The agricultural benefits of symbiotic nitrogen fixation underlie crop rotation. In this practice, a non-legume such as maize is planted one year, and the following year alfalfa or some other legume is planted to restore the concentration of fixed nitrogen in the soil. To ensure that the legume encounters its specific *Rhizobium*, the seeds are soaked in a culture of the bacteria or dusted with bacterial spores before sowing. Instead of being harvested, the legume crop is often plowed under so that it will decompose as "green manure," reducing the need for manufactured fertilizers.

Many plant families besides legumes include species that benefit from symbiotic nitrogen fixation. For example, alder trees and certain tropical grasses host gram-positive bacteria of the actinomycetes group (see Figure 27.13). Rice, a crop of great commercial importance, benefits indirectly from symbiotic

nitrogen fixation. Rice farmers culture a free-floating aquatic fern called *Azolla*, which has symbiotic cyanobacteria that fix nitrogen and increase the fertility of the rice paddy. The growing rice eventually shades and kills the *Azolla*, and decomposition of this organic material adds more nitrogenous compounds to the paddy.

Mycorrhizae and Plant Nutrition

Mycorrhizae ("fungus roots") are modified roots consisting of mutualistic associations of fungi and roots (see Figures 31.1p and 36.10). The fungus benefits from a steady supply of sugar donated by the host plant. In return, the fungus increases the surface area for water uptake and selectively absorbs phosphate and other minerals from the soil and supplies them to the plant. The fungi of mycorrhizae also secrete growth factors that stimulate roots to grow and branch, as well as antibiotics that may help protect the plant from pathogenic bacteria and fungi, in the soil.

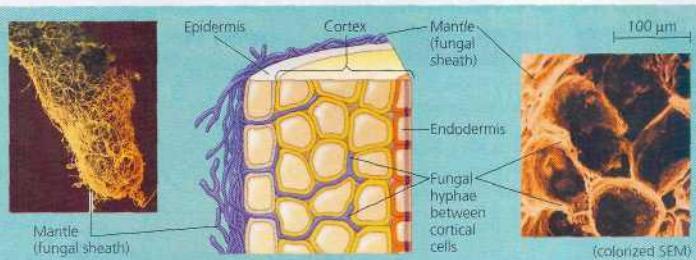

Mycorrhizae are not oddities; they are formed by most plant species. In fact, this plant-fungus symbiosis might have been one of the evolutionary adaptations that made it possible for plants to colonize land in the first place. Indeed, fossilized roots from some of the earliest plants include mycorrhizae. When terrestrial ecosystems were young, the soil was probably not very rich in nutrients. The fungi of mycorrhizae, which are more efficient at absorbing minerals than the roots themselves, would have helped nourish the pioneering plants. Even today, the plants that first became established on nutrient-poor soils, such as abandoned farmland or eroded hillsides, are usually mycorrhizae-rich.

The Two Main Types of Mycorrhizae

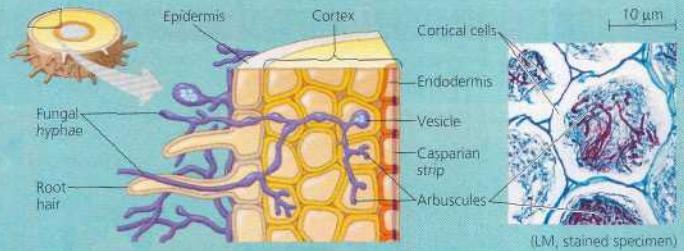

The modified roots formed from the symbiosis of fungi and plants take two major forms: ectomycorrhizae and endomycorrhizae. In ectomycorrhizae, the mycelium (mass of branching hyphae; see Chapter 31) forms a dense sheath, or mantle, over the surface of the root (Figure 37.12a). Fungal hyphae extend from the mantle into the soil, greatly increasing the surface area for water and mineral absorption. Hyphae also grow into the cortex of the root. These hyphae do not penetrate the root cell; but form a network in the apoplast, or extracellular space, that facilitates nutrient exchange between the fungus and the plant. Compared with "uninfected" roots, ectomycorrhizae are generally thicker, shorter, and more branched. They typically do not form root hairs, which would be superfluous given the extensive surface area of the fungal mycelium. About 10% of plant families have species that form ectomycorrhizae, and the vast majority of these species are woody, including members of the pine, spruce oak, walnut, birch, willow, and eucalyptus families.

In contrast, endomycorrhizae do not have a dense mantle ensheathing the root (Figure 37.12b). A microscope is needed to see the fine fungal hyphae that extend from the soil into the

(3) Ectomycorrhizae. The mantle of the fungal mycelium ensheathes the root, fungal hyphae extend from the mantle into the soil, absorbing water and minerals, especially phosphate. Hyphae also extend into the extracellular spaces of the root cortex, providing extensive surface area for nutrient exchange between the fungus and its host plant.

(h) Endomycorrhizae. No mantle forms around the root, but microscopic fungal hyphae extend into the root. Within the root cortex, the fungus makes extensive contact with the plant through branching of hyphae that form arbuscules, providing an enormous surface area for nutrient swapping. The hyphae penetrate the cell walls, but not the plasma membranes, of cells within the cortex.

i. **Figure 37.12 Mycorrhizae.**

root. Hyphae also extend into the root cells (hence the term endomycorrhizae) by digesting small patches of the root cell walls. However, a fungal hypha does not actually pierce the plasma membrane and enter the root cell's cytoplasm. Instead, it grows into a tube formed by imagination of the root cell's membrane. The action is analogous to poking a finger gently into a balloon; your finger is like the fungal hypha, and the balloon skin is like the root cell's membrane. After the fungal hyphae have penetrated in this way, some form densely branched structures called arbuscules ("little trees"), which are important sites of nutrient transfer between the fungus and the plant. Hyphae may also form oval vesicles, which possibly store food for the fungus. To the unaided eye, endomycorrhizae look like "normal" roots with root hairs, but a microscope reveals a symbiotic relationship of enormous importance to plant nutrition. Endomycorrhizae are much more common than ectomycorrhizae and are found in over 85% of plant species, including important crop plants such as maize, wheat, and legumes.

Agricultural Importance of Mycorrhizae

Roots can be transformed into mycorrhizae only if exposed to the appropriate species of fungus. In most natural ecosystems, these fungi are present in the soil, and seedlings develop mycorrhizae. But if seeds are collected in one environment and planted in foreign soil, the plants may show signs of malnutri-

tion (particularly phosphorus deficiency) resulting from absence of the plants' mycorrhizal partners. Researchers observe similar results in experiments in which soil fungi are poisoned. Farmers and foresters are already applying the lessons of such research. For example, inoculating pine seeds with spores of mycorrhizal fungi promotes formation of mycorrhizae by the seedlings. Infected pine seedlings grow more vigorously than trees without the fungal association.

Epiphytes, Parasitic Plants, and Carnivorous Plants

Almost all plant species have mutualistic relationships with fungi, bacteria, or both. Though rarer, there are also plant species with nutritional adaptations that use other organisms in nonmutualistic ways. **Figure 37.13**, on the next page, provides an overview of three unusual adaptations: epiphytes, parasitic plants, and carnivorous plants.

Concept Check 37.4

1. Compare and contrast root nodules and mycorrhizae.
2. Contrast epiphytes with parasitic plants.

For suggested answers, see Appendix A.

Figure 37.13

Exploring Unusual Nutritional Adaptations in Plants

EPIPHYTES

An epiphyte (from the Greek *epi*, upon, and *phyton*, plant) nourishes itself but grows on another plant, usually anchored to branches or trunks of living trees. Epiphytes absorb water and minerals from rain, mostly through leaves rather than roots. Some examples are staghorn ferns and many orchids.

Staghorn fern, an epiphyte. This tropical fern (genus *Platycerium*) grows on large rocks, cliffs, and trees. It has two types of fronds: branched fronds resembling antlers and circular fronds that form a collar around the base of the fern.

PARASITIC PLANTS

Unlike epiphytes, parasitic plants absorb sugars and minerals from their living hosts, although some parasitic species are photosynthetic.

Mistletoe, a photosynthetic parasite. Tacked above doorways during the holiday season, mistletoe (genus *Phoradendron*) lives in nature as a parasite on oaks and other trees.

Dodder, a nonphotosynthetic parasite. Dodder (genus *Cuscuta*), the orange "strings" on this pickleweed, draws its nutrients from the host. The transverse section shows a haustorium tapping the host's phloem (LM).

Indian pipe, a nonphotosynthetic parasite. Also called the ghost flower, this species (*Monotropa uniflora*) absorbs nutrients from the fungal hyphae of mycorrhizae of green plants.

CARNIVOROUS PLANTS

Carnivorous plants are photosynthetic but obtain some nitrogen and minerals by killing and digesting insects and other small animals.

Venus' flytrap. Triggered by electrical impulses from sensory hairs, two leaf lobes close in half a second. Despite its common name, *Dionaea muscipula* usually catches ants and grasshoppers.

Pitcher plants. *Nepenthes*, *Sarracenia*, and other genera have water-filled funnels. The insects drown and are digested by enzymes.

Sundews. Sundews (genus *Drosera*) exude a sticky fluid that glitters like dew. Insects get stuck to the leaf hairs, which enfold the prey.

SUMMARY OF KEY CONCEPTS

Concept 37.1

Plants require certain chemical elements to complete their life cycle

- Plants derive most of their organic mass from the CO_2 of air, but they also depend on soil nutrients in the form of water and minerals. The branching of root and shoot systems helps plants come into contact with the resources that they need from the environment (pp. 756–757).

Macronutrients and Micronutrients (pp. 757–758)

Macronutrients, elements required in relatively large amounts, include carbon, oxygen, hydrogen, nitrogen, and other major ingredients of organic compounds. Micronutrients, elements required in very small amounts, typically have catalytic functions as cofactors of enzymes.

Symptoms of Mineral Deficiency (pp. 758–759)

Deficiency of a mobile nutrient usually affects older organs more than younger ones; the reverse is true for nutrients that are less mobile within a plant. Macronutrient deficiencies are most common, particularly deficiencies of nitrogen, phosphorus, and potassium.

Concept 37.2

Soil quality is a major determinant of plant distribution and growth

- Texture and Composition of Soils (pp. 759–760) Various sizes of particles derived from the breakdown of rock are found in soil, along with organic material (humus) in various stages of decomposition. Acids derived from roots contribute to a plant's uptake of minerals when H^+ displaces mineral cations from clay particles.

Activity How Plants Obtain Minerals from Soil

Investigation How Does Acid Precipitation Affect Mineral Deficiency?

Soil Conservation and Sustainable Agriculture

- (pp. 760–763) In contrast to natural ecosystems, agriculture depletes the mineral content of soil, taxes water reserves, and encourages erosion. The goal of soil conservation strategies is to minimize this damage. A major goal of agricultural researchers is to reduce the amounts of fertilizer added to soils without sacrificing high crop yields.

Graph It Global Soil Degradation

Concept 37.3

Nitrogen is often the mineral that has the greatest effect on plant growth

Soil Bacteria and Nitrogen Availability (pp. 763–764)

Nitrogen-fixing bacteria convert atmospheric N_2 to nitrogenous minerals that plants can absorb as a nitrogen source for organic synthesis.

Activity The Nitrogen Cycle

- Improving the Protein Yield of Crops (p. 764) Such research addresses the most widespread form of human malnutrition: protein deficiency

Concept 37.4

Plant nutritional adaptations often involve relationships with other organisms

- The Role of Bacteria in Symbiotic Nitrogen Fixation (pp. 764–766) The development of nitrogen-fixing root nodules depends on chemical dialogue between *Rhizobium* bacteria and root cells of their specific plant hosts. The bacteria of a nodule obtain sugar from the plant and supply the plant with fixed nitrogen.

Mycorrhizae and Plant Nutrition (pp. 766–767)

Mycorrhizae are modified roots consisting of mutualistic associations of fungi and roots. The fungal hyphae of both ectomycorrhizae and endomycorrhizae absorb water and minerals, which they supply to their plant hosts.

Epiphytes, Parasitic Plants, and Carnivorous Plants

(pp. 767–768) Epiphytes grow on the surfaces of other plants but acquire water and minerals from rain. Parasitic plants absorb nutrients from host plants. Carnivorous plants supplement their mineral nutrition by digesting animals.

TESTING YOUR KNOWLEDGE

Evolution Connection

Imagine taking the plants out of the picture in Figure 37.9. Write a paragraph explaining how the soil bacteria could sustain the recycling of nitrogen *before* land plants evolved.

Scientific Inquiry

Acid precipitation contains an abnormally high concentration of hydrogen ions (H^+). One effect of acid precipitation is to deplete the soil of plant nutrients such as calcium (Ca^{2+}), potassium (K^+), and magnesium (Mg^{2+}). Suggest a hypothesis to explain how acid precipitation washes these nutrients from the soil. How might you test your hypothesis?

Investigation How Does Acid Precipitation Affect Mineral Deficiency?

Science, Technology, and Society

About 10% of U.S. cropland is irrigated. Agriculture is by far the biggest user of water in arid western states, including Colorado, Arizona, and California. The populations of these states are growing, and there is an ongoing conflict between cities and farm regions over water. To ensure adequate water supplies for urban growth, cities are purchasing water rights from farmers. This is often the least expensive way for a city to obtain more water, and it is possible for some farmers to make more money selling water rights than growing crops. Discuss the possible consequences of this trend. Is this the best way to allocate water for all concerned? Why or why not?

C8 Angiosperm Reproduction and Biotechnology

A Figure 38.1 *Rafflesia arnoldii*, "monster flower" of Indonesia.

Overview

To Seed or Not to Seed

The parasitic plant *Rafflesia arnoldii*, found only in Southeast Asia, spends most of its life invisible to passersby, growing within the woody tissue of a host vine. The plant makes its presence known in a spectacular fashion by producing a cabbage-sized floral bud that eventually develops into a gigantic (lower the size of an automobile tire) (**Figure 38.1**). With an odor reminiscent of a decaying corpse, the flower attracts carrion flies that shuttle the pollen from one flower to another. A few days after opening, the flower collapses and shrivels, its function completed. A single female flower may produce up to 4 million seeds. However, sexual reproduction, as in *Rafflesia*, is not the only means by which flowering plants (angiosperms) reproduce. Many species also reproduce asexually, creating offspring that are genetically identical to the parent.

The propagation of flowering plants by sexual and asexual reproduction forms the basis of agriculture. Since the dawn of agriculture about 10,000 years ago, plant breeders have genetically manipulated the traits of a few hundred wild angiosperm

species by artificial selection, transforming them into the crops we cultivate today. The speed and extent of plant modification have increased dramatically in recent decades with the advent of genetic engineering.

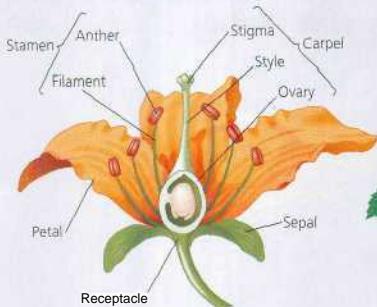

In Chapters 29 and 30, we approached plant reproduction from an evolutionary perspective, tracing the descent of angiosperms and other land plants from their algal ancestors; in this chapter, we will explore the reproductive biology of flowering plants in much greater detail because they are the most important group of plants in most terrestrial ecosystems and in agriculture. After discussing the sexual and asexual reproduction of angiosperms, we will then examine modern plant biotechnology and the role of humans in the genetic alteration of crop species.

Concept 38.1

Pollination enables gametes to come together within a flower

Recall from Chapters 29 and 30 that the life cycles of plants are characterized by an alternation of generations, in which haploid (n) and diploid (2n) generations take turns producing each other (see Figures 29.5 and 30.10). The diploid plant, which is the sporophyte, produces haploid spores by meiosis. These spores divide by mitosis, giving rise to the gametophytes, the small male and female haploid plants that produce gametes (sperm and eggs). Fertilization results in diploid zygotes, which divide by mitosis and form new sporophytes.

In angiosperms, the sporophyte is the dominant generation in the sense that it is the largest, most conspicuous, and longest-living plant we see. Over the course of seed plant

A Figure 38.2 An overview of angiosperm reproduction.

evolution, gametophytes became reduced in size and wholly dependent on the sporophyte generation for nutrients. Angiosperm gametophytes are the most reduced of all plants, consisting of only a few cells. Angiosperm sporophytes develop a unique reproductive structure—the flower.

Figure 38.2 reviews the angiosperm life cycle, which is shown in more detail in Figure 30.10. Male and female gametophytes develop within the anthers and ovules, respectively. Pollination by wind, water, or animals brings a pollen grain containing a male gametophyte to the stigma of a flower. Pollen germination brings sperm produced by the male gametophyte to a female gametophyte contained in an ovule embedded in the ovary of a flower. Union of egg and sperm (fertilization) takes place within each ovule in the ovary. Ovules develop into seeds, while the ovary itself becomes a fruit (another unique structure of the angiosperms). In this section, we will focus on the role of the flower in gametophyte development and the process of pollination.

Flower Structure

Flowers, the reproductive shoots of the angiosperm sporophyte, are typically composed of four whorls of highly modified leaves called floral organs, which are separated by very short internodes. Unlike vegetative shoots, which grow inde-

termately, flowers are determinate shoots, meaning that they cease growing after the flower and fruit are formed.

Floral organs—sepals, petals, stamens, and carpels—are attached to a part of the stem called the receptacle. Stamens and carpels are reproductive organs, whereas sepals and petals are sterile. Sepals, which enclose and protect the floral bud before it opens, are usually green and more leaflike in appearance than the other floral organs. In many species, petals are more brightly colored than sepals and advertise the flower to insects and other pollinators.

A stamen consists of a stalk called the filament and a terminal structure called the anther; within the anther are chambers called pollen sacs, in which pollen is produced. A carpel has an ovary at its base and a long, slender neck called the style. At the top of the style is a sticky structure called the stigma that serves as a landing platform for pollen. Within the ovary are one or more ovules, with the number depending on the species. The flower shown in Figure 38.2 has a single carpel, but the flowers of many species have multiple carpels. In most species, two or more carpels are fused into a single structure; the result is an ovary with two or more chambers, each containing one or more ovules. The term pistil is sometimes used to refer to a single carpel or to a group of fused carpels. **Figure 38.3** shows examples of variations in floral structure that have evolved during the 140 million years of angiosperm history.

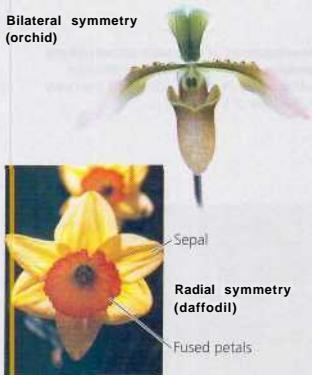

Chapter 30 focused on general characteristics of angiosperms (see Figure 30.12). Here we look at some differences in floral traits. Depending on the species, flowers can vary in the presence or absence of sepals, petals, stamens, or carpels. Complete flowers have all four basic floral organs (see Figure 38.2a). Incomplete flowers lack

one or more of these organs. For example, most grass flowers lack petals. Some incomplete flowers are sterile, lacking functional stamens and carpels. Flowers also vary in size, shape, color, odor, and arrangement of floral organs. Much of this diversity represents adaptation to specific groups of pollinators (see Figure 30.13).

SYMMETRY

Flowers can differ in symmetry. In bilateral symmetry, the flower can be divided into two equal parts by a single imaginary line. In radial symmetry, the sepals, petals, stamens, and carpels radiate out from a center. Floral organs can also be either fused or separate. For instance, daffodil petals are fused into a funnel.

Bilateral symmetry (orchid)

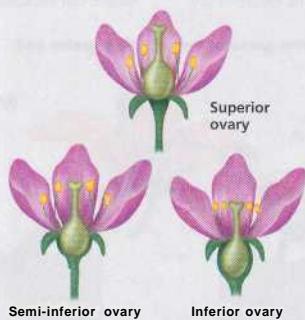

Radial symmetry (daffodil)

OVARY LOCATION

The location of the ovary may vary in relation to the stamens, petals, and sepals. An ovary is called superior if those parts are attached below it, semi-inferior if they are attached alongside it, and inferior if they are attached above it.

FLORAL DISTRIBUTION

Floral distribution can also differ. Some species have individual flowers, while others have clusters called inflorescences.

Lupine inflorescence

Sunflower inflorescence. A sunflower's central disk actually consists of hundreds of tiny incomplete flowers. What look like petals are actually sterile flowers.

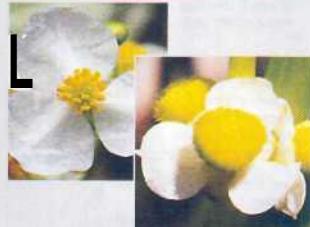

REPRODUCTIVE VARIATIONS

Most species have a single type of flower that has functional stamens and carpels. All complete flowers and some incomplete flowers have functional stamens and carpels. In most incomplete flowers, stamens or carpels are either absent or nonfunctional. Incomplete flowers that have only functional stamens are called staminate, and those with only functional carpels are called carpellate. If staminate and carpellate flowers are on the same plant, the species is said to be monoecious (from the Greek word meaning "one house"). A dioecious ("two houses") species has staminate flowers and carpellate flowers on separate plants.

Maize, a monoecious species. A maize "ear" (left) consists of kernels (one-seeded fruits) that develop from an inflorescence of fertilized carpellate flowers. Each kernel is derived from a single flower. Each "silk" strand consists of a stigma and long style. The tassels (right) are staminate inflorescences.

Dioecious *Sagittaria latifolia* (common arrowhead). The staminate flower (left) lacks carpels, and the carpellate flower (right) lacks stamens. Having these two types of flowers on separate plants reduces inbreeding.

Gametophyte Development and Pollination

Anthers and ovules bear sporangia, structures where spores are produced by meiosis and gametophytes develop. Pollen grains, each consisting of a mature male gametophyte surrounded by a spore wall, are formed within pollen sacs (microsporangia) of anthers. An egg-producing female gametophyte, or embryo sac, forms within each ovule.

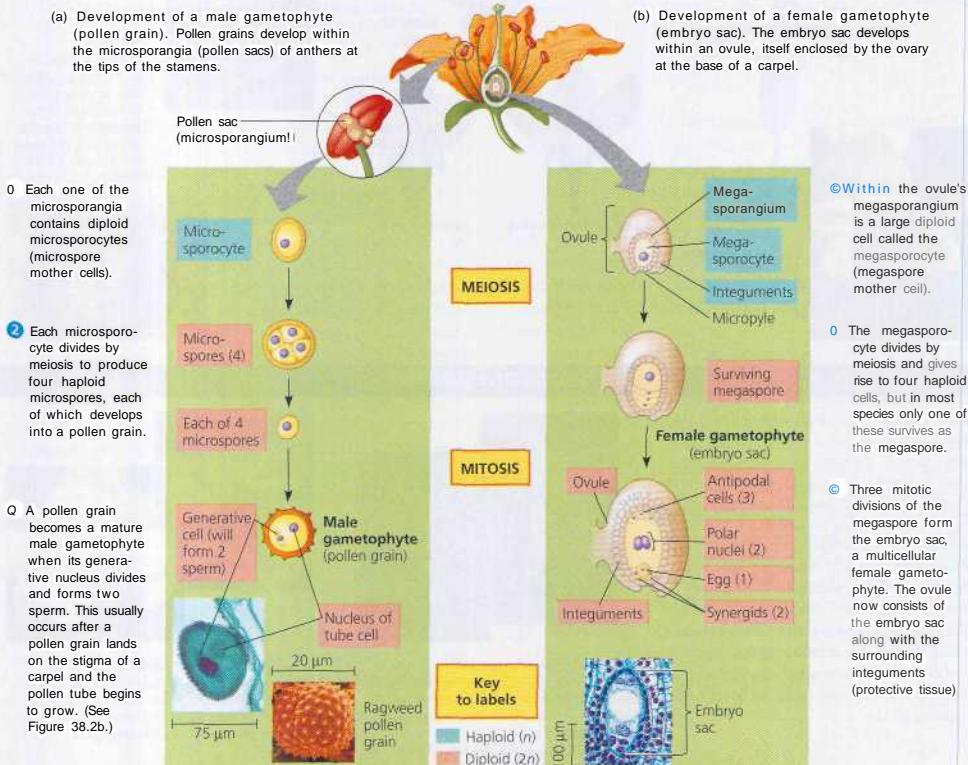

In angiosperms, pollination is the transfer of pollen from an anther to a stigma. If pollination is successful, a pollen grain produces a structure called a pollen tube, which grows and digests its way down into the ovary via the style and discharges sperm in the vicinity of the embryo sac, resulting in fertilization of the egg (see Figure 38.2b). The zygote gives rise to an embryo, and as the embryo grows, the ovule that contains it develops into a seed. The entire ovary,

meanwhile, develops into a fruit containing one or more seeds, depending on the species. Fruits, which disperse by dropping to the ground or being carried by wind or animals, help spread seeds some distance from their source plants. When light, soil, and temperature conditions are suitable, seeds germinate and the embryo carried in the seed grows and develops into a seedling.

We will now look more closely at the development of angiosperm gametophytes and the process of pollination. Keep in mind, however, that there are many variations in the details of these processes, depending on the species.

Within the microsporangia (pollen sacs) of an anther are many diploid cells called microsporocytes, also known as microspore mother cells (Figure 38.4a). Each microsporocyte undergoes meiosis, forming four haploid microspores, each of which can eventually give rise to a haploid male gametophyte

• Figure 38.4 The development of angiosperm gametophytes (pollen grains and embryo sacs).

A microspore undergoes mitosis and cytokinesis, producing two separate cells called the generative cell and tube cell. Together, these two cells and the spore wall constitute a pollen grain, which at this stage of its development is an immature male gametophyte. The spore wall usually exhibits an elaborate pattern unique to the particular plant species. During maturation of the male gametophyte, the generative cell passes into the tube cell. The tube cell now has a completely free-standing cell inside it (the generative cell). The tube cell produces the pollen tube, a structure essential for sperm delivery to the egg. During elongation of the pollen tube, the generative cell usually divides and produces two sperm cells, which remain inside the tube cell (see Figure 30.10). The pollen tube grows through the long style of the carpel and into the ovary, where it then releases the sperm cells in the vicinity of an embryo sac.

One or more ovules, each containing a megasporangium, form within the chambers of the ovary (Figure 38.4b). One cell in the megasporangium of each ovule, the megasporocyte (or megaspore mother cell), grows and then goes through meiosis, producing four haploid megasporocytes.

The details of the next steps vary extensively, depending on the species. In most angiosperm species, only one megasporocyte survives. This megasporocyte continues to grow, and its nucleus divides by mitosis three times without cytokinesis, resulting in one large cell with eight haploid nuclei. Membranes then partition this mass into a multicellular female gametophyte—the embryo sac. At one end of the embryo sac are three cells: the egg cell and two cells called synergids. The synergids flank the egg cell and function in the attraction and guidance of the pollen tube to the embryo sac. At the opposite end of the embryo sac are three antipodal cells of unknown function. The retaining two nuclei, called polar nuclei, are not partitioned into separate cells but instead share the cytoplasm of the large central cell of the embryo sac. The ovule, which will eventually become a seed, now consists of the embryo sac and two surrounding integuments (layers of protective sporophytic tissue that eventually develop into the seed coat).

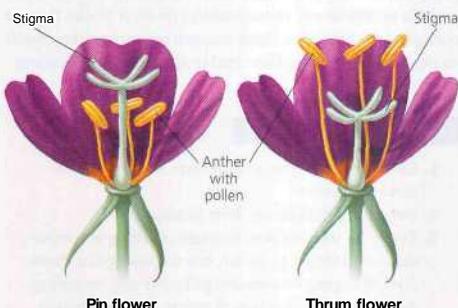

Pollination, the transfer of pollen from anther to stigma, is the first step in a chain of events that can lead to fertilization. This step is accomplished in various ways. In some angiosperms, including grasses and many trees, wind is a pollinating agent. In such plants, the release of enormous quantities of pollen compensates for the randomness of this dispersal mechanism. At certain times of the year the air is loaded with pollen grains, as anyone plagued with pollen allergies can attest. Some aquatic plants rely on water to disperse pollen, while angiosperms, however, depend on insects, birds, or other animals to transfer pollen directly to other flowers.

Mechanisms That Prevent Self-Fertilization

Generally, one of the great advantages of sexual reproduction is that it increases the genetic diversity of offspring, thereby

increasing the likelihood that at least some of the offspring will survive such challenges as environmental change and pathogens (see Chapter 23). Nevertheless, some flowers, such as garden peas, self-fertilize. This process, called "selfing," can be a desirable attribute in some crop plants because it ensures that a seed will develop. Many angiosperm species, however, have mechanisms that make it difficult or impossible for a flower to fertilize itself. The various barriers that prevent self-fertilization contribute to genetic variety by ensuring that sperm and eggs come from different parents. In dioecious species, of course, plants cannot self-fertilize because they have either staminate or carpellate flowers (see Figure 38.3). And in some plants that have flowers with functional stamens and carpels, these floral organs mature at different times or are structurally arranged in such a way that it is unlikely that an animal pollinator could transfer pollen from an anther to a stigma of the same flower (Figure 38.5). However, the most common anti-selfing mechanism in flowering plants is known as self-incompatibility, the ability of a plant to reject its own pollen and sometimes the pollen of closely related individuals. If a pollen grain lands on a stigma of a flower on the same plant, a biochemical block prevents the pollen from completing its development and fertilizing an egg.

Researchers are unraveling the molecular mechanisms that are involved in self-incompatibility. This plant response is analogous to the immune response of animals in that both are based on the ability of organisms to distinguish the cells of "self" from those of "nonself." The key difference is that the animal immune system rejects nonself, as when the system mounts a defense against a pathogen or attempts to reject a transplanted organ. Self-incompatibility in plants, in contrast, is a rejection of self.

A Figure 38.5 "Pin" and "thrum" flower types reduce self-fertilization. Some species produce two types of flowers: "pins," which have long styles and short stamens, and "thrums," which have short styles and long stamens. An insect foraging for nectar would collect pollen on different parts of its body; pin pollen would be deposited on thrum stigmas, and vice versa.

Recognition of "self pollen" is based on genes for self-incompatibility, called S-genes. In the gene pool of a plant population, there can be dozens of alleles of an S-gene. If a pollen grain has an allele that matches an allele of the stigma on which it lands, the pollen tube fails to grow. Depending on the species, self-recognition blocks pollen tube growth by one of two molecular mechanisms: gametophytic self-incompatibility or sporophytic self-incompatibility.

In gametophytic self-incompatibility, the S-allele in the pollen genome governs the blocking of fertilization. For example, an S_1 pollen grain from an $S^A S_1$ parental sporophyte will fail to fertilize eggs of an $S_1 S_2$ flower but will fertilize an $S_2 S_1$ flower. An S_2 pollen grain would not fertilize either flower. Self-recognition of this kind involves the enzymatic destruction of RNA within a rudimentary pollen tube. RNA-hydrolyzing enzymes in the style of the carpel can enter a pollen tube and attack its RNA only if the pollen is of a "self type."

In sporophytic self-incompatibility, fertilization is blocked by S-allele gene products in tissues of the parental sporophyte that adhere to the pollen wall. For example, neither an S_1 nor S_2 pollen grain from an $S^A S_1$ parental sporophyte will fertilize eggs of an $S_1 S_2$ flower or $S_2 S_3$ flower. Sporophytic incompatibility involves a signal transduction pathway in epidermal cells of the stigma that prevents germination of the pollen grain.

Some crops, such as nonhybrid cultivated varieties of peas, maize, and tomatoes, routinely self-pollinate with satisfactory results. However, plant breeders sometimes hybridize different varieties of a crop plant in order to combine the best traits of the varieties and counter the loss of vigor that can result from excessive inbreeding (see Chapter 14). To obtain hybrid seeds, plant breeders currently must prevent self-fertilization either by laboriously removing the anthers from the parent plants that provide the seeds or by developing male sterile plants. The latter option is increasingly important. Eventually, it may also be possible to impose self-incompatibility on crop species that are normally self-compatible. Basic research on mechanisms of self-incompatibility may therefore lead to agricultural applications.

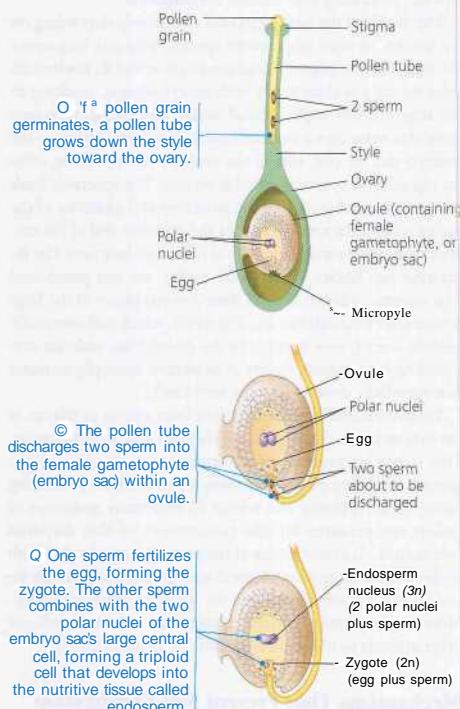

Concept 38.2

After fertilization, ovules develop into seeds and ovaries into fruits

We have traced the processes of gametophyte development and pollination. Now we will look at fertilization and its products: seeds and fruits.

Double Fertilization

After landing on a receptive stigma, a pollen grain absorbs moisture and germinates; that is, it produces a pollen tube that extends down between the cells of the style toward the ovary (Figure 38.6). The nucleus of the generative cell divides by mitosis and forms two sperm. Directed by a chemical attractant, possibly calcium, the tip of the pollen tube enters the ovary, prob(s

A Figure 38.6 Growth of the pollen tube and double fertilization.

Concept Check 38.1

- Give some examples of how form fits function in flower structure.
- Distinguish pollination from fertilization.
- Given the seeming disadvantages of selfing as a reproductive "strategy" in nature, it is surprising that about 20% of angiosperm species primarily rely on selfing. Although fairly common in nature, self-fertilization has been called an "evolutionary dead end." Suggest a reason why selfing might be selected for in nature and yet still be an "evolutionary dead end."

For suggested answers, see Appendix A.

through the micropyle (a gap in the integuments of the ovule), and discharges its two sperm near or within the embryo sac.

The events that follow are a distinctive feature of the angiosperm life cycle. One sperm fertilizes the egg to form the zygote. The other sperm combines with the two polar nuclei to form a triploid (3n) nucleus in the center of the large central cell of the embryo sac. This large cell will give rise to the endosperm, a food-storing tissue of the seed. The union of two sperm cells with different nuclei of the embryo sac is called double fertilization. Double fertilization ensures that the endosperm will develop only in ovules where the egg has been fertilized, thereby preventing angiosperms from squandering nutrients.

The tissues surrounding the embryo sac have prevented researchers from being able to directly observe fertilization in plants grown under normal conditions. Recently, however, scientists have isolated sperm from germinated pollen grains and eggs from embryo sacs and have observed the merging of plant gametes *in vitro* (in an artificial environment). The first cellular event that takes place after gamete fusion is an increase in the cytoplasmic calcium (Ca^{2+}) levels of the egg, as also occurs during animal gamete fusion (see Chapter 47). Another similarity to animals is the establishment of a block to polyspermy—the fertilization of an egg by more than one sperm cell. Thus, maize (*Zea mays*) sperm cannot fuse with zygotes *in vitro*. In maize, this barrier to polyspermy is established as early as 45 seconds after the initial sperm fusion with the egg.

From Ovule to Seed

After double fertilization, each ovule develops into a seed, and the ovary develops into a fruit enclosing the seed(s). As the embryo develops from the zygote, the seed stockpiles proteins, oils, and starch to varying extents, depending on the species. This is why seeds are such major sugar sinks (see Chapter 36). Initially, these nutrients are stored in the endosperm, but later in seed development in many species, the storage function of the endosperm is more or less taken over by the swelling cotyledons of the embryo.

Endosperm Development

Endosperm development usually precedes embryo development. After double fertilization, the triploid nucleus of the ovule's central cell divides, forming a multinucleate "superceil" having a milky consistency. This liquid mass, the endosperm, becomes multicellular when cytokinesis partitions the cytoplasm by forming membranes between the nuclei. Eventually, these "naked" cells produce cell walls, and the endosperm becomes solid. Coconut "milk" is an example of liquid endosperm; coconut "meat" is an example of solid endosperm. The white fluffy part of popcorn is also solid endosperm.

In grains and most other monocots, as well as many eudicots, the endosperm stores nutrients that can be used by the

seedling after germination. In other eudicots (including bean seeds), the food reserves of the endosperm are completely exported to the cotyledons before the seed completes its development; consequently, the mature seed lacks endosperm.

Embryo Development

The first mitotic division of the zygote is transverse, splitting the fertilized egg into a basal cell and a terminal cell (Figure 38.7). The terminal cell eventually gives rise to most of the embryo. The basal cell continues to divide transversely, producing a

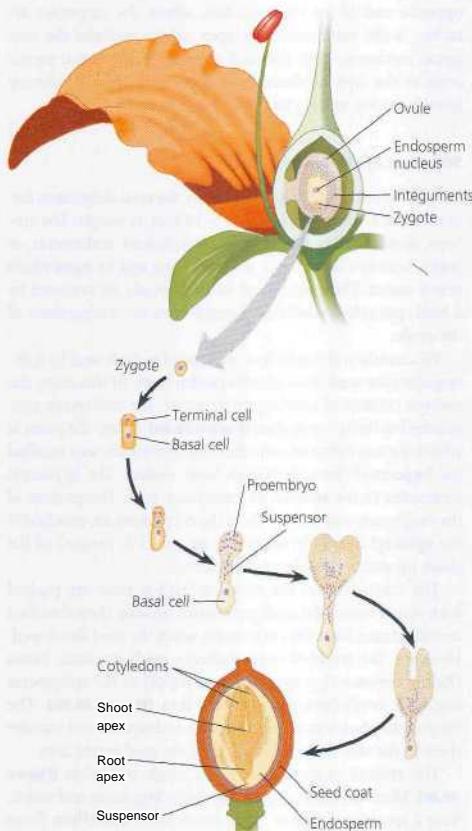

Figure 38.7 The development of a eudicot plant embryo. By the time the ovule becomes a mature seed and the integuments harden and thicken to form the seed coat, the zygote has given rise to an embryonic plant with rudimentary organs.

thread of cells called the suspensor, which anchors the embryo to its parent. The suspensor functions in the transfer of nutrients to the embryo from the parent plant and, in some plants, from the endosperm. As the suspensor elongates, it also pushes the embryo deeper into the nutritive and protective tissues. Meanwhile, the terminal cell divides several times and forms a spherical proembryo attached to the suspensor. The cotyledons begin to form as bumps on the proembryo. A eudicot, with its two cotyledons, is heart-shaped at this stage. Only one cotyledon develops in monocots.

Soon after the rudimentary cotyledons appear, the embryo elongates. Cradled between the cotyledons is the embryonic shoot apex, which includes the shoot apical meristem. At the opposite end of the embryo's axis, where the suspensor attaches, is the embryonic root apex, which includes the root apical meristem. After the seed germinates, the apical meristems at the tips of shoots and roots will sustain primary growth as long as the plant lives (see Figure 35.10).

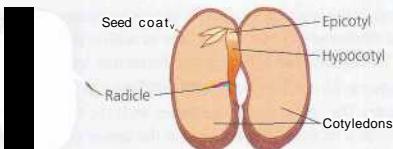

Structure of the Mature Seed

During the last stages of its maturation, the seed dehydrates until its water content is only about 5–15% of its weight. The embryo, surrounded by a food supply (cotyledons, endosperm, or both), becomes dormant; it stops growing and its metabolism nearly ceases. The embryo and its food supply are enclosed by a hard, protective seed coat formed from the integuments of the ovule.

We can take a closer look at one type of eudicot seed by splitting open the seed of a common garden bean. At this stage, the embryo consists of an elongate structure, the embryonic axis, attached to fleshy cotyledons (Figure 38.8a). Below the point at which the cotyledons are attached, the embryonic axis is called the hypocotyl (from the Greek *hypo*, under). The hypocotyl terminates in the radicle, or embryonic root. The portion of the embryonic axis above where the cotyledons are attached is the epicotyl (from the Greek *epi*, on, over). It consists of the shoot tip with a pair of miniature leaves.

The cotyledons of the common garden bean are packed with starch before the seed germinates because they absorbed carbohydrates from the endosperm when the seed developed. However, the seeds of some eudicots, such as castor beans (*Ricinus communis*), retain their food supply in the endosperm and have cotyledons that are very thin (Figure 38.8b). The cotyledons absorb nutrients from the endosperm and transfer them to the rest of the embryo when the seed germinates.

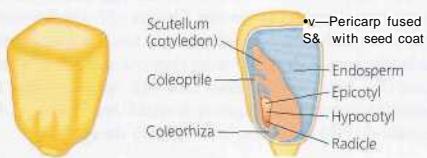

The embryo of a monocot has a single cotyledon (Figure 38.8c). K₄ members of the grass family, including maize and wheat, have a specialized type of cotyledon called a scutellum (from the Latin *scutella*, small shield, a reference to the scutellums shape). The scutellum is very thin, with a large surface area pressed against the endosperm, from which the scutellum absorbs nutrients during germination. The embryo of a grass seed

(a) Common garden bean, a eudicot with thick cotyledons. The fleshy cotyledons store food absorbed from the endosperm before the seed germinates.

(b) Castor bean, a eudicot with thin cotyledons. The narrow, membranous cotyledons (shown in edge and flat views) absorb food from the endosperm when the seed germinates.

(c) Maize, a monocot. Like all monocots, maize has only one cotyledon. Maize and other grasses have a large cotyledon called a scutellum. The rudimentary shoot is sheathed in a structure called the coleoptile, and the coleorhiza covers the young root.

A Figure 38.8 Seed structure.

is enclosed by two sheaths: a coleoptile, which covers the young shoot, and a coleorhiza, which covers the young root.

From Ovary to Fruit

While the seeds are developing from ovules, the ovary of the flower is developing into a fruit, which protects the enclosed seeds and, when mature, aids in their dispersal by wind or animals. Fertilization triggers hormonal changes that cause the ovary to begin its transformation into a fruit. If a flower has not been pollinated, fruit usually does not develop, and the entire flower withers and falls away.

During fruit development, the ovary wall becomes the pericarp, the thickened wall of the fruit. As the ovary grows, the other parts of the flower wither and are shed. For example, the pointed tip of a pea pod is the withered remains of the pea flower's stigma.

Fruits are classified into several types, depending on their developmental origin (Figure 38.9). Most fruits are derived from a single carpel or several fused carpels and are called

simple fruits. Some simple fruits are fleshy, such as a peach, whereas others are dry, such as a pea pod or a nut (see Figure 30.8). An aggregate fruit results from a single flower that has more than one separate carpel, each forming a small fruit. These "fmitlets" are clustered together on a single receptacle, as in a raspberry. A multiple fruit develops from an inflorescence, a group of flowers tightly clustered together. When the walls of the many ovaries start to thicken, they fuse together and become incorporated into one fruit, as in a pineapple.

In some angiosperms, other floral parts in addition to ovaries contribute to what we commonly call the fruit. Such fruits are called accessory fruits. In apple flowers, for example, the ovary is embedded in the receptacle (see Figure 38.2b), and the fleshy part of this simple fruit is derived mainly from the enlarged receptacle; only the apple core develops from the ovary:
[3]Other example is the strawberry, an aggregate fruit consisting of an enlarged receptacle embedded with tiny one-seeded fruits.

A fruit usually ripens about the same time that its seeds complete their development. Whereas the ripening of a dry fruit, such as a soybean pod, involves the aging and drying out of fruit tissues, the process in a fleshy fruit is more elaborate. Complex interactions of hormones result in an edible fruit that serves as an enticement to animals that help spread the seeds. The fruit's "pulp" becomes softer as a result of enzymes digesting components of the cell walls. There is usually a color

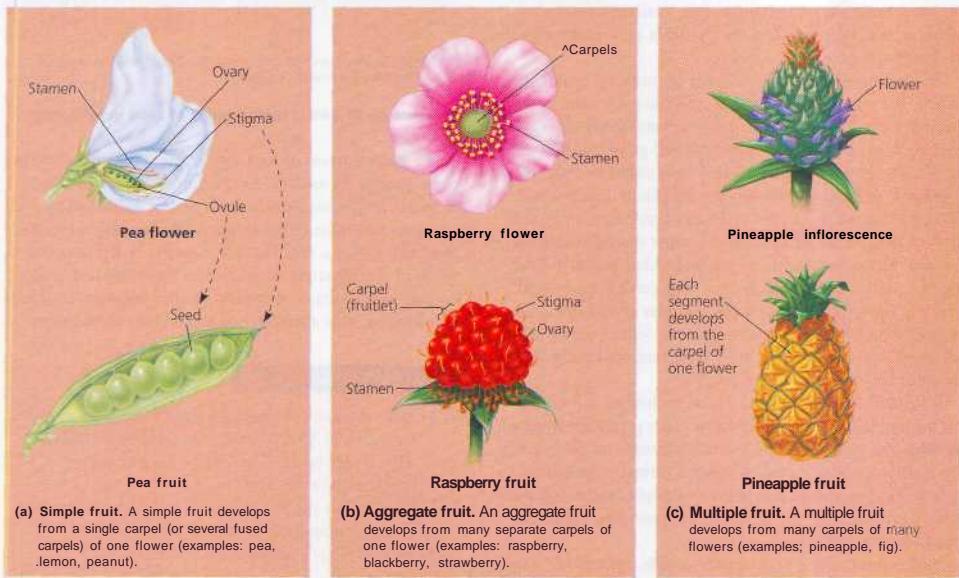

change from green to another color, such as red, orange, or yellow. The fruit becomes sweeter as organic acids or starch molecules are converted to sugar, which may reach a concentration of as much as 20% in a ripe fruit.

Seed Germination

As a seed matures, it dehydrates and enters a phase referred to as dormancy (from the Latin word meaning "to sleep"), a condition of extremely low metabolic rate and suspension of growth and development. Conditions required to break dormancy vary between plant species. Some seeds germinate as soon as they are in a suitable environment. Other seeds remain dormant even if sown in a favorable place until a specific environmental cue causes them to break dormancy.

Seed Dormancy: Adaptation for Tough Times

Seed dormancy increases the chances that germination will occur at a time and place most advantageous to the seedling. Breaking dormancy generally requires certain environmental conditions. Seeds of many desert plants, for instance, germinate only after a substantial rainfall. If they were to germinate after a mild drizzle, the soil might become too dry to support the seedlings. Where natural fires are common, many seeds require intense heat to break dormancy; seedlings are therefore

▲ Figure 38.9 Developmental origin of fruits.

most abundant after fire has cleared away competing vegetation. Where winters are harsh, seeds may require extended exposure to cold. Seeds sown during summer or fall do not germinate until the following spring, ensuring a long growth season before the next winter. Some small seeds, such as those of some varieties of lettuce, require light for germination and will break dormancy only if they are buried shallow enough for the seedlings to poke through the soil surface. Some seeds have coats that must be weakened by chemical attack as they pass through an animal's digestive tract, and thus are likely to be carried some distance before germinating.

The length of time a dormant seed remains viable and capable of germinating varies from a few days to decades or even longer, depending on the species and environmental conditions. Most seeds are durable enough to last a year or two until conditions are favorable for germinating. Thus, the soil has a bank of ungerminated seeds that may have accumulated for several years. This is one reason vegetation reappears so rapidly after a fire, drought, flood, or some other environmental disruption.

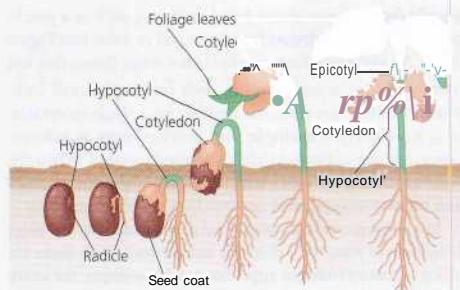

From Seed to Seedling

Germination of seeds depends on the physical process called imbibition, the uptake of water due to the low water potential of the dry seed. Imbibing water causes the seed to expand and rupture its coat and also triggers metabolic changes in the embryo that enable it to resume growth. Following hydration, enzymes begin digesting the storage materials of the endosperm or cotyledons, and the nutrients are transferred to the growing regions of the embryo.

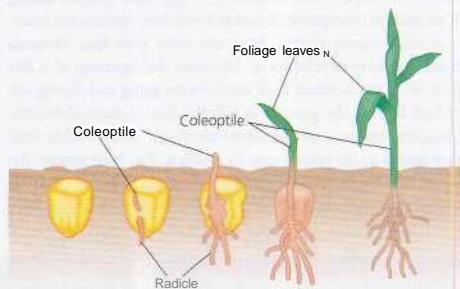

The first organ to emerge from the germinating seed is the radicle, the embryonic root. Next, the shoot must break through the soil surface. In garden beans and many other eudicots, a hook forms in the hypocotyl, and growth pushes the hook above ground (**Figure 38.10a**). Stimulated by light, the hypocotyl straightens, raising the cotyledons and epicotyl. Thus, the delicate shoot apex and bulky cotyledons are pulled upward rather than being pushed tip-first through the abrasive soil. The epicotyl now spreads its first foliage leaves (true leaves, so called to distinguish them from cotyledons, or "seed leaves"). The foliage leaves expand, become green, and begin making food by photosynthesis. The cotyledons shrivel and fall away from the seedling, their food reserves having been exhausted by the germinating embryo.

Maize and other grasses, which are monocots, use a different method for breaking ground when they germinate (**Figure 38.10b**). The coleoptile, the sheath enclosing and protecting the embryonic shoot, pushes upward through the soil and into the air. The shoot tip then grows straight up through the tunnel provided by the tubular coleoptile and eventually breaks out through the coleoptile's tip.

Seed germination is a precarious stage in a plant's life. The tough seed gives rise to a fragile seedling that will be exposed to predators, parasites, wind, and other hazards. In the wild,

(a) **Common garden bean.** In common garden beans, straightening of a hook in the hypocotyl pulls the cotyledons from the soil.

(b) **Maize.** In maize and other grasses, the shoot grows straight up through the tube of the coleoptile.

A Figure 38.10 Two common types of seed germination.

only a small fraction of seedlings endure long enough to become parents themselves. Production of enormous numbers of seeds compensates for the odds against individual survival and gives natural selection ample genetic variations to screen. However, this is a very expensive means of reproduction in terms of the resources consumed in flowering and fruiting. Asexual reproduction, generally simpler and less hazardous for offspring, is an alternative means of plant propagation.

Concept Check 38.2

1. Some dioecious species have the XY sexual genotype for male and XX for female. After double fertilization, what would be the genotypes of the endosperm nuclei and the embryos?
2. Explain how the basic structures of seeds and fruits facilitate reproduction.
3. What is the advantage of seed dormancy?

For suggested answers, see Appendix A.

Concept 38.3

Many flowering plants clone themselves by asexual reproduction

Imagine chopping off your finger and watching it develop into an exact copy of you. This would be an example of asexual reproduction, in which offspring are derived from a single parent without genetic recombination (which, of course, does not occur in humans). The result would be a clone, an asexually produced, genetically identical organism.

Like many seedless plants and some gymnosperms, many angiosperm species reproduce both asexually and sexually. If reproducing asexually, a plant passes on all of its genes to its offspring. If reproducing sexually, a plant passes on only half of its genes. Each reproductive mode offers advantages in certain situations.

If a plant is superbly suited to a stable environment, asexual reproduction has advantages. A plant can clone many copies of itself, and if the environmental conditions remain stable, these clones, too, will be well suited for that environment. Also, the offspring are not as frail as seedlings produced by sexual reproduction in seed plants. The offspring are usually mature vegetative fragments from the parent plant, which is why asexual reproduction in plants is also known as vegetative reproduction. A sprawling clone of prairie grass may cover an area so thoroughly that seedlings of the same or other species have little chance of competing.

In unstable environments, where evolving pathogens and other variables affect survival and reproductive success, sexual reproduction can be an advantage because it generates variation in offspring and populations. In contrast, the genotypic uniformity of asexually produced plants puts them at great risk of local extinction if there is a catastrophic environmental change, such as a new strain of disease. Moreover, seeds (which are almost always produced sexually) facilitate the dispersal of offspring to more distant locations. And finally, seed dormancy allows growth to be suspended until hostile environmental conditions are more favorable.

Mechanisms of Asexual Reproduction

Asexual reproduction in plants is typically an extension of the capacity for indeterminate growth. Plants, remember, have meristematic tissues of dividing, undifferentiated cells that can sustain or renew growth indefinitely. In addition, phloem cells throughout the plant can divide and differentiate into more specialized types of cells, enabling plants to regenerate lost parts. Detached vegetative fragments of some plants can develop into whole offspring; a severed stem, for instance, may develop adventitious roots and become a whole

A Figure 38.11 Asexual reproduction in aspen trees. Some aspen groves, such as those shown here, actually consist of thousands of trees descended by asexual reproduction. Each grove of trees derives from the root system of one parent. Notice that genetic differences between groves descended from different parents result in different timing for the development of fall color and the loss of leaves.

plant. Fragmentation, the separation of a parent plant into parts that develop into whole plants, is one of the most common modes of asexual reproduction. For example, in some species the root system of a single parent gives rise to many adventitious shoots that become separate shoot systems. The result is a clone formed by asexual reproduction from one parent (Figure 38.11). Such asexual propagation has produced the oldest of all known plant clones, a ring of creosote bushes in the Mojave Desert of California, believed to be at least 12,000 years old.

An entirely different mechanism of asexual reproduction has evolved in dandelions and some other plants. These plants can sometimes produce seeds without pollination or fertilization. This asexual production of seeds is called apomixis (from the Greek words meaning "away from the act of mixing") because there is no joining of sperm and egg. Instead, a diploid cell in the ovule gives rise to the embryo, and the ovules mature into seeds, which in the dandelion are dispersed by windblown fruits. Thus, these plants clone themselves by an asexual process but have the advantage of seed dispersal, usually associated with sexual reproduction.

Vegetative Propagation and Agriculture

With the objective of improving crops and ornamental plants, humans have devised various methods for asexual propagation of angiosperms. Most of these methods are based on the ability of plants to form adventitious roots or shoots.

Clones from Cuttings

Most houseplants, woody ornamentals, and orchard trees are asexually reproduced from plant fragments called cuttings. In some cases, shoot or stem cuttings are used. At the cut end of

the shoot, a mass of dividing, undifferentiated cells called a callus forms, and then adventitious roots develop from the callus. If the shoot fragment includes a node, then adventitious roots form without a callus stage. Some plants, including African violets, can be propagated from single leaves rather than stems. For still other plants, cuttings are taken from specialized storage stems. For example, a potato can be cut up into several pieces, each with a vegetative bud, or "eye," that regenerates a whole plant.

Grafting

In a modification of vegetative reproduction from cuttings, a twig or bud from one plant can be grafted onto a plant of a closely related species or a different variety of the same species. Grafting makes it possible to combine the best qualities of different species or varieties into a single plant. The graft is usually done when the plant is young. The plant that provides the root system is called the stock; the twig grafted onto the stock is referred to as the scion. For example, scions from French varieties of vines that produce superior wine grapes are grafted onto root stocks of American varieties, which are more resistant to certain soil pathogens. The genes of the scion determine the quality of the fruit, so it is not diminished by the genetic makeup of the stock. In some cases of grafting, however, the stock can alter the characteristics of the shoot system that develops from the scion. For example, dwarf fruit trees, which allow for more easy harvesting of the fruit, are made by grafting normal twigs onto stocks of dwarf varieties that retard the vegetative growth of the shoot system. Because seeds are produced by the part of the plant derived from the scion, they give rise to plants of the scion species when planted.

Test-Tube Cloning and Related Techniques

Plant biologists have adopted *in vitro* methods to create and clone novel plant varieties. It is possible to grow whole plants by culturing small explants (pieces of tissue cut from the parent) or even single parenchyma cells on an artificial medium containing nutrients and hormones (Figure 38.12a). The cultured cells divide and form an undifferentiated callus. When the hormonal balance is manipulated in the culture medium, the callus can sprout shoots and roots with fully differentiated cells (Figure 38.12b). The test-tube plantlets can then be transferred to soil, where they continue their growth. A single plant can be cloned into thousands of copies by subdividing calluses as they grow. This method is used for propagating orchids and for cloning pine trees that produce wood at unusually fast rates.

Plant tissue culture also facilitates genetic engineering. Most techniques for the introduction of foreign genes into plants require small pieces of plant tissue or single plant cells as the starting material. In plant biology, the term transgenic is used to describe genetically modified (GM) organisms that

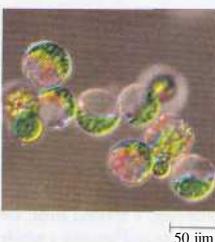

(a) Just a few parenchyma cells from a carrot gave rise to this callus, a mass of undifferentiated cells.

(b) The callus differentiates into an entire plant, with leaves, stems, and roots.

A Figure 38.12 Test-tube cloning of carrots. (See also Figure 21.5.)

have been engineered to express a gene from another species. Test-tube culture makes it possible to regenerate GM plants from a single plant cell into which the foreign DNA has been incorporated. The techniques of genetic engineering are discussed in more detail in Chapter 20.

Some researchers are coupling a technique that is known as protoplast fusion with tissue culture methods to invent new plant varieties that can be cloned. Protoplasts are plant cells with their cell walls removed by treatment with enzymes (cellulases and pectinases) isolated from fungi (Figure 38.13). Before they are cultured, protoplasts can be screened for mutations that may improve the agricultural value of the plant. In some cases, it is possible to fuse two protoplasts from different plant species that would otherwise be reproductively incompatible, and then culture the hybrid protoplasts. Each protoplast can regenerate a wall and eventually form a hybrid plantlet. One success of this method is a hybrid between a potato and a wild relative called black nightshade. The nightshade is resistant to an herbicide commonly used to kill weeds. If the hybrids are also resistant, making it possible to "weed" a field with the herbicide without killing potato plants.

***4 Figure 38.13 Protoplasts**

These wall-less plant cells are prepared by treating cells or tissues with wall-degrading enzymes isolated from certain types of fungi. Researchers can fuse protoplasts from different species to make hybrids and can also culture the hybrid cells to produce a new plant.

The *in vitro* culturing of plant cells and tissues is fundamental to most types of plant biotechnology. The other basic process is the ability to produce transgenic plants through various methods of genetic engineering. In the next section, we take a closer look at plant biotechnology.

Concept Check 38.3

- L. "Explain how both asexual and sexual reproduction contribute to the reproductive success of plants."
1. The seedless banana, the world's most popular fruit, is losing the battle against two fungal epidemics. Why do such epidemics generally pose a greater risk to asexually propagated crops?

For suggested answers, see Appendix A.

Concept 38.4

Plant biotechnology is transforming agriculture

Plant biotechnology has two meanings. In the general sense, it refers to innovations in the use of plants (or substances obtained from plants) to make products of use to humans—an endeavor that began in prehistory. In a more specific sense, biotechnology refers to the use of GM organisms in agriculture and industry. Indeed, in the last two decades, genetic engineering has become such a powerful force that the terms *genetic engineering* and *biotechnology* have become synonymous in the media. In this last section, we expand on the discussion in Chapter 20 by examining how humans have altered plants to suit their purposes.

Artificial Selection

"Humans have intervened in the reproduction and genetic makeup of plants for thousands of years. It is no exaggeration to say that maize is an unnatural monster created by humans. Left on its own in nature, maize would soon become extinct for the simple reason that it cannot spread its seeds. Maize kernels are not only permanently attached to the central axis (the "cob") but also permanently protected by tough, overlapping leaf sheaths (the "husk"). These attributes arose not by natural selection but by artificial selection by humans (Figure 38.14). (See Chapter 22 to review the basic concept of artificial selection.) Indeed, Neolithic (late Stone Age) humans domesticated most of our crop species over a relatively short period about 10,000 years ago. But genetic modification began long before humans started altering crops by artificial selection. For example, the wheat species we rely on for much

of our food are the result of natural hybridization between different species of grasses. Such hybridization is common in plants and has long been exploited by breeders to introduce additional genetic variation for artificial selection and crop improvement. One modern example is the selective breeding of maize.

Maize is a staple in many developing countries, but the most common varieties are poor sources of protein, requiring that diets be supplemented with other sources, such as beans. The proteins in popular maize varieties are very low in lysine and tryptophan, two of the eight essential amino acids that humans cannot synthesize and must obtain from their diet (see Figure 41.10). Forty years ago, researchers discovered a mutant known as *opaque-2* that has much higher levels of lysine and tryptophan. This maize variety is more nutritious, as reflected in the fact that swine fed with *opaque-2* maize gain weight three times faster than those fed with normal maize. However, as is often the case in plant breeding, a highly desirable trait was linked with undesirable ones. The *opaque-2* maize kernels have a soft endosperm that makes them difficult to harvest and more vulnerable to attack by pests. Using the conventional methods of hybridization and artificial selection, plant breeders converted the soft *opaque-2* endosperm into a more desirable hard endosperm type, a transition that took hundreds of scientists nearly 20 years to accomplish. If modern methods of genetic engineering had been available, one laboratory might have inserted genes for the high lysine and tryptophan condition into hard-endosperm maize varieties over a period of only a few years.

Unlike traditional plant breeders, modern plant biologists, using techniques of genetic engineering, are not limited to the transfer of genes between closely related species or varieties of the same species. For example, traditional breeding techniques could not be used to insert a desired gene from daffodil into rice because the many intermediate species between rice and

A Figure 38.14 Maize: a product of artificial selection.

Modern maize (bottom) was derived from teosinte (top). Teosinte kernels are tiny, and each row has a husk that must be removed to get at the kernel. The seeds are loose at maturity, allowing dispersal, which probably made harvesting difficult for early farmers. Neolithic farmers selected for larger cob and kernel size as well as the permanent attachment of seeds to the cob and the encasing of the entire cob by a tough husk.

daffodil and their common ancestor are extinct. In theory, if breeders had the intermediate species, over the course of several centuries they could probably introduce a daffodil gene into rice by traditional hybridization and breeding methods. With genetic engineering technology, however, such gene transfers can be done more quickly and without the need for intermediate species.

Reducing World Hunger and Malnutrition

Eight hundred million people on Earth suffer from nutritional deficiencies. Forty thousand people die each day of malnutrition, half of them children. There is much disagreement about the causes of such hunger. Some argue that food shortages arise not from a lack of food production but from inequities in distribution: The dire poor simply cannot afford food. Others regard food shortages as evidence that the world is overpopulated—that the human species has exceeded the carrying capacity of the planet (see Chapter 52). Whatever the social and demographic causes of malnutrition, increasing food production is a humane objective. Because land and water are the most limiting resources for food production, the best option will be to increase yields on the available land. Indeed, there is very little "extra" land that can be put to the plow, especially if the few remaining pockets of wilderness are to be conserved. Based on conservative estimates of population growth, the world's farmers will have to produce 40% more grain per hectare to feed the human population in 2020. Plant biotechnology can help make these crop yields possible.

Already, the commercial adoption by farmers of transgenic crops has been one of the most dramatic examples of rapid technology adoption in the history of agriculture. These crops include transgenic varieties and hybrids of cotton, maize, and potatoes that contain genes from the bacterium *Bacillus thuringiensis*. These "transgenes" encode for a protein (*Bt* toxin) that effectively controls a number of serious insect pests. The use of such plant varieties greatly reduces the need for spraying crops with chemical insecticides. The *Bt* toxin used in crops is produced in the plant as a harmless protoxin that only becomes toxic if activated by alkaline conditions, such as occur in the guts of insects. Since vertebrates have highly acidic stomachs, the protoxin is destroyed without becoming active. Thus, *Bt* toxin is completely harmless to vertebrates, including humans.

Considerable progress also has been made in the development of transgenic plants of cotton, maize, soybeans, sugar beets, and wheat that are tolerant to a number of herbicides. The cultivation of these plants may reduce production costs and enable farmers to "weed" crops with herbicides that do not damage the transgenic crop plants instead of by heavy tillage, which can cause erosion of soil. Researchers are also engineering plants with enhanced resistance to disease. In one case, a transgenic papaya resistant to a ring spot virus was introduced into Hawaii, thereby saving its papaya industry (Figure 38.15).

◀ Figure 38.15 Genetically engineered papaya. A ring spot virus has devastated papaya cultivation worldwide. A transgenic papaya variety rescued the industry in Hawaii. The genetically engineered papaya on the left is more resistant to ring spot virus than the nontransgenic papaya on the right.

The nutritional quality of plants is also being improved. "Golden Rice," a transgenic variety with a few daffodil genes that increase quantities of vitamin A, is under development to prevent the blindness that develops in many of the world's poor whose diet is chronically deficient in vitamin A (Figure 38.16).

The Debate over Plant Biotechnology

Much of the debate regarding GM organisms in agriculture is political, social, economic, or ethical and outside the scope of this book. But we *should* consider the biological concerns about GM crops. There are some biologists, particularly ecologists, who are concerned about the unknown risks associated with the release of GM organisms (GMOs) into the environment. The most fundamental debate centers on the extent to which GMOs are an unknown risk that could potentially harm human health or the environment. Those who want to proceed more slowly with agricultural biotechnology (or end it) are concerned about the unstoppable nature of the "experiment." If a drug trial produces unanticipated harmful results, the trial is stopped. But we may not be able to stop the "trial" of novel organisms introduced into the biosphere.

Chapter 20 introduced the key concerns regarding biotechnology in general. Here we take a closer look at issues as they relate to plant biotechnology. Laboratory and field studies continue to examine the possible consequences of using GM crops, including the effects on human health and nontarget organisms and the potential for transgene escape.

Issues of Human Health

One concern is that genetic engineering may transfer allergens, molecules to which some humans are allergic, from a gene source to a plant used for food. However, biotechnologists are engaged in removing genes that encode allergenic proteins from soybeans and other crops. So far, there is no

Genetically modified rice

Figure 38.16 Grains of "Golden Rice" interspersed with grains of ordinary rice. The golden color and increased nutritional value of Golden Rice are attributable to its ability to make beta-carotene. The three transgenes that gave Golden Rice the ability to make beta-carotene in its grains were introduced from daffodils (*Narcissus*).

credible evidence that GM plants specifically designed for human consumption have adverse effects on human health. In fact, some GM foods are potentially a healthier alternative to non-GM foods. *Bt* maize, for example, contains 90% less of a cancer-causing mycotoxin called fumonisin that is highly resistant to degradation and has been found in alarmingly high concentrations in some batches of processed maize products ranging from corn flakes to beer. Fumonisin is produced by a fungus (*Fusarium*) that infects insect-damaged maize. Since *Bt* maize generally suffers less insect damage than non-GM maize, it contains much less fumonisin.

Nevertheless, because of health concerns, GMO opponents lobby for the clear labeling of all foods containing products of GMOs. Some also argue for strict regulations against the mixing of GM foods with non-GM foods during food transport, storage, and processing. Some biotechnology advocates, however, note that similar demands were not raised when "transgenic" crops produced by traditional plant-breeding techniques were put on the market. For example, triticale was a completely new crop that was artificially synthesized a few decades ago by hybridizing wheat and rye—two distinct genera that do not interbreed in nature. Triticale is now grown on over 3 million acres worldwide.

Possible Effects on Nontarget Organisms

Many ecologists are concerned that the growing of GM crops might have unforeseen effects on nontarget organisms. One study indicated that the larvae (caterpillars) of monarch butterflies responded adversely and even died following their consumption in the laboratory of milkweed leaves (their preferred food) heavily dusted with pollen from transgenic *Bt*-maize. This study has since been discredited and affords a good example of the self-correcting nature of science. As it turns out, when the original researchers shook the male maize inflorescences onto the milkweed leaves in the laboratory, staminal filaments, opened pollen sacs, and other floral parts also rained onto the leaves. Subsequent research found that it was these other floral parts, *not* the pollen, that contained *Bt* toxin in high concentrations. Unlike pollen, these floral parts

would not be carried by the wind to neighboring milkweed plants when shed under natural field conditions. Only one *Bt* maize line, accounting for less than 2% of commercial *Bt* maize production (and now discontinued), produced pollen with high *Bt* toxin concentrations.

In considering the negative effects of *Bt* pollen on monarch butterflies, one must also weigh the effects of an alternative to the cultivation of *Bt* maize—the spraying of non-*Bt* maize with chemical pesticides. Recent studies have shown that such spraying was much more harmful to nearby monarch populations than was *Bt* maize production. Although the nontarget effects of *Bt* maize pollen on monarch butterfly larvae appear to be minor, the controversy has emphasized the need for accurate field testing of all GM crops.

Addressing the Problem of Transgene Escape

Perhaps the most serious concern that some scientists raise about GM crops is the possibility of the introduced genes escaping from a transgenic crop into related weeds through crop-to-weed hybridization. The fear is that the spontaneous hybridization between a crop engineered for herbicide resistance and a wild relative, for example, might give rise to a "superweed" that would have a selective advantage over other weeds in the wild and would be much more difficult to control in the field. Some crops do hybridize with weedy relatives, and crop-to-weed transgene escape is a possibility. Its likelihood depends on the ability of the crop and weed to hybridize and on how the transgenes affect the overall fitness of the hybrids. A desirable crop trait—a dwarf phenotype, for example—might be disadvantageous to a weed growing in the wild; in other instances, there are no weedy relatives nearby with which to hybridize; soybean, for example, has no wild relatives in the United States. However, canola, sorghum, and many other crops do hybridize readily with weeds.

Because of concerns over transgene escape, efforts are under way to breed male sterility into transgenic crops. These plants will still produce seeds and fruit if pollinated by nearby nontransgenic plants, but they will produce no viable pollen. Another approach is to engineer the transgene into the chloroplast DNA of the crop. Chloroplast DNA in many plant species is inherited strictly from the maternal plant, so transgenes in the chloroplast cannot be transferred by pollen (see Chapter 15 to review maternal inheritance).

"Terminator technology" offers another potential approach toward reducing the problem of transgene escape. Terminator technology employs "suicide" genes that disrupt critical developmental sequences, precluding pollen development or seed maturation. Plants that are genetically modified to undergo the terminator process grow normally until the last stages of seed or pollen maturation. At this point, a gene expressing a "terminator" protein toxic to plants but harmless to animals is activated only in the nearly mature seed or pollen. Although

the newly formed seeds or pollen are practically mature, they are inviable. Terminator proteins are only produced if the original seeds are pretreated with a specific chemical. Most research has focused on applying this technology to the killing of seeds, to force farmers to purchase GM seed every growing season. However, applying the technology to kill developing pollen grains could be an effective strategy for reducing transgene escape.

The continuing debate about GMOs in agriculture exemplifies one of this textbook's themes: the relationships of science and technology to society. Technological advances almost always involve the risk of unintended outcomes. In plant biotechnology, zero risk is probably unattainable. On a case-

by-case basis, scientists and the public must assess possible benefits of transgenic products versus the risks society is willing to take. The best scenario is for these discussions and decisions to be based on sound scientific information and testing rather than on reflexive fear or blind optimism.

Concept Check 38.4

1. Compare traditional plant breeding with genetic engineering.
2. Explain how GM crops have benefits and risks.

For suggested answers, see Appendix A.

Chapter 38 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 38.1

Pollination enables gametes to come together within a flower

- The sporophyte, the dominant generation, produces spores that develop within flowers into male gametophytes (pollen grains) and female gametophytes (embryo sacs) (pp. 771–772).
Activity Angiosperm Life Cycle
- **Flower Structure** (pp. 772–773) The four floral organs are sepals, petals, stamens, and carpels.
- **Gametophyte Development and Pollination** (pp. 774–775) Pollen develops from microspores within the microsporangia of anthers; embryo sacs develop from megasporangia within ovules. Pollination, which precedes fertilization, is the placing of pollen on the stigma of a carpel.
- **Mechanisms That Prevent Self-Fertilization** (pp. 775–776) Some plants reject pollen that has an S-gene matching an allele in the stigma cells. Recognition of "self" pollen triggers a signal transaction pathway leading to a block in growth of a pollen tube.

Concept 38.2

After fertilization, ovules develop into seeds and ovaries into fruits

- **Double Fertilization** (pp. 776–777) The pollen tube discharges two sperm into the embryo sac; one fertilizes the egg, while the other combines with the polar nuclei, giving rise to the food-storing endosperm.
- **From Ovule to Seed** (pp. 777–778) The seed coat encloses the embryo along with a food supply stocked in either the cotyledons or the endosperm.
Activity Seed and Fruit Development

Concept 38.3

Many flowering plants clone themselves by asexual reproduction

- Asexual reproduction enables successful clones to spread; sexual reproduction generates the genetic variation that makes evolutionary adaptation possible (p. 781).
- **Mechanisms of Asexual Reproduction** (p. 781) One important mode of asexual reproduction is the fragmentation of a parent plant into parts that become whole plants.
- **Vegetative Propagation and Agriculture** (pp. 781–783) Cloning plants from cuttings is an ancient practice. We can now clone plants from single cells, which can be genetically manipulated before cloning.

Concept 38.4

Plant biotechnology is transforming agriculture

- **Artificial Selection** (pp. 783–784) Interspecific hybridization of plants is common in nature and has been used by breeders, ancient and modern, to introduce new genes.
- **Reducing World Hunger and Malnutrition** (p. 784) Genetically modified plants have the potential of increasing the quality and quantity of food worldwide.
Activity Making Decisions About DNA Technology: Golden Rice
- **The Debate over Plant Biotechnology** (pp. 784–786) There are concerns about the unknown risks of releasing genetically modified organisms into the environment, but the potential benefits of transgenic crops should be considered.

TESTING YOUR KNOWLEDGE

Evolution Connection

With respect to sexual reproduction, some plant species are fully self-fertile, others are fully self-incompatible, and some have adapted a "mixed strategy" with partial self-incompatibility. These reproductive strategies differ in their implications for evolutionary potential. How, for example, might a self-incompatible species fare as small founder populations or remnant populations in a severe population bottleneck, as compared with a self-fertile species?

Scientific Inquiry

Critics of GM foods have argued that because the insertion of foreign genes may cause a disturbance of normal cellular functioning, unexpected and potentially harmful substances may appear. Toxic intermediary substances that normally occur in very small amounts may increase considerably, or new substances may appear. There is also a potential risk that the disruption may lead to the loss of substances that are important for maintaining normal metabolism. If you were your country's chief scientific advisor, how would you respond to these criticisms?

Biology inquiry: A Workbook of investigative Cases Explore

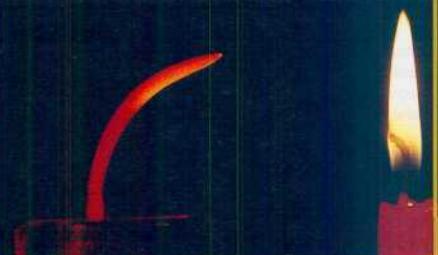

GM crops further with the case "Corn Under Construction."

Investigation What Tells Desert Seeds When to Germinate?

Science, Technology, and Society

Humanity has used genetic manipulation for millennia, producing plant and animal varieties through selective breeding and hybridization processes that modify the genomes of organisms on a significant level. Why do you think modern genetic engineering, which often entails introducing or modifying only one or a few genes, has met with so much public opposition? Should some forms of genetic engineering be of greater concern than others? Explain.

39 Plant Responses to Internal and External Signals

A Figure 39.1 Grass seedling growing toward light.

Key Concepts

- 39.1 Signal transduction pathways link signal reception to response
- 39.2 Plant hormones help coordinate growth, development, and responses to stimuli
- 39.3 Responses to light are critical for plant success
- 39.4 Plants respond to a wide variety of stimuli other than light
- 39.5 Plants defend themselves against herbivores and pathogens

Overview

Stimuli and a Stationary Life

Being rooted to the ground, plants must respond to whatever environmental change comes their way. For example, bending of a grass seedling toward light (Figure 39.1) begins with the plant sensing the direction, quantity, and color of the light. After integrating this information, cells in the tip of the seedling undergo a complex series of biochemical changes that influence distribution of chemical signals in the plant. Ultimately, changes in distribution of these growth-regulating chemicals lead to the bending of the seedling toward the light. This is one example of how a plant's morphology and physiology are constantly tuned to its surroundings by complex interactions between environmental stimuli and internal signals.

This chapter focuses on how plants respond to external and internal cues. At the organismal level, plants and animals respond to environmental stimuli by very different means. Animals, being mobile, respond mainly by behavioral mechanisms, moving toward positive stimuli and away from negative

stimuli. Being stationary, a plant generally responds to environmental cues by adjusting its pattern of growth and development. For this reason, plants of the same species vary in body form much more than do animals of the same species. All lions have four limbs and approximately the same body proportions, but oak trees vary considerably in their number of limbs and their shape. We begin our study of plant response with the role of signal transduction in plant cells.

Concept 39.1

Signal transduction pathways link signal reception to response

All organisms receive specific environmental signals and respond to them in ways that enhance survival and reproductive success. For example, bees, which possess UV-sensitive photoreceptors in their eyes, can discern nectar-guiding patterns on flower petals—patterns that are completely invisible to humans. Plants, too, have cellular receptors that they use to detect important changes in their environment, whether the change is an increase in the concentration of a growth hormone, an injury from a caterpillar munching on leaves, or a decrease in day length as winter approaches.

For a stimulus to elicit a response, certain cells must have an appropriate receptor, a molecule affected by the stimulus. For example, our blindness to UV-reflecting floral patterns is due to our eyes lacking UV photoreceptors. Upon receiving a stimulus, a receptor initiates a series of biochemical steps, a signal transduction pathway, that couples reception to response. Plants are sensitive to a wide range of stimuli, each initiating a specific signal transduction pathway. Chapter 11 introduced general concepts of signal transduction in cells. Here, we apply those concepts to plants.

Consider a forgotten potato in the back corner of a kitchen cupboard. This modified underground stem, or tuber, has sprouted shoots from its "eyes" (axillary buds). These shoots, however, scarcely resemble those of a typical plant. Instead of broad green leaves and sturdy stems, these plants are ghostly pale, bear leaves that are unexpanded, and lack elongated roots (**Figure 39.2a**). These morphological adaptations for growing in darkness, collectively referred to as etiolation, make sense if we consider that a young potato plant in nature usually encounters continuous darkness when sprouting underground. Under these circumstances, expanded leaves would be a hindrance to soil penetration and would be damaged as the shoots pushed through the soil. Because the leaves are unexpanded and underground, there is little evaporative loss of water and little requirement for an extensive root system to replace the water lost by transpiration. Moreover, the energy expended in producing green chlorophyll would be wasted because there is no light for photosynthesis. Instead, a potato plant growing in the dark allocates as much energy as possible to the elongation of stems. This adaptation enables the shoots to break ground before the nutrient reserves in the tuber are exhausted. The etiolation response is one example of how a plant's morphology and physiology are tuned to its variable surroundings by complex interactions between environmental and internal signals.

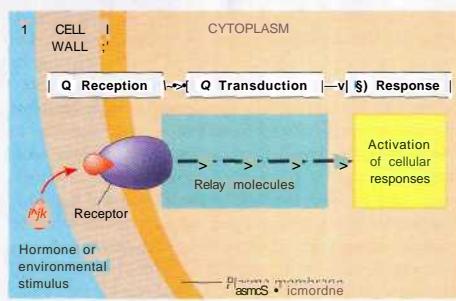

When a shoot reaches the sunlight, the plant undergoes profound changes collectively called de-etiolation (informally known as greening). The elongation rate of the stems slows; leaves expand; roots elongate; and the shoot produces chlorophyll. In short, it begins to resemble a typical plant (**Figure 39.2b**). We

(a) **Before exposure to light.** A dark-grown potato has tall, spindly stems and non-expanded leaves—morphological adaptations that enable the shoots to penetrate the soil. The roots are short, but there is little need for water absorption because little water is lost by the shoots.

(b) **After a week's exposure to natural daylight.** The potato plant begins to resemble a typical plant with broad green leaves, short sturdy stems, and long roots. This transformation begins with the reception of light by a specific pigment, phytochrome,

Figure 39.2 Light-induced de-etiolation (greening) of dark-grown potatoes.

& Figure 39.3 Review of a general model for signal transduction pathways. As discussed in Chapter 11, a hormone or another signal binding to a specific receptor stimulates the cell to produce relay molecules, such as second messengers. These relay molecules trigger the cell's various responses to the original signal. In this diagram, the receptor is on the surface of the target cell. In other cases, hormones enter cells and bind to specific receptors inside.

will use this de-etiolation response as an example of how a plant cell's reception of a signal—in this case, light—is transduced into a response (greening). Along the way, we will explore how studies of mutants provide insights into roles played by molecules in the stages of cell-signal processing: reception, transduction, and response (**Figure 39.3**).

Reception

Signals are first detected by receptors, proteins that undergo conformational changes in response to a specific stimulus. The receptor involved in de-etiolation is a type of *phytochrome*, a photoreceptor that we will examine more closely later in the chapter. Unlike many receptors, which are built into the plasma membrane, the phytochrome that functions in de-etiolation occurs in the cytoplasm. Researchers demonstrated the requirement for phytochrome in de-etiolation through studies of the tomato, a close relative of the potato. The *aurea* tomato mutant, which has lower-than-normal levels of phytochrome, greens less than wild-type tomatoes when exposed to light. The name *aurea* comes from the Latin for "gold-colored." In the absence of chlorophyll, the yellow plant pigments called carotenoids are more obvious. Researchers produced a normal de-etiolation response in individual *aurea* leaf cells by injecting phytochrome from other plants and exposing the cells to light. Such experiments indicate that phytochrome functions in light detection during de-etiolation.

Transduction

Receptors are sensitive to very weak environmental and chemical signals. Some de-etiolation responses are triggered by extremely low levels of light. For example, light levels equivalent to a few seconds of moonlight are sufficient to cause a slowing

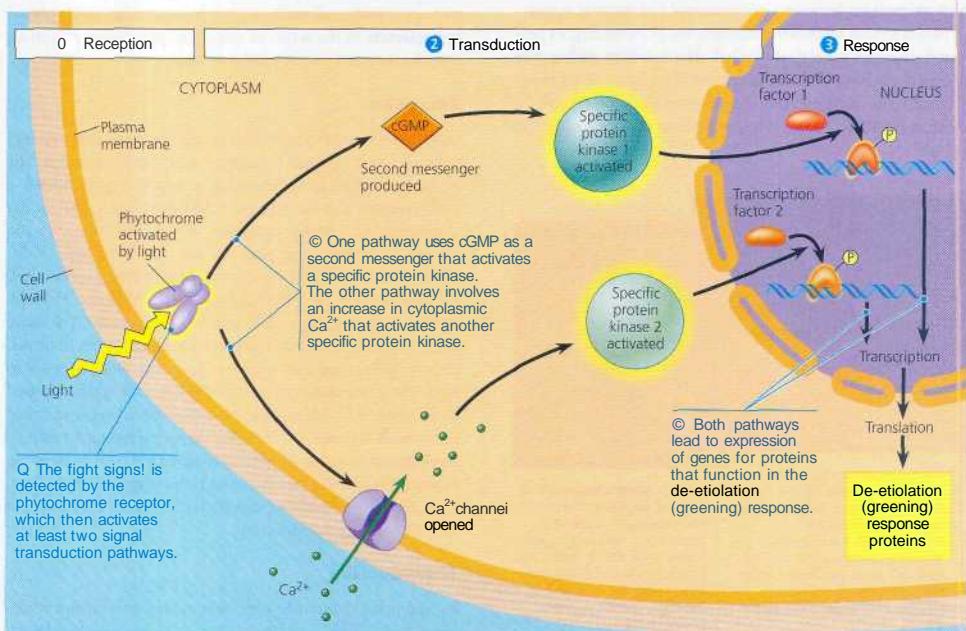

of stem elongation in dark-grown oat seedlings. How is the information from these extremely weak signals amplified, and how is their reception transduced into a specific response by the plant? The answer is second messengers—small, internally produced chemicals that transfer and amplify the signal from the receptor to other proteins that cause the response. In de-etiolation, for example, each activated phytochrome molecule may give rise to hundreds of molecules of a second messenger, each of which may lead to the activation of hundreds of molecules of a specific enzyme. By such mechanisms, the second messenger of a signal transduction pathway leads 10 a rapid amplification of the signal. In Chapter 11, we examined this role of second messengers in general (see Figure 11.12). Here, we consider the production and function of second messengers in de-etiolation. Refer to **Figure 39.4** frequently as you read the following description of this complex process.

Light causes phytochrome to undergo a conformational change that leads to increases in levels of the second messengers cyclic GMP (cGMP) and Ca^{2+} . Changes in cGMP levels can lead to ionic changes within the cell by influencing properties of ion channels. Cyclic GMP also activates protein kinases, a diverse class of enzymes that influence activation of

other enzymes by phosphorylation, a modification in which a phosphate group is attached to the protein at a specific site. Injection of cGMP into *mirta* tomato leaf cells induces a partial de-etiolation response, even without the addition of phytochrome. Changes in cytosolic Ca^{2+} levels also play an important role in phytochrome signal transduction. The concentration of Ca^{2+} is generally very low in the cytosol (about 10^{-7} M). But phytochrome activation can open Ca^{2+} channels and lead to a transient 100-fold increase in cytosolic Ca^{2+} levels. Like cGMP, cytosolic Ca^{2+} can influence activity of specific ion channels and protein kinases.

Response

Ultimately, a signal transduction pathway leads to regulation of one or more cellular activities. In most cases, these responses to stimulation involve the increased activity of certain enzymes. There are two main mechanisms by which a signaling pathway can activate an enzyme. One mechanism involves stimulating transcription of mRNA for the enzyme (transcriptional regulation). The other involves activating existing enzyme molecules (post-translational modification).

A Figure 39.4 An example of signal transduction in plants: the role of phytochrome in the de-etiolation (greening) response.

Transcriptional Regulation

Transcription factors bind directly to specific regions of DNA and control the transcription of specific genes (see Figure 19.5). In the case of phytochrome-induced de-etiolation, several transcription factors are activated by phosphorylation in response to the appropriate light conditions. The activation of some of these transcription factors depends on cGMP, whereas the activation of others requires Ca^{2+} .

The mechanism by which a signal promotes a new developmental course may depend on the activation of positive transcription factors (proteins that *increase* transcription of specific genes) or negative transcription factors (proteins that *decrease* transcription) or both. For example, there are *Avabiciup*⁸ mutants that, except for their pale color, have a light-grown morphology (expanded leaves and short, sturdy stems) when grown in the dark (they are not green because the final step in chlorophyll production requires direct light). These mutants have defects in a negative transcription factor that inhibits the expression of other genes normally activated by light. When the negative factor is eliminated by mutation, the pathway that it normally blocks becomes activated. Hence, these mutants, except for their pale color, appear to have been grown in the light.

Post-Translational Modification of Proteins

Although the syntheses of new proteins by transcription and translation are important molecular events associated with de-etiolation, so are post-translational modifications of existing proteins. Most often, these existing proteins are modified by phosphorylation. Many second messengers, including cGMP, aid some receptors themselves, including some forms of phytochrome, activate protein kinases directly. Often, one protein kinase will phosphorylate another protein kinase, which then phosphorylates another, and so on. Such kinase cascades may eventually link initial stimuli to responses at the level of gene expression, usually via the phosphorylation of transcription factors. By such mechanisms, many signal pathways ultimately regulate the synthesis of new proteins, usually by turning specific genes on or off.

Signal pathways must also have a means for turning off once the initial signal is no longer present. For example, what if we put the potato back into the cupboard? Protein phosphatases, enzymes that dephosphorylate specific proteins, are involved in these "switch-off" processes. At any moment, activities of a cell depend on the balance of activity of many types of protein kinases and protein phosphatases.

De-Etiolation ("Greening") Proteins

What sorts of proteins are either newly transcribed or activated by phosphorylation during the de-etiolation process? Many are enzymes that function in photosynthesis directly; others are enzymes involved in supplying the chemical precursors necessary for chlorophyll production; still others affect the levels of plant

hormones that regulate growth. For example, the levels of two kinds of hormones, auxin and brassinosteroids, that enhance stem elongation decrease following phytochrome activation—hence, the reduction in stem elongation that accompanies de-etiolation.

We have discussed the signal transduction involved in the de-etiolation response of a potato in some detail to give you a sense of the complexity of biochemical changes that underlie this one process. Every plant hormone and every environmental stimulus triggers one or more signal transduction pathways of comparable complexity. As with the tomato mutant *aurea*, techniques of molecular biology combined with studies of mutants are helping researchers identify these various pathways. But molecular biology builds on a long history of careful physiological and biochemical investigations into how plants work. As you will read in the next section, classical observations and experiments provided biologists with the first clues that chemical signals—hormones—are internal regulators of plant growth and development.

Concept Check 39.1

1. The sexual dysfunction drug Viagra inhibits an enzyme that breaks down cyclic GMP. Assuming that tomato leaf cells have a similar enzyme, would you predict that applying Viagra will cause a normal de-etiolation of *aurea* tomato leaves?
2. Cycloheximide is a drug that inhibits protein synthesis. Predict what effect cycloheximide would have on de-etiolation.

For suggested answers, see Appendix A.

Concept 39.2

Plant hormones help coordinate growth, development, and responses to stimuli

The word *hormone* is derived from a Greek verb meaning "to excite." Found in all multicellular organisms, hormones are chemical signals that coordinate the different parts of an organism. By definition, a hormone is a compound that is produced by one part of the body and then transported to other parts of the body, where it binds to a specific receptor and triggers responses in target cells and tissues. Another important characteristic of hormones is that only minute amounts are required to induce substantial changes in an organism. Hormone concentrations or the rates of their transport can change in response to environmental stimuli. Often, the response of a plant is governed by the interaction of two or more hormones.

of stem elongation in dark-grown oat seedlings. How is the in-

The Discovery of Plant Hormones

The concept of chemical messengers in plants emerged from a series of classic experiments on how stems respond to light. The shoot of a houseplant on a windowsill grows toward light. If you rotate the plant, it soon reorients its growth until its leaves again face the window. Any growth response that results in curvatures of whole plant organs toward or away from stimuli is called a tropism (from the Greek *tropos*, turn). The growth of a shoot toward light is called positive phototropism, whereas growth away from light is negative phototropism.

In a forest or other natural ecosystem where plants may be crowded, phototropism directs growing seedlings toward the sunlight that powers photosynthesis. What is the mechanism for this adaptive response? Much of what is known about phototropism has been learned from studies of grass seedlings, particularly oats. The shoot of a sprouting grass seedling is enclosed in a sheath called the coleoptile (see Figure 38.10b), which grows straight upward if the seedling is kept in the dark or if it is illuminated uniformly from all sides. If the growing coleoptile is illuminated from one side, it grows toward the light. This response results from a differential growth of cells on opposite sides of the coleoptile; the cells on the darker side elongate faster than the cells on the brighter side.

Charles Darwin and his son Francis conducted some of the earliest experiments on phototropism in the late 19th century. They observed that a grass seedling could bend toward light only if the tip of the coleoptile was present (Figure 39.5). If the tip was removed, the coleoptile would not curve. The seedling would also fail to grow toward light if the tip was covered with an opaque cap; neither a transparent cap over the tip nor an opaque shield placed below the coleoptile tip prevented the phototropic response. It was the tip of the coleoptile, the Darwins concluded, that was responsible for sensing light. However, the actual growth response, the curvature of the coleoptile, occurred some distance below the tip. The Darwins postulated that some signal was transmitted downward from the tip to the elongating region of the coleoptile. A few decades later, Peter Boysen-Jensen of Denmark demonstrated that the signal was a mobile chemical substance. He separated the tip from the remainder of the coleoptile by a block of gelatin, which would prevent cellular contact but allow⁷ chemicals to pass. These seedlings responded normally, bending toward light. However, if the tip was experimentally segregated from the lower coleoptile by an impermeable barrier, such as the mineral mica, no phototropic response occurred.

In 1926, Frits Went, a Dutch graduate student, extracted the chemical messenger for phototropism by modifying the experiments of Boysen-Jensen (Figure 39.6). Went removed the coleoptile tip and placed it on a block of agar, a gelatinous material. The chemical messenger from the tip, Went

other enzymes by phosphorylation, a modification in which a

Figure 39.5

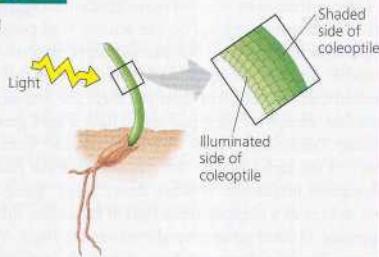

inquiry What part of a coleoptile senses light, and how is the signal transmitted?

EXPERIMENT

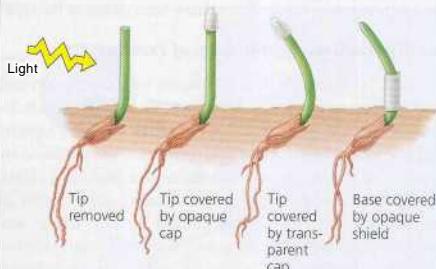

In 1880, Charles Darwin and his son Francis designed an experiment to determine what part of the coleoptile senses light. In 1913, Peter Boysen-Jensen conducted an experiment to determine how the signal for phototropism is transmitted.

RESULTS

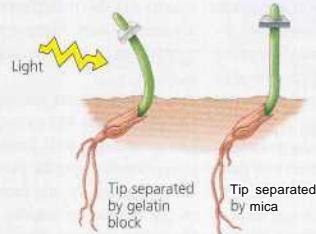

Control

Darwin and Darwin (1880)

Boysen-Jensen (1913)

CONCLUSION

In the Darwins' experiment, a phototropic response occurred only when light could reach the tip of coleoptile. Therefore, they concluded that only the tip senses light. Boysen-Jensen observed that a phototropic response occurred if the tip was separated by a permeable barrier (gelatin) but not if separated by an impermeable solid barrier (a mineral called mica). These results suggested that the signal is a light-activated mobile chemical.

Figure 39.6

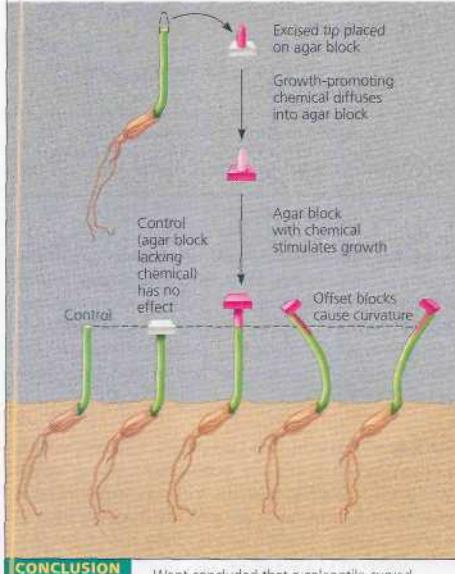

Inquiry Does asymmetric distribution of a growth-promoting chemical cause a coleoptile to grow toward the light?

EXPERIMENT

In 1926, Frits Went's experiment identified how a growth-promoting chemical causes a coleoptile to grow toward light. He placed coleoptiles in the dark and removed their tips, putting some tips on agar blocks that he predicted would absorb the chemical. On a control coleoptile, he placed a block that lacked the chemical. On others, he placed blocks containing the chemical, either centered on top of the coleoptile to distribute the chemical evenly or offset to increase the concentration on one side.

RESULTS

The coleoptile grew straight if the chemical was distributed evenly. If the chemical was distributed unevenly, the coleoptile curved away from the side with the block, as if growing toward light, even though it was grown in the dark.

CONCLUSION

Went concluded that a coleoptile curved toward light because its dark side had a higher concentration of the growth-promoting chemical, which he named auxin.

seasoned, should diffuse into the agar, and the agar block should then be able to substitute for the coleoptile tip. Went placed the agar blocks on decapitated coleoptiles that were kept in the dark. A block that was centered on top of the coleoptile caused the stem to grow straight upward. However, if the block was placed off center, then the coleoptile began to bend away from the side with the agar block, as though growing

toward light. Went concluded that the agar block contained a chemical produced in the coleoptile tip, that this chemical stimulated growth as it passed down the coleoptile, and that a coleoptile curved toward light because of a higher concentration of the growth-promoting chemical on the darker side of the coleoptile. For this chemical messenger, or hormone, Went chose the name auxin (from the Greek *auxein*, to increase). Auxin was later purified by Kenneth Thirnann at the California Institute of Technology and its structure was determined to be indoleacetic acid (IAA).

The classical hypothesis for what causes grass coleoptiles to grow toward light, based on the work of the Darwins and Went, is that an asymmetrical distribution of auxin moving down from the coleoptile tip causes cells on the darker side to elongate faster than cells on the brighter side. However, studies of phototropism by organs other than grass coleoptiles provide less support for this idea. For example, there is no evidence that illumination from one side causes an asymmetrical distribution of auxin in the stems of sunflowers, radishes, and other eudicots. There is, however, an asymmetrical distribution of certain substances that may act as growth inhibitors, with these substances more concentrated on the lighted side of a stem. Early studies on phototropism provided the basis for subsequent research on plant hormones.

A Survey of Plant Hormones

Table 39.1, on the next page, previews some major classes of plant hormones: auxin, cytokinins, gibberellins, brassinosteroids, abscisic acid, and ethylene. Many molecules that function in defense of the plant against pathogens are probably plant hormones as well. (These molecules will be discussed later in the chapter.) Plant hormones are relatively small molecules. Their transport from cell to cell often involves passage across cell walls, which block movement of large molecules.

In general, hormones control plant growth and development by affecting the division, elongation, and differentiation of cells. Some hormones also mediate shorter-term physiological responses of plants to environmental stimuli. Each hormone has multiple effects, depending on its site of action, its concentration, and the developmental stage of the plant.

Plant hormones are produced in very low concentrations, but a minute amount of hormone can have a profound effect on the growth and development of a plant organ. This implies that the hormonal signal must be amplified in some way. A hormone may act by altering the expression of genes, by affecting the activity of existing enzymes, or by changing properties of membranes. Any of these actions could redirect the metabolism and development of a cell responding to a small number of hormone molecules. Signal transduction pathways amplify the hormonal signal and connect it to a cell's specific responses.

Table 39.1 An Overview of Plant Hormones

| Hormone | Where Produced or Found in Plant | Major Functions |
|------------------|---|---|
| Auxin (IAA) | Embryo of seed, meristems of apical buds, young leaves | Stimulates stem elongation (low concentration only), root growth, cell differentiation, and branching; regulates development of fruit; enhances apical dominance; functions in phototropism and gravitropism; promotes xylem differentiation; retards leaf abscission |
| Cytokinins | Synthesized in roots and transported to other organs | Affect root growth and differentiation; stimulate cell division and growth; stimulate germination; delay senescence |
| Gibberellins | Meristems of apical buds and roots, young leaves, embryo | Promote seed and bud germination, stem elongation, and leaf growth; stimulate flowering and development of fruit; affect root growth and differential ion |
| Brassinosteroids | Seeds, fruit, shoots, leaves, and floral buds | Inhibit root growth, retard leaf abscission; promote xylem differentiation |
| Abscisic acid | Leaves, stems, roots, green fruit | Inhibits growth; closes stomata during water stress; promotes seed dormancy |
| Ethylene | Tissues of ripening fruit, nodes of stems, aging leaves and flowers | Promotes fruit ripening, opposes some auxin effects; promotes or inhibits growth and development of roots, leaves, and flowers, depending on species |

Response to a hormone usually depends not so much on the amount of that hormone as on its relative concentration compared with other hormones. It is hormonal balance, rather than hormones acting in isolation, that may control growth and development. These interactions will become apparent in the following survey of hormone function.

Auxin

The term **auxin** is used for any chemical substance that promotes the elongation of coleoptiles, although auxins actually have multiple functions in flowering plants. The natural auxin occurring in plants is indoleacetic acid, or IAA, but several other compounds, including some synthetic ones, have auxin activity. Throughout this chapter, however, the term auxin is used specifically to refer to IAA. Although IAA was the first plant hormone to be discovered, much remains to be learned about auxin signal transduction and the regulation of auxin biosynthesis.

The speed at which auxin is transported down the stem from the shoot apex is about 10 mm/hr, a rate that is much too fast for diffusion, although it is slower than translocation in phloem. Auxin seems to be transported directly through parenchyma tissue, from one cell to the next. It moves only from shoot tip to base, not in the reverse direction. This unidirectional transport of auxin is called polar transport. Polar transport has nothing to do with gravity; experiments have

shown that auxin travels upward when a stem or coleoptile segment is placed upside down. Rather, the polarity of auxin movement is attributable to the polar distribution of auxin transport protein in the cells. Concentrated at the basal end of a cell, the auxin transporters move the hormone out of the cell. The auxin can then enter the apical end of the neighboring cell (Figure 39.7).

The Role of Auxin in Cell Elongation. Although auxin affects several aspects of plant development, one of its chief functions is to stimulate elongation of cells within young developing shoots. The apical meristem of a shoot is a major site of auxin synthesis. As auxin from the shoot apex moves down to the region of cell elongation (see Figure 35.15), the hormone stimulates growth of the cells, probably by binding to a receptor in the plasma membrane. Auxin stimulates growth only over a certain concentration range, from about 10^{-8} to 10^{-4} M. At higher concentrations, auxin may inhibit cell elongation, probably by inducing production of ethylene, a hormone that generally inhibits elongation. We will return to this hormonal interaction when we discuss ethylene.

According to a model called the acid growth hypothesis, proton pumps play a major role in the growth response of cells to auxin. In a shoot's region of elongation, auxin stimulates the plasma membrane's proton pumps. This pumping of H⁺ increases the voltage across the membrane (membrane

Figure 39.7

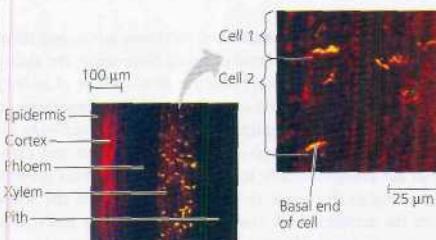

Inquiry > What causes polar movement of auxin from shoot tip to base?

EXPERIMENT

To investigate how auxin is transported Unidirectionally, researchers designed an experiment to identify the location of the auxin transport protein. They used a greenish-yellow fluorescent molecule to label antibodies that bind to the auxin transport protein. They applied the antibodies to longitudinally sectioned *Arabidopsis* stems.

RESULTS

The left micrograph shows that the auxin transport protein is not found in all tissues of the stem, but only in the xylem parenchyma. In the right micrograph, a higher magnification reveals that the auxin transport protein is primarily localized to the basal end of the cells.

CONCLUSION

The results support the hypothesis that concentration of the auxin transport protein at the basal ends of cells is responsible for polar transport of auxin.

potential) and lowers the pH in the cell wall within minutes (Figure 39.8). Acidification of the wall activates enzymes called expansins that break the cross-links (hydrogen bonds) between cellulose microfibrils and other cell wall constituents, loosening the wall's fabric. (Expansins can even weaken the integrity of filter paper made of pure cellulose.) Increasing the membrane potential enhances ion uptake into the cell, which causes osmotic uptake of water and increased turgor. Increased turgor and increased cell wall plasticity enable the cell to elongate.

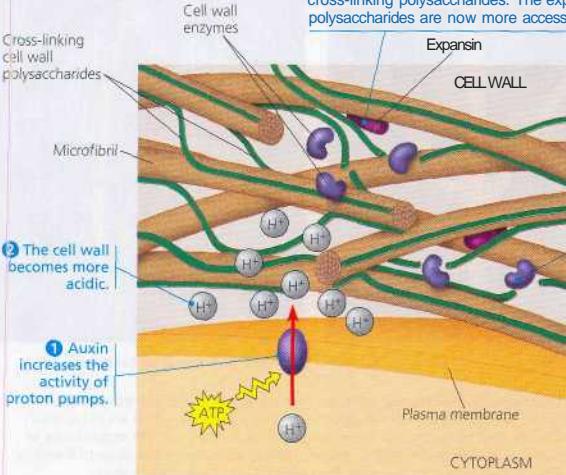

Auxin also alters gene expression rapidly, causing cells in the region of elongation to produce new proteins within minutes. Some of these proteins are short-lived transcription factors that repress or activate the expression of other genes. For sustained growth after this initial spurt, cells must make more cytoplasm and wall material. Auxin also stimulates this sustained growth response.

Lateral and Adventitious Root Formation. Auxins are used commercially in the vegetative propagation of plants by cuttings. Treating a detached leaf or stem with rooting powder containing auxin often causes adventitious roots to form near the cut surface. Auxin is also involved in the branching of roots. Researchers found that an *Arabidopsis* mutant that exhibits extreme proliferation of lateral roots has an auxin concentration 17-fold higher than normal.

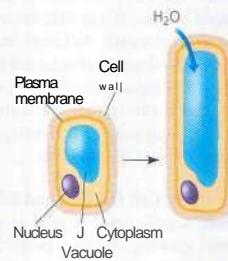

Auxins as Herbicides. A number of synthetic auxins, such as 2,4-dichlorophenoxyacetic acid (2,4-D), are widely used as herbicides. Monocots, such as maize and turfgrass, can rapidly

④ Wedge-shaped expansins, activated by low pH, separate cellulose microfibrils from cross-linking polysaccharides. The exposed cross-linking polysaccharides are now more accessible to cell wall enzymes.

▲ Figure 39.8 Cell elongation in response to auxin: the acid growth hypothesis.

⑤ The enzymatic cleaving of the cross-linking polysaccharides allows the microfibrils to slide. The extensibility of the cell wall is increased. Turgor causes the cell to expand.

⑥ With the cellulose loosened, the cell can elongate.

inactivate such synthetic auxins. However, eudicots cannot and therefore die from hormonal overdose. Spraying cereal fields or turf with 2,4-D eliminates eudicot (broadleaf) weeds such as dandelions.

Other Effects of Auxin. In addition to stimulating cell elongation for primary growth, auxin affects secondary growth. It induces cell division in the vascular cambium and influences differentiation of secondary xylem (see Figures 35.18 and 35.19).

Developing seeds synthesize auxin, which promotes the growth of fruits in plants. Under greenhouse conditions, seed set is often poor because of the lack of insect pollinators; this makes for poorly developed tomato fruits. Synthetic auxins sprayed on greenhouse-grown tomato vines induce fruit development without a need for pollination. This makes it possible to grow seedless tomatoes by substituting synthetic auxin for the auxin normally synthesized by the developing seeds.

Cytokinins

Trial-and-error attempts to find chemical additives that would enhance the growth and development of plant cells in tissue culture led to the discovery of **cytokinins**. In the 1940s, Johannes van Overbeek, working at the Cold Spring Harbor Laboratory in New York, found he could stimulate the growth of plant embryos by adding coconut milk, the liquid endosperm of a coconuts giant seed, to his culture medium. A decade later, Folke Skoog and Carlos O. Miller, at the University of Wisconsin-Madison, induced cultured tobacco cells to divide by adding degraded samples of DNA. The active ingredients of both experimental additives turned out to be some modified forms of adenine, one of the components of nucleic acids. These growth regulators were named cytokinins because they stimulate cytokinesis, or cell division. Of the variety of cytokinins that occur naturally in plants, the most common is zeatin, so named because it was first discovered in maize (*Zea mays*). Although much remains to be learned about cytokinin synthesis and signal transduction, some of the major effects that cytokinins have on the physiology and development of plants are well documented.

Control of Cell Division and Differentiation. Cytokinins are produced in actively growing tissues, particularly in roots, embryos, and fruits. Cytokinins

produced in the root reach their target tissues by moving up the plant in the xylem

sap. Acting in concert with auxin, cytokinins stimulate cell division and influence the pathway of differentiation. The effects of cytokinins on cells growing in tissue culture provide clues about how this class of hormones may function in an intact plant. When a piece of parenchyma tissue from a stem is cultured in the absence of cytokinins, the cells grow very large but do not divide. But if cytokinins are added along with auxin, the cells divide. Cytokinins alone have no effect. The ratio of cytokinin to auxin controls cell differentiation. When the concentrations of the two hormones are at the appropriate levels, the mass of cells continues to grow, but it remains a cluster of undifferentiated cells called a callus (see Figure 38.12). If cytokinin levels are raised, shoot buds develop from the callus. If auxin levels are raised, roots form.

Control of Apical Dominance. Cytokinins, auxin, and other factors interact in the control of apical dominance, the ability of the terminal bud to suppress the development of axillary buds (Figure 39.9a). Until recently, the leading hypothesis to explain the hormonal regulation of apical dominance—the direct inhibition hypothesis—proposed that auxin and cytokinin act antagonistically in regulating axillary bud growth. According to this view, auxin transported down the shoot from the terminal bud directly inhibits axillary buds from growing, causing a shoot to lengthen at the expense of lateral branching. Meanwhile, cytokinins entering the shoot system

A Figure 39.9 Apical dominance. (a) Auxin from the apical bud inhibits the growth of axillary buds. This favors elongation of the shoot's main axis. Cytokinins, which are transported upward from roots, counter auxin, stimulating the growth of axillary buds. This explains why, in many plants, axillary buds near the shoot tip are less likely to grow than those closer to the roots. (b) Removal of the apical bud from the same plant enabled lateral branches to grow.

fro in roots counter the action of auxin by signaling axillary buds to begin growing. Thus, the ratio of auxin and cytokinin was viewed as the critical factor in controlling axillary bud inhibition. Many observations are consistent with the direct inhibition hypothesis. If the terminal bud, the primary source of auxin, is removed, the inhibition of axillary buds is removed and the plant becomes bushier (**Figure 39.9b**). Application of auxin to the cut surface of the decapitated shoot resuppresses the growth of the lateral buds. Mutants that overproduce cytokinins or plants treated with cytokinins also tend to be bushier than normal. One prediction of the direct inhibition hypothesis not borne out by experiment is that decapitation, by removing the primary source of auxin, should lead to a decrease in the auxin levels of axillary buds. Biochemical studies, however, have revealed the opposite: Auxin levels actually increase in the axillary buds of decapitated plants. The direct inhibition hypothesis, therefore, does not account for all experimental findings. It is likely that plant biologists have not uncovered all the pieces of this puzzle.

Anti-Aging Effects. Cytokinins retard the aging of some plant organs by inhibiting protein breakdown, by stimulating RNA and protein synthesis, and by mobilizing nutrients from surrounding tissues. If leaves removed from a plant are dipped in a cytokinin solution, they stay green much longer than otherwise. Cytokinins also slow the deterioration of leaves on intact plants. Because of this anti-aging effect, florists use cytokinin sprays to keep cut flowers fresh.

Gibberellins

A century ago, farmers in Asia noticed that some rice seedlings in their paddies grew so tall and spindly that they toppled over before they could mature and flower. In 1926, Eiwiti Kurosawa, a Japanese plant pathologist, discovered that a fungus of the genus *Gibberella* caused this "foolish seedling disease." By the 1950s, Japanese scientists had determined that the fungus produced hyperelongation of rice stems by secreting a chemical, which was given the name **gibberellin**. In the 1950s, researchers discovered that plants also produce gibberellins. In the past 50 years, scientists have identified more than 100 different gibberellins that occur naturally in plants, although a much smaller number occur in each plant species. "Foolish rice" seedlings, it seems, suffer from an overdose of gibberellins normally found in plants in lower concentrations. Gibberellins have a variety of effects, such as stem elongation, fruit growth, and seed germination.

Stem Elongation. Roots and young leaves are major sites of gibberellin production. Gibberellins stimulate growth of both leaves and stems, but have little effect on root growth. In stems, gibberellins stimulate cell elongation and cell division. Like auxin, gibberellins cause cell wall loosening, but

not by acidifying the cell wall. One hypothesis proposes that gibberellins stimulate cell-wall-loosening enzymes that facilitate the penetration of expansin proteins into the cell wall. Thus, in a growing stem, auxin, by acidifying the cell wall and activating expansins, and gibberellins, by facilitating the penetration of expansins, act in concert to promote elongation.

The effects of gibberellins in enhancing stem elongation are evident when certain dwarf (mutant) varieties of plants are treated with gibberellins. For instance, some dwarf pea plants (including the variety Mendel studied; see Chapter 14) grow to normal height if treated with gibberellins. If gibberellins are applied to plants of normal size, there is often no response. Apparently, these plants are already producing an optimal dose of the hormone.

The most dramatic example of gibberellin-induced stem elongation is bolting, the rapid growth of the floral stalk. In their vegetative state, some plants, such as cabbage, develop in a rosette form, low to the ground with very short internodes. As the plant switches to reproductive growth, a surge of gibberellins induces internodes to elongate rapidly, elevating floral buds that develop at stem tips.

Fruit Growth. In many plants, both auxin and gibberellins must be present for fruit to set. The most important commercial application of gibberellins is in the spraying of Thompson seedless grapes (**Figure 39.10**). The hormone makes the individual grapes grow larger, a trait prized by the consumer. The gibberellin sprays also make the internodes of the grape bunch elongate, allowing more space for the individual grapes. This increase in space, by enhancing air circulation between the grapes, also makes it harder for yeast and other microorganisms to infect the fruits.

A. Figure 39.10 The effect of gibberellin treatment on Thompson seedless grapes. The grape bunch on the left is an untreated control. The bunch on the right is growing from a vine that was sprayed with gibberellin during fruit development.

Germination. The embryo of a seed is a rich source of gibberellins. After water is imbibed, the release of gibberellins from the embryo signals the seeds to break dormancy and germinate. Some seeds that require special environmental conditions to germinate, such as exposure to light or cold temperatures, break dormancy if they are treated with gibberellins. Gibberellins support the growth of cereal seedlings by stimulating the synthesis of digestive enzymes such as α -amylase that mobilize stored nutrients (**Figure 39.11**).

Brassinosteroids

Brassinosteroids are steroids that are chemically similar to cholesterol and the sex hormones of animals. They induce cell elongation and division in stem segments and seedlings at concentrations as low as 10^{-12} M. They also retard leaf abscission and promote xylem differentiation. These effects are so qualitatively similar to those of auxin that it took several years for plant physiologists to determine that brassinosteroids were not types of auxins.

Evidence from molecular biology established brassinosteroids as plant hormones. Joanne Chory and colleagues at the Salk Institute in San Diego were interested in an *Arabidopsis* mutant that had morphological features similar to light-grown plants even though the mutants were grown in the dark. They discovered that the mutation affects a gene that normally codes for an enzyme similar to one involved in steroid synthesis in mammals. They also showed that mutant plants could be re-

stored to normal phenotype by experimental application of brassinosteroids. The mutant studied by Chory was brassinosteroid-deficient.

Abscisic Acid

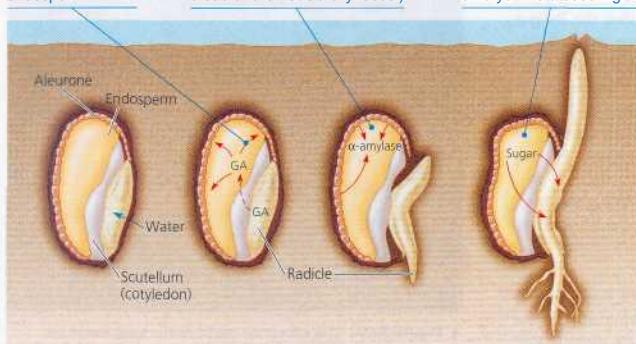

In the 1960s, one research group studying the chemical changes that precede bud dormancy and leaf abscission in deciduous trees and another team investigating chemical changes preceding abscission of cotton fruits isolated the same compound, abscisic acid (ABA). Ironically ABA is no longer drought to play a primary role in bud dormancy or leaf abscission, but it is very important in other functions. Unlike the growth-stimulating hormones we have studied so far—auxin, cytokinins, gibberellins, and brassinosteroids—ABA slows growth. Often, ABA antagonizes the actions of the growth hormones, and it is the ratio of ABA to one or more growth hormones that determines the final physiological outcome. We will consider two of ABAs many effects: seed dormancy and drought tolerance.

Seed Dormancy. Seed dormancy has great survival value because it ensures that the seed will germinate only when there are optimal conditions of light, temperature, and moisture (see Chapter 38). What prevents a seed dispersed in autumn from germinating immediately, only to be killed by winter? What mechanisms ensure that such seeds germinate in the spring? For that matter, what prevents seeds from germinating in the dark, moist interior of the fruit? The answer to these questions is ABA. The levels of ABA may increase 100-fold during seed maturation. The high levels of ABA in maturing seeds inhibit germination and induce the production of special proteins that help the seeds withstand the extreme dehydration that accompanies maturation.

O After a seed imbibes water, the embryo releases gibberellin (GA) as a signal to the aleurone, the thin outer layer of the endosperm.

Q The aleurone responds by synthesizing and secreting digestive enzymes that hydrolyze stored nutrients in the endosperm. One example is α -amylase, which hydrolyzes starch. (A similar enzyme in our saliva helps in digesting bread and other starchy foods.)

Q Sugars and other nutrients absorbed from the endosperm by the scutellum (cotyledon) are consumed during growth of the embryo into a seedling.

A Figure 39.11 Gibberellins mobilize nutrients during the germination of grain seeds.

Many types of dormant seeds germinate when ABA is removed or inactivated in some way. The seeds of some desert plants break dormancy only when heavy rains wash ABA out of the seed. Other seeds require light or prolonged exposure to cold to trigger the inactivation of ABA. Often, the ratio of ABA to gibberellins determines whether the seed remains dormant or germinates, and the addition of ABA to seeds that are primed to germinate returns them to the dormant condition. A maize mutant that has grains that germinate while still on the cob lacks a functional transcription factor required for ABA to induce expression of certain genes (**Figure 39.12**).

A Figure 39.12 Precocious germination of mutant maize seeds.

Abscisic acid induces dormancy in seeds. When its action is blocked—in this case, by a mutation affecting an abscisic-acid-regulated transcription factor—precocious germination results.

Drought Tolerance. ABA is the primary internal signal that enables plants to withstand drought. When a plant begins to wilt, ABA accumulates in leaves and causes stomata to close rapidly, reducing transpiration and preventing further water loss. ABA, through its effects on second messengers such as calcium, causes an increase in the opening of outwardly directed potassium channels in the plasma membrane of guard cells, leading to a massive loss of potassium from them. The accompanying osmotic loss of water leads to a reduction in guard cell turgor and a decrease in stomatal aperture (see Figure 36.15). In some cases, water shortage can stress the root system before the shoot system, and ABA transported from roots to leaves may function as an "early warning system." Mutants that are especially prone to wilting are in many cases deficient in the production of ABA.

Ethylene

During the 1800s, when coal gas was used for street illumination, leakage from gas mains caused nearby trees to drop leaves prematurely. In 1901, the Russian scientist Dmitry Ndjubow demonstrated that the gas ethylene was the active factor in "illuminating gas." The idea that ethylene is a plant hormone only became widely accepted, however, when the advent of gas chromatography simplified measurement.

Plants produce ethylene in response to stresses such as drought, flooding, mechanical pressure, injury, and infection. Production also occurs in fruit ripening and programmed cell death and in response to high concentrations of externally applied auxin. Indeed, many effects previously ascribed to auxin, such as inhibition of root elongation, may be due to auxin-induced ethylene production. We will focus on four of ethylene's many effects: response to mechanical stress, programmed cell death, leaf abscission, and fruit ripening.

The Triple Response to Mechanical Stress, imagine a pea seedling pushing upward through the soil, only to come up against a stone. As it pushes against the obstacle, the stress in its delicate tip induces the seedling to produce ethylene. The hormone then instigates a growth maneuver known as the triple response that enables the shoot to avoid the obstacle. The three parts of this response are a slowing of stem elongation, a thickening of the stem (which makes it stronger), and a curvature that causes the stem to start growing horizontally. As the stem continues to grow, its tip touches upward intermittently. If these movements continue to detect a solid object above, then another pulse of ethylene is generated and the stem continues its horizontal progress. If, however, the upward touch detects no solid object, then ethylene production decreases, and the stem, now clear of the obstacle, resumes its normal upward growth. It is ethylene that induces the stem to grow horizontally rather than the physical obstruction per se; when ethylene is applied to normal seedlings growing free of all physical impediments, they still undergo the triple response (Figure 39.13).

Figure 39.13

Inquiry How does ethylene concentration affect the triple response in seedlings?

EXPERIMENT Germinating pea seedlings were placed in the dark and exposed to varying ethylene concentrations. Their growth was compared with a control seedling not treated with ethylene.

RESULTS All the treated seedlings exhibited the triple response. Response was greater with increased concentration.

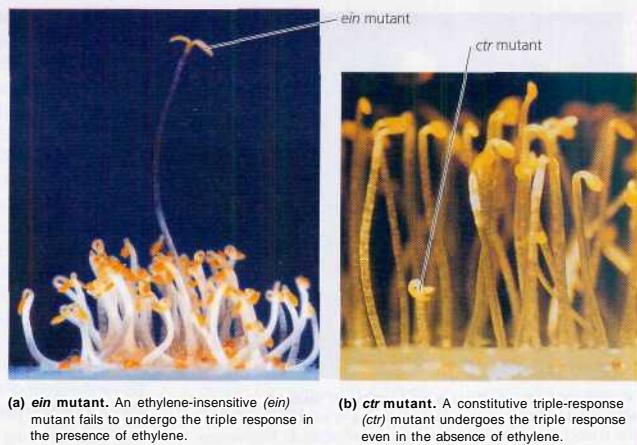

CONCLUSION Ethylene induces the triple response in pea seedlings; with increased ethylene concentration causing increased response.

Studies of *Arabidopsis* mutants with abnormal triple responses are an example of how biologists identify a signal transduction pathway. Scientists isolated ethylene-insensitive (*ein*) mutants that fail to undergo the triple response after exposure to ethylene (Figure 39.14a). Some types of *ein* mutants are insensitive to ethylene because they lack a functional ethylene receptor. Other mutants undergo the triple response even out of soil, in the air, where there are no physical obstacles. Some mutants of this type have a regulatory defect that causes them to produce ethylene at rates 20 times normal. The phenotype of such ethylene-overproducing (*eto*) mutants can be restored to wild-type by treating the seedlings with inhibitors of ethylene synthesis. Still other mutants, called constitutive triple-response (*ctr*) mutants, undergo the triple response in air but do not respond to inhibitors of ethylene synthesis (Figure 39.14b). In this case, ethylene signal transduction is permanently turned on, even though there is no ethylene present. Figure 39.15 summarizes the responses of *ein*, *eto*, and *ctr* mutants to ethylene and ethylene synthesis inhibitors.

The affected gene in *ctr* mutants turns out to encode a protein kinase. The fact that this mutation activates the ethylene response suggests that the normal kinase product of the wild-type allele is a negative regulator of ethylene signal transduction. Here is one hypothesis for how the pathway works in wild-type plants: Binding of the hormone ethylene to the ethylene receptor leads to inactivation of the kinase; and inactivation of this negative regulator allows synthesis of the proteins required for the triple response.

Apoptosis: Programmed Cell Death. Consider the shedding of a leaf in autumn or the death of an annual after flowering. Or think about the final step in differentiation of a vessel element, when its living contents are destroyed, leaving a hollow tube behind. Such events involve programmed death of certain cells or organs—or of the entire plant. Cells, organs, and plants genetically programmed to die on a schedule do not simply shut down cellular machinery and await death. Rather, the onset of programmed cell death, called apoptosis, is a very busy time in a cell's life, requiring new gene expression (see Figure 21.17). During apoptosis, newly formed enzymes break down many chemical components, including chlorophyll, DNA, RNA, proteins, and membrane lipids. The plant salvages many of the breakdown products. A burst of ethylene is almost always associated with this programmed destruction of cells, organs, or the whole plant.

A Figure 39.14 Ethylene triple-response *Arabidopsis* mutants.

| | Control | Ethylene added | Ethylene synthesis inhibitor |
|---|---------|----------------|------------------------------|
| Wild-type | Normal | Bent | Normal |
| Ethylene insensitive (<i>ein</i>) | Normal | Normal | Normal |
| Ethylene overproducing (<i>eto</i>) | Bent | Bent | Normal |
| Constitutive triple response (<i>ctr</i>) | Bent | Bent | Bent |

A Figure 39.15 Ethylene signal transduction mutants can be distinguished by their different responses to experimental treatments.

Leaf Abscission. The loss of leaves each autumn is an adaptation that keeps deciduous trees from desiccating during winter when the roots cannot absorb water from the frozen ground. Before leaves abscise, many essential elements are salvaged from the dying leaves and are stored in stem parenchyma cells. These

nutrients are recycled back to developing leaves the following spring. Fall color is a combination of new red pigments made during autumn and yellow and orange carotenoids (see Chapter 10) that were already present in the leaf but are rendered visible by the breakdown of the dark green chlorophyll in autumn.

When an autumn leaf falls, the breaking point is an abscission layer that develops near the base of the petiole (Figure 39.16). The small parenchyma cells of this layer have very thin walls, and there are no fiber cells around the vascular tissue. The abscission layer is further weakened when enzymes hydrolyze polysaccharides in the cell walls. Finally, the weight of the leaf, with the help of wind, causes a separation within the abscission layer. Even before the leaf falls, a layer of cork forms a protective scar on the twig side of the abscission layer, preventing pathogens from invading the plant.

A change in the balance of ethylene and auxin controls abscission. An aging leaf produces less and less auxin, and this renders the cells of the abscission layer more sensitive to ethylene. As the influence of ethylene on the abscission layer

▲ Figure 39.16 Abscission of a maple leaf. Abscission is controlled by a change in the balance of ethylene and auxin. The abscission layer can be seen here as a vertical band at the base of the petiole. After the leaf falls, a protective layer of cork becomes the leaf scar that helps prevent pathogens from invading the plant (LM).

prevails, the cells produce enzymes that digest the cellulose and other components of cell walls.

Fruit Ripening. Immature fleshy fruits that are tart, hard, and green help protect the developing seeds from herbivores. After ripening, the mature fruits help *attract* animals that disperse the seeds (see Figures 30.8 and 30.9). A burst of ethylene production in the fruit triggers the ripening process. The enzymatic breakdown of cell wall components softens the fruit, and the conversion of starches and acids to sugars makes the fruit sweet. The production of new scents and colors will help advertise ripeness to animals, which eat the fruit and disperse the seeds.

A chain reaction occurs during ripening: Ethylene triggers ripening, and ripening then triggers even more ethylene production—one of the rare examples of positive feedback in physiology (see Figure 1.12). The result is a huge burst in ethylene production. Because ethylene is a gas, the signal to ripen even spreads from fruit to fruit: One bad apple, in fact, does spoil the lot. If you pick or buy green fruit, you may be able to speed ripening by storing the fruit in a paper bag, allowing the ethylene gas to accumulate. On a commercial scale, many kinds of fruits are ripened in huge storage containers in which ethylene levels are enhanced. In other cases, measures are taken to retard ripening caused by natural ethylene. Apples, for instance, are stored in bins flushed with carbon dioxide. Circulating air prevents ethylene from accumulating, and carbon dioxide inhibits synthesis of new ethylene. Stored in this way, apples picked in autumn can still be shipped to grocery stores the following summer.

Given the importance of ethylene in the post-harvest physiology of fruits, the genetic engineering of ethylene signal transduction pathways has potentially important commercial applications. For example, molecular biologists, by engineering a way to block the transcription of one of the genes required for ethylene synthesis, have created tomato fruits that ripen on demand. These fruits are picked while green and will not ripen unless ethylene gas is added. As such methods are refined, they will reduce spoilage of fruits and vegetables, a problem that currently ruins almost half the produce harvested in the United States.

Systems Biology and Hormone Interactions

As we have discussed, plant responses often involve interactions of many hormones and their signal transduction pathways. The study of hormone interactions can be a complex problem. For example, flooding of deepwater rice leads to a 50-fold increase in internal ethylene and a rapid increase in stem elongation. But ethylene's role in this response is a small part of the story. Flooding also leads to an increase in sensitivity to GA that is mediated by a decrease in ABA levels. Thus, stem elongation is actually the result of an interaction among these three hormones and their signal transduction chains.

Imagine yourself as a molecular biologist assigned the task of genetically engineering a deepwater rice plant so that it grows even faster when submerged. What would be the best molecular targets for genetic manipulation? An enzyme that inactivates ABA? An enzyme that produces more GA? An ethylene receptor? It is difficult to predict. And this is by no means an isolated problem. Virtually every plant response discussed in this chapter is of comparable complexity. Because of this pervasive and unavoidable problem of complex interactions, many plant biologists, including Natasha Raikhel, who is interviewed on pages 710–711, are promoting a new systems-based approach to plant biology.

Chapter 1 provided a general description of systems biology, which attempts to discover and understand biological properties that emerge from the interactions of many system elements (for example, mRNAs, proteins, hormones, and metabolites). Using genomic techniques, biologists can now identify all the genes in a plant and have already sequenced two plant genomes—the research plant *Ambidopsis* and the crop plant rice (*Oryza sativa*). Moreover, using microarray and proteomic techniques (see Chapter 20), scientists can resolve which genes are activated or inactivated during development or in response to an environmental change. However, identifying all the genes and proteins (system elements) in an organism is comparable to listing all the parts of an airplane. Although such a list provides a catalog of components, it is not sufficient for understanding the complexity underlying the integrated system. What plant biologists really need to know is how all these system elements interact.

A systems-based approach may greatly alter how plant biology is done. The dream is that laboratories will be equipped with fast-moving (high-throughput) robotic scanners that record which genes in a plant's genome are activated in which cells and under what conditions. New hypotheses and avenues of research will emerge from analysis of these comprehensive data sets. Ultimately one goal of systems biology is to model a living plant predictably. Armed with such detailed knowledge, a molecular biologist attempting to genetically engineer faster stem elongation into rice could proceed much more efficiently. The ability to model a living plant would facilitate predicting the result of a genetic manipulation before even setting foot in the laboratory.

Concept Check 39.2

- Predict the triple-response phenotype of a plant with the double mutation *ctr* and *tin*. Explain.
- In a diseased state known as "witch's broom," branches grow and proliferate excessively. Suggest a hypothesis to explain how a pathogen might induce this growth pattern.
- Fusicoccin is a fungal toxin that stimulates the plasma membrane H⁺ pump of plant cells. How might it affect growth of isolated stem sections?

For suggested answers, see Appendix A.

Concept 39.3

Responses to light are critical for plant success

Light is an especially important environmental factor in the lives of plants. In addition to being required for photosynthesis, light cues many key events in plant growth and development. Effects of light on plant morphology are what plant biologists call **photomorphogenesis**. Light reception also allows plants to measure the passage of days and seasons.

Plants can detect not only the presence of light but also its direction, intensity, and wavelength (color). A graph called an **action spectrum** depicts the relative effectiveness of different wavelengths of radiation in driving a particular process. For example, the action spectrum for photosynthesis has two peaks, one in the red and one in the blue (see Figure 10.9). This is because chlorophyll absorbs light primarily in the red and blue portions of the visible spectrum. Action spectra are useful in the study of *any* process that depends on light, such as phototropism (Figure 39.17). By comparing action spectra of different plant responses, researchers determine which responses are mediated by the same photoreceptor (**pigment**). They also compare action spectra with absorption spectra of pigments. A close correspondence suggests that the pigment may be the photoreceptor mediating the response. Action spectra reveal that red and blue light are the most important colors in regulating a plant's photomorphogenesis. These observations led researchers to two major classes of light receptors: **blue-light photoreceptors** and **phytochromes**, photoreceptors that absorb mostly red light.

Blue-Light Photoreceptors

Blue light initiates diverse responses in plants, including phototropism, the light-induced opening of stomata (see Figure 36.14), and the light-induced slowing of hypocotyl elongation that occurs when a seedling breaks ground. The biochemical identity of the blue-light photoreceptor was so elusive that in the 1970s, plant physiologists began to call this putative receptor cryptochrome (from the Greek *kryptos*, hidden, and *chrom*, pigment). In the 1990s, molecular biologist; analyzing *Arabidopsis* mutants found that plants use at least three different types of pigments to detect blue light: *cryptochromes* (for inhibition of hypocotyl elongation), *phototropin* (for phototropism), and a carotenoid-based photoreceptor, called *zeaxanthin* (for stomatal opening).

Phytochromes as Photoreceptors

When we introduced signal transduction in plants earlier in the chapter, we discussed the role of a family of plant pigments called phytochromes in the de-etiolation process

Figure 39.17

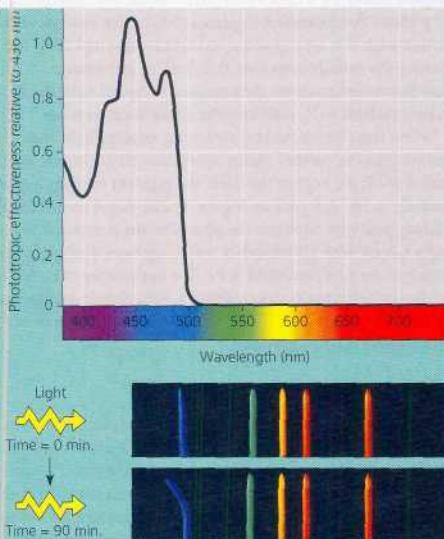

Inquiry! What wavelengths stimulate phototropic bending toward light?

EXPERIMENT

Researchers exposed maize (*zea mays*) coleoptiles to violet, blue, green, yellow, orange, and red light to test which wavelengths stimulate the phototropic bending toward light.

RESULTS

The graph below shows phototropic effectiveness (curvature per photon) relative to effectiveness of light with a wavelength of 436 nm. The photo collage shows coleoptiles before and after 90-minute exposure to side lighting of the indicated colors. Pronounced curvature occurred only with wavelengths below 500 nm and was greatest with blue light.

CONCLUSION

The phototropic bending toward light is caused by a photoreceptor that is sensitive to blue and violet light, particularly blue light.

Figure 39.18

fsHussy! How does the order of red and far-red illumination affect seed germination?

EXPERIMENT

During the 1930s, USDA scientists briefly exposed batches of lettuce seeds to red light or far-red light to test the effects on germination. After the light exposure, the seeds were placed in the dark, and the results were compared with control seeds that were not exposed to light.

RESULTS

The bar below each photo indicates the sequence of red-light exposure, far-red light exposure, and darkness. The germination rate increased greatly in groups of seeds that were last exposed to red light (left). Germination was inhibited in groups of seeds that were last exposed to far-red light (right).

CONCLUSION

Red light stimulated germination, and far-red light inhibited germination. The final exposure was the determining factor. The effects of red and far-red light were reversible.

Phytochromes regulate many of a plant's responses to light throughout its life. Let's look at a couple of examples.

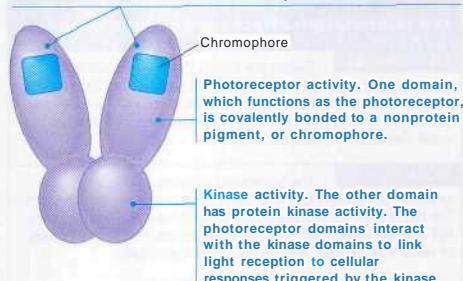

Phytochromes and Seed Germination

Studies of seed germination led to the discovery of phytochromes. Because of their limited nutrient reserves, the successful sprouting of many types of small seeds, such as lettuce, requires germination only when conditions, especially the light environment, are near optimal. Such seeds often remain

dormant for many years until a change in light conditions occurs. For example, the death of a shading tree or the plowing of a field may create a favorable light environment.

In the 1930s, scientists at the U.S. Department of Agriculture determined the action spectrum for light-induced germination of lettuce seeds (Figure 39.18). They exposed water-swollen

A phytochrome consists of two identical proteins joined to form one functional molecule. Each of these proteins has two domains.

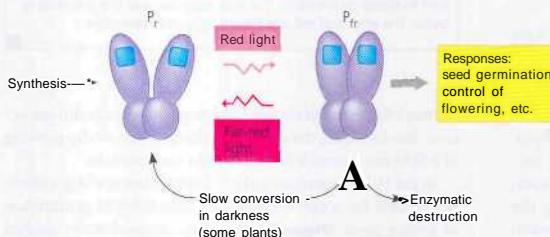

A Figure 39.19 Structure of a phytochrome.

seeds to a few minutes of monochromatic (single-colored) light of various wavelengths and then stored the seeds in the dark. After two days, the researchers counted the number of seeds that had germinated under each light regimen. They found that red light of wavelength 660 nm increased the germination percentage of lettuce seeds maximally, whereas far-red light—that is, light of wavelengths just near the edge of human visibility (730 nm)—inhibited germination compared with dark controls. What happens when the lettuce seeds are subjected to a flash of red (R) light followed by a flash of far-red (FR) light or, conversely, to FR light followed by R light? The last flash of light determines the seeds' response. In other words, the effects of red and far-red light are reversible.

The photoreceptor responsible for the opposing effects of red and far-red light is a phytochrome. It consists of a protein component covalently bonded to a nonprotein part that functions as a chromophore, the light-absorbing part of the molecule (Figure 39.19). So far, researchers have identified five phytochromes in *Arabidopsis*, each with a slightly different protein component.

The chromophore of a phytochrome is photoreversible, reverting back and forth between two isomeric forms, depending on the color of light provided (see Figure 4.7 to review isomers).

In its P_r isomer form, a phytochrome absorbs red light mainly, whereas in its P_{fr} isomer form, it absorbs far-red light:

Red light

Far-red light

$P_r^{\wedge}P_{fr}$ interconversion is a switching mechanism that controls various light-induced events in the life of the plant (Figure 39.20). P_{fr} is the form of phytochrome that triggers many of a plant's developmental responses to light. For example, P_r in lettuce seeds that are exposed to red light is converted to P_{fr} , stimulating the cellular responses that lead to germination. When red-illuminated seeds are then exposed to far-red light, the P_{fr} is converted back to P_r , inhibiting the germination response.

How does phytochrome switching explain light-induced germination in nature? Plants synthesize phytochrome as P_r , and if seeds are kept in the dark, the pigment remains almost entirely in the P_r form (see Figure 39.20). But if the seeds are illuminated with sunlight, the phytochrome is exposed to red light (along with all the other wavelengths in sunlight), and much of the P_r is converted to P_{fr} . The appearance of P_{fr} is one of the ways that plants detect sunlight. When seeds are exposed to adequate sunlight for the first time, it is the appearance of P_{fr} that triggers their germination.

Phytochromes and Shade Avoidance

The phytochrome system also provides the plant with information about the *quality* of light. Sunlight includes both red and far-red radiation. Thus, during the day, the $P_r^{\wedge}P_{fr}$ photo-reversion reaches a dynamic equilibrium, with the ratio of the two phytochrome forms indicating the relative amounts of red and far-red light. This sensing mechanism enables plants to adapt to changes in light conditions. Consider, for example, the "shade-avoidance" response of a tree that requires relatively high light intensity. If other trees in a forest shade this tree, the phytochrome ratio shifts in favor of P_r because the forest canopy screens out more red light than far-red light.

< Figure 39.20 Phytochrome: a molecular switching mechanism. Absorption of red light causes the bluish P_r to change to the blue-greenish P_{fr} . Far-red light reverses this conversion. In most cases, it is the P_{fr} form of the pigment that switches on physiological and developmental responses in the plant.

This is because the chlorophyll pigments in the leaves of the canopy absorb red light and allow far-red light to pass. This shift in the ratio of red to far-red light induces the tree to allocate more of its resources to growing taller. In contrast, direct sunlight increases the proportion of P_{iv} , which stimulates branching and inhibits vertical growth.

In addition to helping plants detect light, phytochrome helps a plant to keep track of the passage of days and seasons. To understand phytochromes' role in these timekeeping processes, we must first examine the clock itself.

B Biological Clocks and Circadian Rhythms

Many plant processes, such as transpiration and synthesis of certain enzymes, oscillate during the course of a day. Some of these cyclic variations are responses to the changes in light levels, temperature, and relative humidity that accompany the 24-hour cycle of day and night. However, one can eliminate these exogenous (external) factors by growing plants in growth chambers under rigidly maintained conditions of light, temperature, and humidity. Even under artificially constant conditions, many physiological processes in plants, such as the opening and closing of stomata and the production of photosynthetic enzymes, continue to oscillate with a frequency of about 24 hours. For example, many legumes lower their leaves in the evening and raise them in the morning (Figure 39.21). A bean plant continues these "sleep movements" even if kept in constant light or constant darkness; the leaves are not simply responding to sunrise and sunset. Such cycles with a frequency that is about 24 hours and not directly paced by any known environmental variable are called circadian rhythms from the Latin *circa*, approximately, and *dies*, day), and they are common to all eukaryotic life. Your pulse, blood pressure, temperature, rate of cell division, blood cell count, alertness, urine composition, metabolic rate, sex drive, and response to medications all fluctuate in a circadian manner.

Current research indicates that the molecular "gears" of the circadian clock are endogenous (internal), rather than a daily

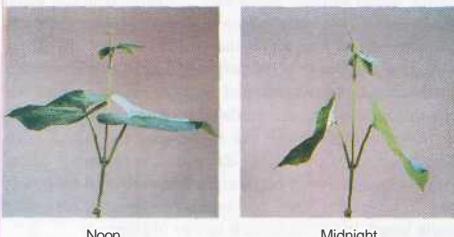

response to some subtle but pervasive environmental cycle, such as geomagnetism or cosmic radiation. Organisms, including plants and humans, will continue their rhythms when placed in the deepest mine shafts or when orbited in satellites, conditions that alter these subtle geophysical periodicities. The circadian clock, however, can be entrained (set) to a period of precisely 24 hours by daily signals from the environment.

If an organism is kept in a constant environment, its circadian rhythms deviate from a 24-hour period (a period is the duration of one cycle). These free-running periods, as they are called, vary from about 21 to 27 hours, depending on the particular rhythmic response. The sleep movements of bean plants, for instance, have a period of 26 hours when the plants are kept in free-running conditions of constant darkness. Deviation of the free-running period from exactly 24 hours does not mean that biological clocks drift erratically. Free-running clocks are still keeping perfect time, but they are not synchronized with the outside world.

How do biological clocks work? In attempting to answer this question, we must distinguish between the clock and the rhythmic processes it controls. For example, the leaves of the bean plant in Figure 39.21 are the clock's "hands," but are not the essence of the clock itself. If bean leaves are restrained for several hours and then released, they will rush to the position appropriate for the time of day. We can interfere with a biological rhythm, but the clockwork continues.

Researchers are tracing the clock to a molecular mechanism that may be common to all eukaryotes. A leading hypothesis is that biological timekeeping may depend on the synthesis of a protein that regulates its own production through feedback control. This protein may be a transcription factor that inhibits transcription of the gene that encodes for the transcription factor itself. The concentration of this transcription factor may accumulate during the first half of the circadian cycle and then decline during the second half owing to self-inhibition of its own production.

Researchers have recently used a novel technique to identify clock mutants of *AroHdopsk*. One prominent circadian rhythm in plants is the daily production of certain photosynthesis-related proteins. Molecular biologists traced this rhythm to the promoter that regulates the transcription of the genes for these photosynthesis proteins. To identify clock mutants, scientists spliced the gene for an enzyme called luciferase to the promoter. Luciferase is the enzyme responsible for the bioluminescence of fireflies. When the biological clock turned on the promoter in the *Arabidopsis* genome, it also turned on the production of luciferase. The plants began to glow with a circadian periodicity. Clock mutants were then isolated by selecting specimens that glowed for a longer or shorter time than normal. The altered genes in some of these mutants affect proteins that normally bind photoreceptors. Perhaps these particular mutations disrupt a light-dependent mechanism that sets the biological clock.

A Figure 39.21 Sleep movements of a bean plant (*Phaseolus vulgaris*). The movements are caused by reversible changes in the turgor pressure of cells on opposing sides of the pulvini, motor organs of the leaf.

The Effect of Light on the Biological Clock

As we have discussed, the free-running period of the circadian rhythm of bean leaf movements is 26 hours. Consider a bean plant placed at dawn in a dark cabinet for 72 hours: Its leaves would not rise again until 2 hours after natural dawn on the second day, and 4 hours after natural dawn on the third day and so on. Shut off from environmental cues, the plant becomes desynchronized. Desynchronization also happens when we cross several time zones in an airplane; when we reach our destination, the clocks on the wall are not synchronized with our internal clocks. All eukaryotes are probably prone to jet lag.

The factor that entrains the biological clock to precisely 24 hours every day is light. Both phytochrome and blue-light photoreceptors can entrain circadian rhythms in plants, but our understanding of how phytochrome does this is more complete. The mechanism involves turning cellular responses on and off by means of the P^AFfr switch.

Consider again the photoreversible system in Figure 39.20. In darkness, the phytochrome ratio shifts gradually in favor of the P_r form, partly a result of turnover in the overall phytochrome pool. The pigment is synthesized in the P_r form, and enzymes destroy more P_f than P_r. In some plant species, P_f present at sundown slowly converts to P_r. In darkness, there is no means for the P_r to be reconverted to P_f, but upon illumination, the P_{fr} level suddenly increases again by rapid conversion from P_r. This increase in P_{fr} each day at dawn resets the biological clock: Bean leaves reach their most extreme night position 16 hours after dawn.

In nature, interactions between phytochrome and the biological clock enable plants to measure the passage of night and day. The relative lengths of night and day, however, change over the course of the year (except at the equator). Plants use this change to adjust activities in synchrony with the seasons.

Photoperiodism and Responses to Seasons

Imagine the consequences if a plant produced flowers when pollinators were not present or if a deciduous tree produced leaves in the middle of winter. Seasonal events are of critical importance in the life cycles of most plants. Seed germination, flowering, and the onset and breaking of bud dormancy are all stages that usually occur at specific times of the year. The environmental stimulus plants use most often to detect the time of year is the photoperiod, the relative lengths of night and day. A physiological response to photoperiod, such as flowering, is called photoperiodism.

Photoperiodism and Control of Flowering

An early clue to how plants detect seasons came from a mutant variety of tobacco, Maryland Mammoth, which grew tall

but failed to flower during summer. It finally bloomed in a greenhouse in December. After trying to induce earlier flowering by varying temperature, moisture, and mineral nutrition, researchers learned that the shortening days of winter stimulated this variety to flower. If the plants were kept in light-tight boxes so that lamps could manipulate "day" and "night," flowering occurred only if the day length was 14 hours or shorter. It did not flower during summer because at Maryland's latitude, the days were too long during that season.

The researchers called Maryland Mammoth a short-day plant, because it apparently required a light period *shorter* than a critical length to flower. Chrysanthemums, poinsettias, and some soybean varieties are some other short-day plants, which generally flower in late summer, fall, or winter. Another group of plants will flower only when the light period is *longer* than a certain number of hours. These long-day plants will generally flower in late spring or early summer. Spinach, for example, flowers when days are 14 hours or longer. "Radish, lettuce, iris, and many cereal varieties are also long-day plants. Day-neutral plants are unaffected by photoperiod and flower when reaching a certain stage of maturity, regardless of day length. Tomatoes, rice, and dandelions are examples.

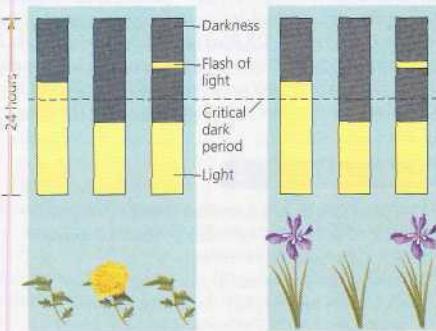

Critical Night Length. In the 1940s, researchers discovered that flowering and other responses to photoperiod are actually controlled by night length, not day length (Figure 39.22). Many of these scientists worked with cocklebur (*Xanthium strumifolium*), a short-day plant that flowers only when days are 16 hours or shorter (and nights are at least 8 hours long!). These researchers found that if the daytime portion of the photoperiod is broken by a brief exposure to darkness, there is no effect on flowering. However, if the nighttime part of the photoperiod is interrupted by even a few minutes of dim light, cocklebur will not flower, and this turned out to be true for other short-day plants as well (see Figure 39.22a). Cocklebur is actually unresponsive to day length, but it requires at least 8 hours of continuous darkness to flower. Short-day plants are really long-night plants, but the older term is embedded firmly in the jargon of plant physiology. Similarly, long-day plants are actually short-night plants. A long-day plant grown on photoperiods of long nights that would not normally induce flowering will flower if the period of continuous darkness is interrupted by a few minutes of light (see Figure 39.22b). Notice that we distinguish long-day from short-day plants *not* by an absolute night length but by whether the critical night length sets a maximum (long-day plants) or minimum (short-day plants) number of hours of darkness required for flowering. In both cases, the actual number of hours in the critical night length is specific to each species of plant.

Red light is the most effective color in interrupting the nighttime portion of the photoperiod. Action spectra and photoreversibility experiments show that phytochrome is the pigment that receives the red light (Figure 39.23). For example, if a flash

Figure 39.22

Inquiry How does interrupting the dark period with a brief exposure to light affect flowering?

EXPERIMENT During the 1940s, researchers conducted experiments in which periods of darkness were interrupted with brief exposure to light to test how the light and dark portions of a photoperiod affected flowering in "short-day" and "long-day" plants.

RESULTS

(a) "Short-day" plants flowered only if a period of continuous darkness was longer than a critical dark period for that particular species (13 hours in this example). A period of darkness can be ended by a brief exposure to light.

(b) "Long-day" plants flowered only if a period of continuous darkness was shorter than a critical dark period for that particular species (13 hours in this example).

CONCLUSION

The experiments indicated that flowering of each species was determined by a critical period of darkness ("critical night length") for that species, not by a specific period of light. Therefore, "short-day" plants are more properly called "long-night" plants, and "long-day" plants are really "short-night" plants.

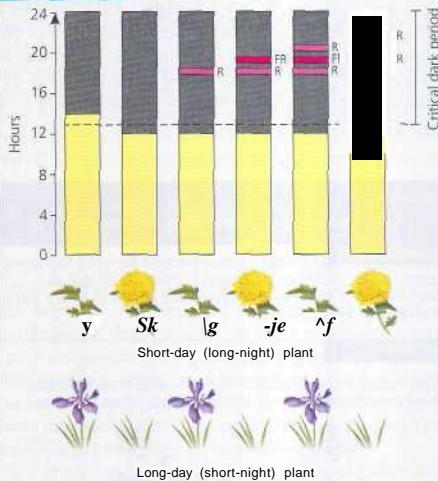

of red light (R) during the dark period is followed by a flash of far-red (FR) light, then the plant detects no interruption, or Light length. As in the case of phytochrome-mediated seed germination, red/far-red photoreversibility occurs.

Plants detect night length very precisely; some short-day plants will not flower if night is even 1 minute shorter than the critical length. Some plant species always flower on the same day each year. It appears that plants use their biological clock, apparently entrained with the help of phytochrome, to tell the season of the year by measuring night length. The floriculture (flower-growing) industry has applied this knowledge to produce flowers out of season. Chrysanthemums, for instance, are short-day plants that normally bloom in fall, but

Figure 39.23

Inquiry Is phytochrome the pigment that measures the interruption of dark periods in photoperiodic response?

EXPERIMENT A unique characteristic of phytochrome is reversibility in response to red and far-red light. To test whether phytochrome is the pigment measuring interruption of dark periods, researchers observed how flashes of red light and far-red light affected flowering in "short-day" and "long-day" plants.

RESULTS

CONCLUSION A flash of red light shortened the dark period. A subsequent flash of far-red light canceled the red light's effect. If a red flash followed a far-red flash, the effect of the far-red light was canceled. This reversibility indicated that it is phytochrome that measures the interruption of dark periods.

their blooming can be stalled until Mother's Day in May by punctuating each long night with a flash of light, thus turning one long night into two short nights.

Some plants bloom after a single exposure to the photoperiod required for flowering. Other species need several successive days of the appropriate photoperiod. Still other plants will respond to a photoperiod only if they have been previously exposed to some other environmental stimulus, such as a period of cold temperatures. Winter wheat, for example, will not flower unless it has been exposed to several weeks of temperatures below 10°C. This use of pretreatment with cold to induce flowering is called vernalization (Latin for "spring"). Several weeks after winter wheat is vernalized, a photoperiod with long days (short nights) induces flowering.

A Flowering Hormone?

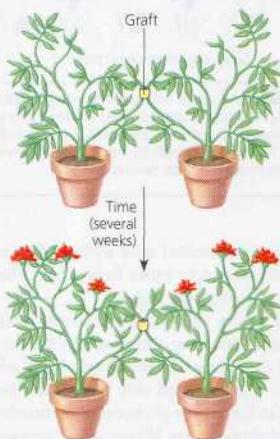

Floral buds develop into flowers, but in many species it is leaves that detect photoperiod. When the photoperiodic requirement for flowering is met, signals from leaves cue buds to develop as flowers. To induce a short-day or long-day plant to flower, it is enough in many species to expose one leaf to the appropriate photoperiod. Indeed, if only one leaf is left attached to the plant, photoperiod is detected and floral buds are induced. If all leaves are removed, the plant is insensitive to photoperiod. The flowering signal, not yet chemically identified, is called **florigen**, and it may be a hormone or change in relative concentrations of multiple hormones (Figure 39.24). The flowering stimulus appears to be the same for short-day and long-day plants, despite differing photoperiodic conditions required for leaves to send this signal.

Figure 39.24
Inquiry Is there a flowering hormone?

EXPERIMENT To test whether there is a flowering hormone, researchers conducted an experiment in which a plant that had been induced to flower by photoperiod was grafted to a plant that had not been induced.

RESULTS

Plant subjected to photoperiod that induces flowering Plant subjected to photoperiod that does not induce flowering

CONCLUSION Both plants flowered, indicating the transmission of a flower-inducing substance. In some cases, the transmission worked even if one was a short-day plant and the other was a long-day plant.

Meristem Transition and Flowering

Whatever combination of environmental cues (such as photoperiod or vernalization) and internal signals (such as hormones) is necessary for flowering to occur, the outcome is the transition of a bud's meristem from a vegetative state to a flowering state. This transition requires changes in the expression of genes that regulate pattern formation. Meristem identity genes that induce the bud to form a flower instead of a vegetative shoot must first be switched on. Then the organ identity genes that specify the spatial organization of the floral organs—sepals, petals, stamens, and carpels—are activated in the appropriate regions of the meristem (see Figure 35.31). Research on flower development is progressing rapidly, and one goal is to identify the signal transduction pathways that link such cues as photoperiod and hormonal changes to the gene expression required for flowering.

Concept Check 39.3

1. A plant flowers in a controlled chamber with a daily cycle of 10 hours of light and 14 hours of darkness. Is it a short-day plant? Explain.
2. Assume that poinsettias grown in a greenhouse require at least 14 hours of darkness to flower. If work has to be done at night, what light source would not disrupt the flowering schedule? Explain.
3. Upon germination, some vine seedlings grow toward darkness until reaching an upright structure. This adaptation helps the vine "find" a shaded object to climb. Suggest an experiment to test whether this negative phototropism is mediated by blue light photoreceptors or by phytochrome.

For suggested answers, see Appendix A.

Concept 39.4

Plants respond to a wide variety of stimuli other than light

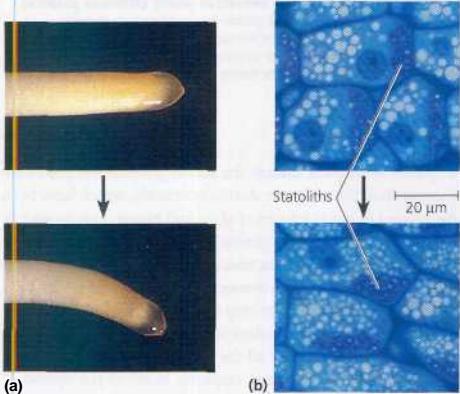

Plants can neither migrate to a watering hole when water is scarce nor seek shelter when the weather is too windy. A seed, landing upside down in the soil, cannot maneuver itself into an upright position. Because of their immobility, plants must adjust to a wide range of environmental circumstances through developmental and physiological mechanisms. Natural selection has refined these responses. Light is so important in the life of a plant that we devoted the entire previous section to a plant's reception of and response to this one environmental factor. In this section, we examine responses to some of the other environmental stimuli that a plant commonly faces in its "struggle for existence."

Gravity

Because plants are solar-powered organisms, it is not surprising that mechanisms for growing toward sunlight have evolved. But what environmental cue does the shoot of a young seedling use to grow upward when it is completely underground and there is no light for it to detect? Similarly, what environmental factor prompts the young root to grow downward? The answer to both questions is gravity.

Place a plant on its side, and it adjusts its growth so that the shoot bends upward and the root curves downward. In their responses to gravity, or gravitropism, roots display positive gravitropism (**Figure 39.25a**) and shoots exhibit negative gravitropism. Gravitropism functions as soon as a seed germinates, ensuring that the root grows into the soil and the shoot reaches sunlight, regardless of how the seed is oriented when it lands. Auxin plays a key role in gravitropism.

Plants may detect gravity by the settling of statoliths, specialized plastids containing dense starch grains, to the lower portions of cells (**Figure 39.25b**). In roots, statoliths are located in certain cells of the root cap. According to one hypothesis, the aggregation of statoliths at the low points of these cells triggers redistribution of calcium, which causes lateral transport of auxin within the root. The calcium and auxin accumulate on the lower side of the root's zone of elongation. Because these chemicals are dissolved, they do not respond to gravity but must be actively

M Figure 39.25 Positive gravitropism in roots: the statolith hypothesis. (a) Over the course of hours, a horizontally oriented primary root of maize will bend gravitropically until its growing tip becomes vertically oriented. (b) Within minutes after the root is placed horizontally, statoliths begin settling to the lowest sides of root cap cells. The statolith hypothesis proposes that this settling may be the gravity-sensing mechanism that leads to redistribution of auxin and differential rates of elongation by cells on opposite sides of the root. (LMs)

transported to one side of the root. At high concentration, auxin inhibits cell elongation, an effect that slows growth on the root's lower side. The more rapid elongation of cells on the upper side causes the root to curve as it grows. This tropism continues until the root grows straight down.

Plant physiologists are refining the "falling statolith" hypothesis of root gravitropism as they try new experiments. For example, mutants of *Ambidopsis* and tobacco that lack statoliths are still capable of gravitropism, though the response is slower than in wild-type plants. It could be that the entire cell helps the root sense gravity by mechanically pulling on proteins that tether the protoplast to the cell wall, stretching the proteins on the "up" side and compressing the proteins on the "down" side of the root cells. Dense organelles, in addition to starch granules, may also contribute by distorting the cytoskeleton as they are pulled by gravity. Stoliths, because of their density, may enhance gravitational sensing by a mechanism that works more slowly in their absence.

Mechanical Stimuli

A tree growing on a windy mountain ridge usually has a shorter, stockier trunk than a tree of the same species growing in a more sheltered location. The advantage of this stunted morphology is that it enables the plant to hold its ground against strong gusts of wind. The term thigmomorphogenesis (from the Greek *thigma*, touch) refers to the changes in form that result from mechanical perturbation. Plants are very sensitive to mechanical stress: Even the act of measuring the length of a leaf with a ruler alters its subsequent growth.

Rubbing the stems of a young plant a couple of times daily results in plants that are shorter than controls (**Figure 39.26**).

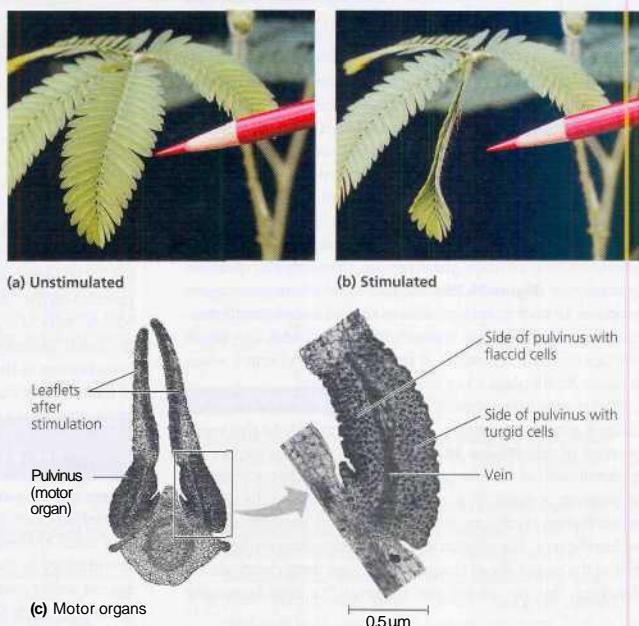

A Figure 39.26 Altering gene expression by touch in *Arabidopsis*. The shorter plant on the left was rubbed twice a day. The untouched plant (right) grew much taller.

Mechanical stimulation activates a signal transduction pathway involving an increase in cytosolic Ca^{2+} that mediates the activation of specific genes, some of which encode for proteins that affect cell wall properties.

Some plant species have become, over the course of their evolution, "touch specialists." Acute responsiveness to mechanical stimuli is an integral part of these plants' life "strategies." Most vines and other climbing plants have tendrils that coil rapidly around supports (see Figure 35.7a). These grasping organs usually grow straight until they touch something; the contact stimulates a coiling response caused by differential growth of cells on opposite sides of the tendril. This directional growth in response to touch is called **thigmotropism**, and it allows the vine to take advantage of whatever mechanical supports it comes across as it climbs upward toward a forest canopy.

Other examples of touch specialists are plants that undergo rapid leaf movements in response to mechanical stimulation. For example, when the compound leaf of the sensitive plant *Mimosa pudica* is touched, it collapses and its leaflets fold together (Figure 39.27). This response, which takes only a second or two, results from a rapid loss of turgor by cells within pulvini, specialized motor organs located at the joints of the leaf. The motor cells suddenly become flaccid after stimulation because they lose potassium, which causes water to leave the cells by osmosis. It takes about 10 minutes for the cells to regain their turgor and restore the "unstimulated" form of the leaf. The function of the sensitive plant's behavior invites speculation. Perhaps by folding its leaves and reducing its surface area when jostled by strong winds, the plant conserves water. Or perhaps because the collapse of the leaves exposes thorns on the stem, the rapid response of the sensitive plant discourages herbivores.

A remarkable feature of rapid leaf movements is the mode of transmission of the stimulus through the plant. If one leaflet on a sensitive plant is touched, first that leaflet responds, then the adjacent leaflet responds, and so on, until all the leaflet pairs have folded together. From the point of stimulation, the signal that produces this response travels at a speed of about 1 cm/sec. An electrical impulse, traveling at the same rate, can be detected by attaching electrodes to the leaf. These impulses, called **action potentials**, resemble nerve

A Figure 39.27 Rapid turgor movements by the sensitive plant (*Mimosa pudica*). (a) In the unstimulated plant, leaflets are spread apart, (b) Within a second or two of being touched, the leaflets have folded together, (c) In these light micrographs of a leaflet pair in the closed (stimulated) state, you can see the motor cells in the sectioned pulvinus (motor organs). The curvature of a pulvinus is caused by motor cells on one side losing water and becoming flaccid while cells on the opposite side retain their turgor.

impulses in animals, though the action potentials of plants are thousands of times slower. Action potentials, which have been discovered in many species of algae and plants, may be widely used as a form of internal communication. Another example is the Venus' flytrap (*Dionaea muscipula*), in which action potentials are transmitted from sensory hairs in the trap to the cells that respond by closing the trap (see Figure 37.13). In the case of *Mimosa pudica*, more violent stimuli, such as touching a leaf with a hot needle, causes all the leaves and leaflets on a plant to droop, but this systemic response involves the spread of chemical signals released from the injured area to other parts of the shoot.

Environmental Stresses

Occasionally, certain factors in the environment change severely enough to have a potentially adverse effect on a plant's survival, growth, and reproduction. Environmental stresses,

such as flooding, drought, or extreme temperatures, can have a devastating impact on crop yields in agriculture. In natural ecosystems, plants that cannot tolerate an environmental stress will either succumb or be outcompeted by other plants, and they will become locally extinct. Thus, environmental stresses are also important in determining the geographic ranges of plants. Here, we will consider some of the more common **abiotic** (nonliving) stresses that plants encounter. In the last section of the chapter, we will examine the defensive responses of plants to common **biotic** (living) stresses, such as pathogens and herbivores.

Drought

On a bright, warm, dry day, a plant may be stressed by a water deficiency because it is losing water by transpiration faster than the water can be restored by uptake from the soil. Prolonged drought can stress crops and the plants of natural ecosystems for weeks or months. Severe water deficit, of course, will kill a plant, as you may know from experience with neglected houseplants. But plants have control systems that enable them to cope with less extreme water deficits.

Many of a plant's responses to water deficit help the plant conserve water by reducing the rate of transpiration. Water deficit in a leaf causes guard cells to lose turgor, a simple control mechanism that slows transpiration, by closing stomata (see Figure 36.15). Water deficit also stimulates increased synthesis and release of abscisic acid in the leaf, and this hormone helps keep stomata closed by acting on guard cell membranes. Leaves respond to water deficit in several other ways. Because cell expansion is a turgor-dependent process, a water deficit will inhibit the growth of young leaves. This response minimizes the transpiration loss of water by slowing the increase in leaf surface. When the leaves of many grasses and other plants wilt from a water deficit, they roll into a shape that reduces transpiration by exposing less leaf surface to dry air and wind. While all of these responses of leaves help the plant conserve water, they also reduce photosynthesis. This is one reason a drought diminishes crop yield.

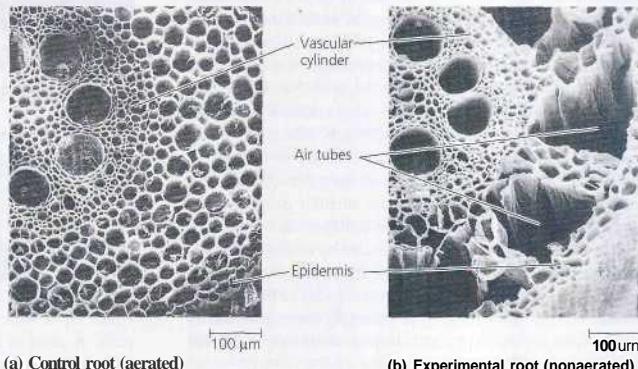

Root growth also responds to water deficit. During a drought, the soil usually dries from the surface down. This inhibits the growth of shallow roots, partly because cells cannot maintain the turgor required for elongation. Deeper roots surrounded by soil that is still moist continue to grow. Thus, the root system proliferates in a way that maximizes exposure to soil water.

Flooding

An overwatered houseplant may suffocate because the soil lacks the air spaces that provide oxygen for cellular respiration in the roots. Some plants are structurally adapted to very wet habitats. For example, the submerged roots of trees called mangroves, which inhabit coastal marshes, are continuous with aerial roots that provide access to oxygen. But how do plants less specialized for aquatic environments cope with oxygen deprivation in waterlogged soils? Oxygen deprivation stimulates the production of the hormone ethylene, which causes some of the cells in the root cortex to undergo apoptosis (programmed cell death). Enzymatic destruction of cells creates air tubes that function as "snorkels," providing oxygen to the submerged roots (Figure 39.28).

Salt Stress

An excess of sodium chloride or other salts in the soil threatens plants for two reasons. First, by lowering the water potential of the soil solution, salt can cause a water deficit in plants even though the soil has plenty of water. As the water potential of the soil solution becomes more negative, the water potential gradient from soil to roots is lowered, thereby reducing water uptake (see Chapter 36). The second problem with saline soil is that sodium and certain other ions are toxic to plants when their concentrations are relatively high. The selectively permeable membranes of root cells impede the uptake of most harmful ions, but this only aggravates the problem of acquiring water from soil that is rich in solutes. Many plants can respond to moderate soil salinity by producing solutes that are well tolerated at high concentrations, mostly organic compounds that keep the water potential of cells more negative than that of the

* **Figure 39.28** A developmental response of maize roots to flooding and oxygen deprivation. (a) A transverse section of a control root grown in an aerated hydroponic medium. (b) An experimental root grown in a non-aerated hydroponic medium. Ethylene-stimulated apoptosis (programmed cell death) creates the air tubes. (SEM)

soil solution without admitting toxic quantities of salt. However, most plants cannot survive salt stress for long. The exceptions are halophytes, salt-tolerant plants with adaptations such as salt glands. These glands pump salts out across the leaf epidermis.

Heat Stress

Excessive heat can harm and eventually kill a plant by denaturing its enzymes and damaging its metabolism in other ways. One function of transpiration is evaporative cooling. On a warm day, for example, the temperature *of* a leaf may be 3–10°C below the ambient air temperature. Of course, hot, dry weather also tends to cause water deficiency in many plants; the closing of stomata in response to this stress conserves water but then sacrifices evaporative cooling. This dilemma is one of the reasons that very hot, dry days take such a toll on most plants.

Most plants have a backup response that enables them to survive heat stress. Above a certain temperature—about 40°C for most plants that inhabit temperate regions—plant cells begin synthesizing relatively large quantities of special proteins called heat-shock proteins. Researchers have also discovered this response in heat-stressed animals and microorganisms. Some heat-shock proteins are chaperone proteins, which function in unstressed cells as temporary scaffolds that help other proteins fold into their functional shapes (see Chapter 5). In their roles as heat-shock proteins, perhaps these molecules embrace enzymes and other proteins and help prevent denaturation.

Cold Stress

One problem plants face when the temperature of the environment falls is a change in the fluidity of cell membranes. Recall from Chapter 7 that a biological membrane is a fluid mosaic, with proteins and lipids moving laterally in the plane of the membrane. When a membrane cools below a critical point, it loses its fluidity as the lipids become locked into crystalline structures. This alters solute transport across the membrane and also adversely affects the functions of membrane proteins. Plants respond to cold stress by altering the lipid composition of their membranes. For example, membrane lipids increase in their proportion of unsaturated fatty acids, which have shapes that help keep membranes fluid at lower temperatures by impeding crystal formation (see Figure 7.5b). Such molecular modification of the membrane requires from several hours to days, which is one reason rapid chilling is generally more stressful to plants than the more gradual drop in air temperature that occurs seasonally.

Freezing is a more severe version of cold stress. At sub-freezing temperatures, ice forms in the cell walls and intercellular spaces of most plants. The cytosol generally does not freeze at the cooling rates encountered in nature because it

contains more solutes than the very dilute solution found in the cell wall, and solutes depress the freezing point of a solution. The reduction in liquid water in the cell wall caused by ice formation lowers the extracellular water potential, causing water to leave the cytoplasm. The resulting increase in the concentration of ionic salts in the cytoplasm is harmful and can lead to cell death. Whether the cell survives depends to a large extent on how resistant it is to dehydration. Plants that are native to regions where winters are cold have special adaptations that enable them to cope with freezing stress. For example, before the onset of winter, the cells of many frost-tolerant species increase their cytoplasmic levels of specific solutes, such as sugars, that are better tolerated at high concentrations and that help reduce the loss of water from the cell during extracellular freezing.

Concept Check 39.4

1. Thermal images are photographs of the heat emitted by an object. Researchers have used thermal imaging of plants to isolate mutants that overproduce abscisic acid. Suggest a reason why these mutants are warmer than wild-type plants under conditions that are normally nonstressful.
2. A worker in a commercial greenhouse finds that the potted chrysanthemums nearest to the aisles are often shorter than those growing in the middle of the bench. Suggest an explanation.

For suggested answers, see Appendix A.

Concept 39.5

Plants defend themselves against herbivores and pathogens

Plants do not exist in isolation but interact with many other species in their communities. Some of these interspecific interactions—for example, the associations of plants with fungi in mycorrhizae (see Figure 37.12) or with pollinators (see Figure 30.13)—are mutually beneficial. Most of the interactions that plants have with other organisms, however, are not beneficial to the plant. As primary producers, plants are at the base of most food webs and are subject to attack by a wide range of plant-eating (herbivorous) animals. A plant is also subject to infection by a diversity of pathogenic viruses, bacteria, and fungi that have the potential to damage tissues or even kill the plant. Plants counter these threats with defense systems that deter herbivory and prevent infection or combat pathogens that do manage to infect the plant.

Defenses Against Herbivores

Herbivoi—animals eating plants—is a stress that plants face in any ecosystem. Plants counter excessive herbivory with both physical defenses, such as thorns, and chemical defenses, such as the production of distasteful or toxic compounds. For example, some plants produce an unusual amino acid called *cNAVANINE*, which is named for one of its sources, the jackbean (*Panavalia ensiformis*). Canavanine resembles arginine, one of the 20 amino acids organisms incorporate into their proteins. If an insect eats a plant containing canavanine, the molecule is incorporated into the insects proteins in place of arginine. Because canavanine is different enough from arginine to adversely affect the conformation and hence the function of the proteins, the insect dies.

Some plants even "recruit" predatory animals that help defend the plant against specific herbivores. For example, insects called parasitoid wasps inject their eggs into their prey, including caterpillars feeding on plants. The eggs hatch within the caterpillars, and the larvae eat through their organic containers from the inside out. The plant, which benefits from the destruction of the herbivorous caterpillars, has an active role in this drama. A leaf damaged by caterpillars releases volatile compounds that attract parasitoid wasps. The stimulus for this response is a combination of physical damage to the leaf caused by the munching caterpillar and a specific compound in the caterpillar's saliva (Figure 39.29).

The volatile molecules a plant releases in response to herbivore damage can also function as an "early warning system" for nearby plants of the same species. Lima bean plants infested with spider mites release volatile chemicals that signal "news"

of the attack to neighboring, noninfested lima bean plants. In response to these volatiles, noninfested lima bean leaves activate defense genes. Volatiles released from leaves mechanically wounded in experiments do not have the same effect. Genes activated by infestation-released volatiles overlap considerably with those produced by exposure to jasmonic acid, an important molecule in plant defense. As a result of this gene activation, noninfested neighbors become less susceptible to spider mites and more attractive to another species of mite that preys on spider mites.

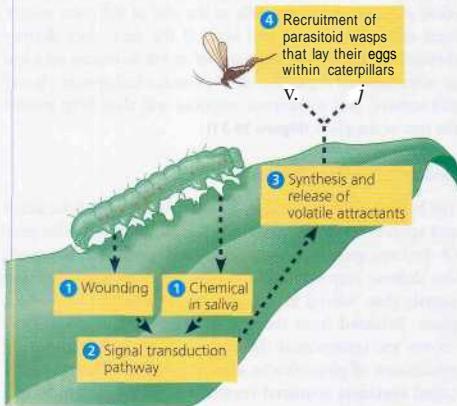

Defenses Against Pathogens

A plant's first line of defense against infection is the physical barrier of the plants "skin," the epidermis of the primary plant body and the periderm of the secondary plant body (see Figure 35.18). This first defense system, however, is not impenetrable. Viruses, bacteria, and the spores and hyphae of fungi can still enter the plant through injuries or through the natural openings in the epidermis, such as stomata. Once a pathogen invades, the plant mounts a chemical attack as a second line of defense that kills the pathogens and prevents their spread from the site of infection. This second defense system is enhanced by the plant's inherited ability to recognize certain pathogens.

Gene-for-Gene Recognition

Plants are generally resistant to most pathogens. This is because plants have the ability to recognize invading pathogens and then to mount successful defenses. In a converse manner, successful pathogens cause disease because they are able to evade recognition or suppress host defense mechanisms. Pathogens against which a plant has little specific defense are said to be **virulent**. They are the exceptions, for if they were not, then hosts and pathogens would soon perish together. A kind of "compromise" has coevolved between plants and most of their pathogens. In such cases, the pathogen gains enough access to its host to enable it to perpetuate itself without severely damaging or killing the plant. Strains of pathogens that only mildly harm but do not kill the host plant are termed avirulent.

Gene-for-gene recognition is a widespread form of plant disease resistance that involves recognition of pathogen-derived molecules by the protein products of specific plant disease resistance (R) genes. There are many pathogens, and plants have many R genes—*Arabidopsis* has at least several hundred. An R protein usually recognizes only a single corresponding pathogen molecule that is encoded by an avirulence (Avr) gene. Many Avr proteins play an active role in pathogenesis and are thought to redirect the host metabolism to the advantage of the pathogen. The questions of how R proteins function and evolve are currently topics of intense research. In the simplest biochemical model (the receptor-ligand model), an

▲ Figure 39.29 A maize leaf "recruits" a parasitoid wasp as a defensive response to an herbivore, an army-worm caterpillar.

R protein functions as a plant receptor molecule that triggers resistance upon binding to the correct corresponding Avr protein (**Figure 39.30**). If the plant lacks the R gene that counteracts the pathogen's Avr gene, then the pathogen can invade and kill the plant. An alternative model of gene-for-gene recognition, dubbed the "guard" hypothesis, proposes that R proteins function as a surveillance system of other plant

proteins that undergo activity or conformational changes induced by Avr proteins. Regardless of the exact mechanism involved, recognition of pathogen-derived molecules by R proteins triggers a signal transduction pathway leading to a defense response in the infected plant tissue. This defense includes both an enhancement of the localized response at the site of infection and a more general systemic response of the whole plant.

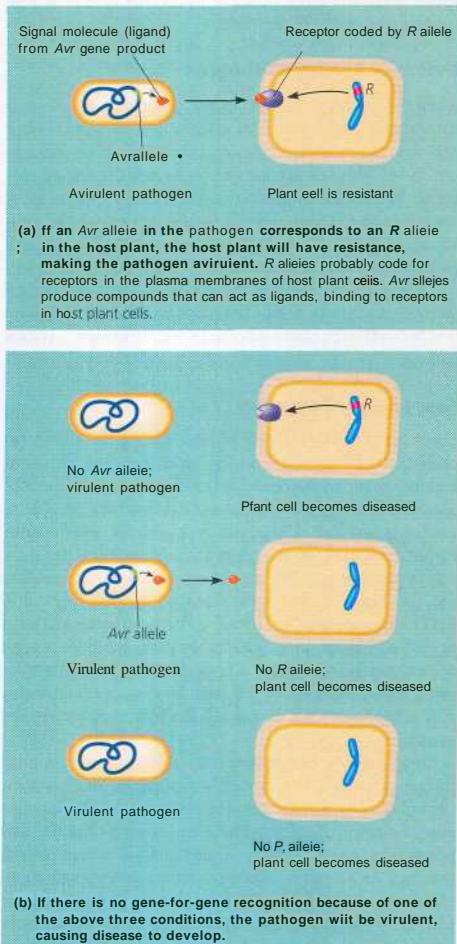

Plant Responses to Pathogen Invasions

In contrast to the strain-specific Avr-R interactions that control plant disease resistance to very narrow groups of pathogens (specifically, strains that contain the appropriate Avr allele), molecules called elicitors induce a broader type of host defense response. Oligosaccharins, derived from cellulose fragments released by cell wall damage, are one of the major classes of elicitors. Elicitors stimulate the production of antimicrobial compounds called phytoalexins. Infection also activates genes that produce PR proteins (pathogenesis-related proteins). Some of these proteins are antimicrobial, attacking molecules in the cell wall of a bacterium, for example. Others may function as signals that spread "news" of the infection to nearby cells. Infection also stimulates the cross-linking of molecules in the cell wall and the deposition of lignin, responses that set up a local barricade that slows spread of the pathogen to other parts of the plant.

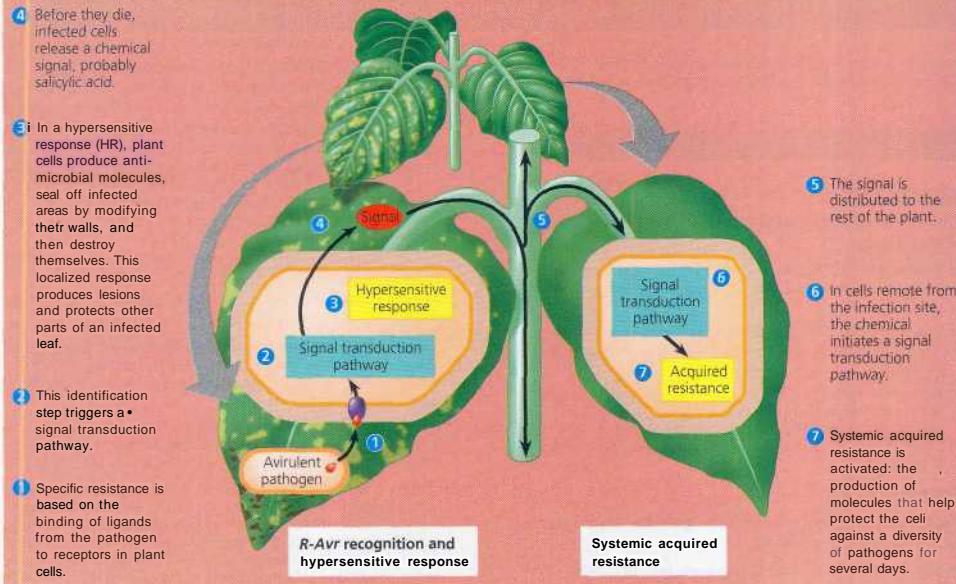

If the pathogen is avirulent based on an R-Avr match, then the localized defense response is even more vigorous and is known as a hypersensitive response (abbreviated HR). There is an enhanced production of phytoalexins and PR proteins, and the "sealing" response that contains the infection is more effective. After the cells at the site of infection mount their chemical defense and seal off the area, they destroy themselves. We can see the result of an HR as lesions on a leaf or other infected organ. As "sick" as such a leaf appears, it will still survive, and its defense response will then help protect the rest of the plant (**Figure 39.31**).

Systemic Acquired Resistance

The hypersensitive response, as you have learned, is localized and specific, a containment response based on gene-for-gene (*R-Avr*) recognition between host and pathogen. However, this defense response also includes production of chemical signals that "sound the alarm" of infection to the whole plant. Released from the site of infection, the alarm hormones are transported throughout the plant, stimulating production of phytoalexins and PR proteins. This response, called systemic acquired resistance (SAR), is nonspecific, providing protection against a diversity of pathogens for days (see Figure 39.31).

A **Figure 39.30** Gene-for-gene resistance of plants to pathogens: the receptor-ligand model.

A **Figure 39.31** Defense responses against an avirulent pathogen.

A good candidate for one of the hormones responsible for activating SAR is **salicylic acid**. A modified form of this compound, acetylsalicylic acid, is the active ingredient in aspirin. Centuries before aspirin was sold as a pain reliever, some cultures had learned that chewing the bark of a willow tree (*Salix*) would lessen the pain of a toothache or headache. With the discovery of systemic acquired resistance, biologists have finally learned one function of salicylic acid in plants. Aspirin turns out to be a natural medicine in the plants that produce it, but with effects entirely different from the medicinal action in humans who consume the drug.

Plant biologists investigating disease resistance and other evolutionary adaptations of plants are getting to the heart of how a plant responds to internal and external signals. These scientists, along with thousands of other plant biologists working on other questions and millions of students experimenting with plants in biology courses, are all extending a

centuries-old tradition of curiosity about the green organisms that feed the biosphere.

Concept Check 39.5

- Chewing insects mechanically damage plants and lessen the surface area of leaves for photosynthesis. In addition, these insects make plants more vulnerable to pathogen attack. Suggest a reason why.
- A scientist finds that a population of plants growing in a breezy location is more prone to defoliation by insects than a population of the same species growing in a sheltered area. Suggest a hypothesis to account for this observation.

For suggested answers, see Appendix A.

Chapter 39 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 39.1

Signal transduction pathways link signal reception to response

- **Reception** (p. 789) Internal and external signals are detected by receptors, proteins that change in response to specific stimuli.
- **Transduction** (pp. 789–790) Second messengers transfer and amplify signals from receptors to proteins that cause specific responses.
- **Response** (pp. 790–791) Responses to stimulation typically involve activation of enzymes by stimulating transcription of mRNA for the enzyme (transcriptional regulation) or by activating existing enzyme molecules (post-translational modification of proteins).

Concept 39.2

Plant hormones help coordinate growth, development, and responses to stimuli

- **The Discovery of Plant Hormones** (pp. 792–793) Researchers discovered auxin by identifying the compound responsible for transmitting a signal downward through coleoptiles, from the tips to the elongating regions, during phototropism.
 - **A Survey of Plant Hormones** (pp. 793–801) Auxin, produced primarily in the apical meristem of the shoot, stimulates cell elongation in different target tissues. Cytokinins, produced in actively growing tissues such as roots, embryos, and fruits, stimulate cell division. Gibberellins, produced in roots and young leaves, stimulate growth in leaves and stems. Brassinosteroids, chemically similar to the sex hormones of animals, induce cell elongation and division. Abscisic acid maintains dormancy in seeds. Ethylene helps control fruit ripening.
- Activity *Leaf Abscission*
Investigation *What Plant Hormones Affect Organ Formation?*
- **Systems Biology and Hormone Interactions** (pp. 801–802) Interactions between hormones and their signal transduction pathways makes it difficult to predict what effect a genetic manipulation will have on a plant. Systems biology seeks a comprehensive understanding of plants that will permit successful modeling of plant functions.

Concept 39.3

Responses to light are critical for plant success

- **Blue-Light Photoreceptors** (p. 802) Various blue-light photoreceptors control hypocotyl elongation, stomatal opening, and phototropism.
- **Phytochromes as Photoreceptors** (pp. 802–805) Phytochromes exist in two photoreversible states, with conversion of P_r to P_f triggering many developmental responses.
- **Biological Clocks and Circadian Rhythms** (p. 805) Free-running circadian cycles are approximately 24 hours long but are entrained to exactly 24 hours by the day/night cycle.

- **The Effect of Light on the Biological Clock** (p. 806) Phytochrome conversion marks sunrise and sunset, providing the clock with environmental cues.

- **Photoperiodism and Responses to Seasons** (pp. 806–808) Some developmental processes, including flowering in many plant species, require a certain photoperiod. For example, a critical night length sets a minimum (in short-day plants) or maximum (in long-day plants) number of hours of darkness required for flowering.

Activity Flowering Lab

Concept 39.4

Plants respond to a wide variety of stimuli other than light

- **Gravity** (p. 809) Response to gravity is known as gravitropism. Roots show positive gravitropism, and stems show negative gravitropism. Specialized plastids called statoliths may enable plants to detect gravity.
- **Mechanical Stimuli** (pp. 809–810) Growth in response to touch is called thigmotropism. Rapid leaf movements are transmissions of electrical impulses called action potentials.
- **Environmental Stresses** (pp. 810–812) During drought, plants respond to water deficit by reducing transpiration. Enzymatic destruction of cells creates air tubes that help plants survive oxygen deprivation during flooding. Plants respond to salt stress by producing solutes tolerated at high concentrations, keeping the water potential of cells more negative than that of the soil solution. Heat-shock proteins help plants survive heat stress. Altering lipid composition of membranes is a response to cold stress.

Concept 39.5

Plants defend themselves against herbivores and pathogens

- **Defenses Against Herbivores** (p. 813) Physical defenses include morphological adaptations such as thorns, chemical defenses such as distasteful or toxic compounds, and airborne attractants that bring animals that destroy herbivores.
- **Defenses Against Pathogens** (pp. 813–815) A pathogen is avirulent if it has a specific *Avr* gene corresponding to a particular *R* allele in the host plant. A hypersensitive response against an avirulent pathogen seals off the infection and kills both pathogen and host cells in the region of the infection. Salicylic acid is a signal molecule that triggers systemic acquired resistance (SAR), generalized defense responses in organs distant from the original site of infection.

TESTING YOUR KNOWLEDGE

Evolution Connection

Coevolution is defined as reciprocal adaptations between two species, with each species adapting in how it interacts with the other. In this context of coevolution, write a paragraph explaining the relationship between a plant and an avirulent pathogen.

Scientific Inquiry

A plant biologist observed a peculiar pattern when a tropical shrub was attacked by caterpillars. After a caterpillar ate a leaf, it would skip over nearby leaves and attack a leaf some distance away. The researcher found that when a leaf was eaten, nearby leaves started making a chemical that deterred caterpillars. Simply removing a leaf did not deter them from eating nearby leaves. The biologist suspected that a damaged leaf sent out a chemical that signaled other leaves. How could the researcher test this hypothesis?

Investigation What Plant Hormones Affect Organ Formation?

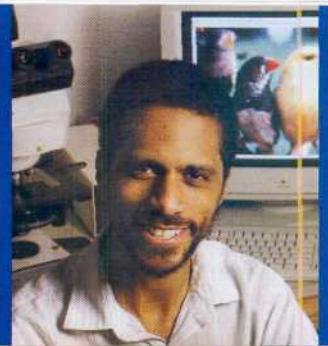

Science, Technology, and Society

Based on your study of this chapter, write a short essay explaining at least three examples of how knowledge about the control systems of plants is applied in agriculture or horticulture.

UNIT

7

Animal Form and Function

AN INTERVIEW WITH Erich Jarvis

Erich Jarvis is an assistant professor at the Duke University Medical Center, where he teaches neuroscience and studies the brain, using vocal communication by zebra finches and other songbirds as his main model system. Growing up in New York City, he attended the High School of the Performing Arts, where he showed great promise as a dancer. However, he chose to go another route, completing a double major in biology and mathematics at Hunter College and then a Ph.D. in molecular neurobiology and animal behavior at Rockefeller University. Dr. Jarvis has won numerous awards, including the National Science Foundation's highest honor for young researchers, the Alan T. Waterman Award. In addition to research and teaching, Dr. Jarvis has long been active in recruiting minority students to science.

What were your educational inspirations and challenges growing up?

Although my parents were separated and we were sometimes poor, I had a lot of support from both sides of my family, and my mother always encouraged me to aspire to something great. Most of my family were in the performing arts, and continuing in that tradition, I had the goal of becoming a dancer. I began with ballet and then went on to jazz and modern dance. But in my senior year of high school, I had a change of heart. I realized I wanted to have a bigger, positive impact in the world, and I thought I could do that best as a scientist. I was an okay student, but I didn't have a strong academic background. So when I got to college, I had to take remedial classes—I had a lot of catching up to do.

Do you see any connection between dance and science?

In terms of what's required for a successful career, I don't really see much of a difference. As a

dancer, you need to have discipline. It's a very difficult field, there's a lot of competition, and you have to practice and practice. As a scientist, you also need discipline, and you have to deal with competition. There are actually more opportunities in science, although science is very difficult. Nature doesn't give up its secrets without a struggle!

On top of that, both fields require creativity. As a performing artist, you want to do something new and beautiful, it's the same for science: You're trying to do something new and creative. Also, in both fields, you have to adapt your schedule to what is required. There's so much overlap between being an artist and being a scientist that I'm amazed people don't see it more.

Why did biology appeal to you?

I think I had something to do with my cultural background. Like many of us in this country, I have a mixed ancestry—mine is African, Native American, and "European. There was something about the cultural atmosphere in my family that seems especially connected to earthly things, nature, and so forth. Perhaps for that reason, I felt more at home in biology than in chemistry or physics, though I liked those subjects too.

Did you get to do research as an undergraduate?

At Hunter College, I benefited from several programs that promoted minority access to careers in scientific research. For four years, I worked in the laboratory of Professor Rivka Rudner, who was studying bacterial genes for ribosomal RNA. It took me almost a year to start to understand things, but then the excitement of laboratory research overcame me like a passion. Dr. Rudner would have to throw me out of the laboratory sometimes and tell me to go home and sleep. But soon after graduation, I published six papers.

What led you to neuroscience?

I was fascinated by the human brain. I wanted to know how the brain generates behavior, how it perceives it, and how it learns it. Of course, I realized that neurobiologists mostly have to work with nonhuman animals. When I got to graduate school, I started reading lots of papers, and I was disappointed to learn how little was known about the behavior of most common model organisms, such as the rat. At the time, neuroscience consisted of anatomy, neurophysiology (the study of nerve impulses and so forth), and an increasing amount of molecular biology—but very little behavior. But then I learned about Fernando Nottebohm's exciting research with songbirds, and I joined his laboratory.

The wonderful thing about the songbird system was that, when I began, there were already 40 years of research on the ecology and natural behavior of these animals. This research was like a box full of ideas for studying the brain mechanisms of songbird behavior, in particular their imitation of sounds. Very few animals have the ability to imitate what they hear—only songbirds, parrots, hummingbirds, bats, dolphins, and humans. Usually the animal imitates sound of its own species, though some species can imitate other species and even mechanical sounds like a car. Fernando Nottebohm had identified nearly the complete brain pathway responsible for a songbird's production of a learned sound. I wanted to combine my molecular biology training with Dr. Nottebohm's discoveries and his knowledge of behavior. Already, an assistant professor in the laboratory, David Clayton, was using molecular biology. I was fascinated by the idea of figuring out the molecular genetics of imitative behavior in songbirds.

How might genes be connected to this sort of behavior?

After years of work on this question, I have now come to believe that what makes a vocal learner are genes that control the construction

of brain circuits that connect to vocal muscles. In addition to studying how genes regulate behavior, we're also studying how behavior regulates genes! The act of producing the learned sounds causes huge, short-term changes in gene expression in certain brain areas. Many of the genes involved encode transcription factors, which regulate the expression of a variety of other genes. When a songbird is singing, we see up to a 60-fold change in the amount of specific mRNAs and proteins in these brain areas.

We think this is happening for most behaviors; in most animals, although we don't yet know the full circuits in other cases—in the zebra finch, for example. But in songbirds, we can study every single group of neurons involved in the singing pathway and how their genes are regulated.

So now we're trying to find out the relationship between the rapid changes in gene expression in the brain as a result of the singing behavior, the electrical impulses that are going through the neural circuitry to regulate both the song genes and the behavior, and the behavior itself. To do this, we have to measure the mRNA and protein synthesis of certain brain cells and record electrical impulses from those same cells, both during the behavior.

How do you do these things?

To detect the electrical impulses, we implant hair-thin microelectrodes in different brain areas of a songbird, usually a zebra finch. The wires are connected to what's called a commutator, a mechanism originally used in helicopters. It allows the bird to fly around in the cage

without getting tangled in the wires. The bird can sing and communicate with other birds while we record the electrical impulses.

To find out which genes are expressed in the nerve cells that are firing, we use DNA microarrays (see Figure 20.14). For this part of our work, we are sequencing the "transcriptome" of the zebra finch brain—the DNA corresponding to all the different mRNAs made in brain tissue. We want to be able to put all the genes expressed in the songbird brain on microarrays. Then we'll be able to identify which genes are involved in any given behavior.

You have also studied birds in the wild. Why?

I wanted to see if the singing-driven gene expression we find in the lab occurs in the real world. So my colleague Claudio Mello and I visited songbird sites in a station wagon loaded with lab equipment and dry ice. To attract wild birds, we played recorded songs, causing males in the vicinity to sing like crazy. After about half an hour, when the products of gene expression in the brain should have accumulated, we captured the birds with a net. Then we took the brains back to the laboratory, and we did find robust singing-driven gene expression in those brains. But more exciting, we also found phenomena that we hadn't seen in the lab: Some brain regions showed different patterns of gene expression that, I later discovered, depended on the social context in which the birds had been singing—to another male, to a female, or something else. And there turns out to be evidence for context-dependent patterns of activity in comparable

brain areas in other animals, such as monkeys. We think there's a context-dependent brain pathway that is used for learned vocalization, speech, and other learned cognitive behaviors.

You're combining many approaches in your work!

Yes, and in addition to molecular biology, anatomy, electrophysiology, and behavior, we're making a lot of use of bioinformatics, which involves math and computer science. Biologists routinely use the computer to analyze gene expression data from DNA microarrays, but we also include in our computer analyses information about anatomical connectivity, behavioral data from song sonograms, and patterns of neural impulses. Our inference algorithm software helps us identify causal relationships and even proposes models we can test experimentally.

We are trying to look at what we study as an integrated system, not just a pattern of regulated genes or a combination of neural circuits. This is the way I approach science: If I'm going to study how something works, I've got to look at all aspects of it. I really encourage people to look at the big picture. That's probably the only way to reach the ultimate goal of understanding how the brain generates speech and language.

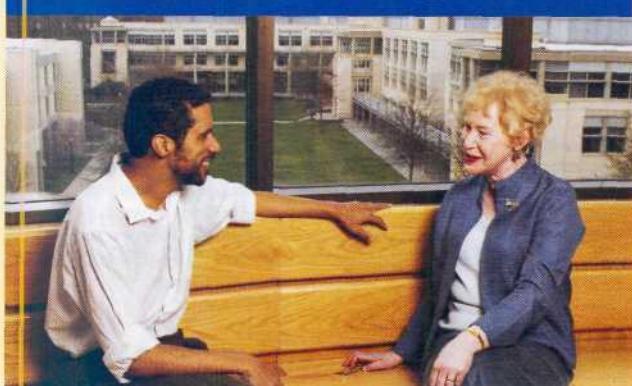

Are there potential medical benefits from this research?

One of our projects relates to Parkinson's disease, which is caused by a degeneration of neurons in certain parts of the brain. We're studying birds with similar defects. The songbird brain area that functions differently in different social contexts is the same area affected by Parkinson's disease in humans, and we see some similarities in vocal behavior associated with this area. For example, people with Parkinson's disease often stutter, and when damage occurs to this area of the bird brain, the affected bird sometimes does too. So we think we might be able to use these birds to study speech disorders.

What is your advice to students interested in biology?

It's important for students, especially those coming from a disadvantaged background, to know that biological research can be a very rewarding career, if you have a passion for it. Like an artist, you have to find your work intrinsically interesting. Figuring out how nature works is not an easy job; there are many frustrations. But intellectually, it can be one of the most rewarding and empowering of career choices.

We are trying to look at what we study as an integrated system. . . . This is the way I approach science: If I'm going to study how something works, I've got to look at all aspects of it. I really encourage people to look at the big picture.

40 Basic Principles of Animal Form and Function

A Figure 40.1 A sphinx moth feeding on orchid nectar.

Key Concepts

- 40.1 Physical laws and the environment constrain animal size and shape
- 40.2 Animal form and function are correlated at all levels of organization
- 40.3 Animals use the chemical energy in food to sustain form and function
- 40.4 Many animals regulate their internal environment within relatively narrow limits
- 40.5 Thermoregulation contributes to homeostasis and involves anatomy, physiology, and behavior

Overview

Diverse Forms, Common Challenges

Animals inhabit almost every part of the biosphere. Despite their amazing diversity of habitat, form, and function, all animals must solve a common set of problems: Animals as different as hydras, halibut, and humans must obtain oxygen, nourish themselves, excrete waste products, and move. How do animals of diverse evolutionary history and varying complexity solve these general challenges of life? As we explore this question throughout Unit 7, note the recurring theme of natural selection and adaptation.

This chapter introduces the unit by presenting some unifying concepts that apply across the animal kingdom. For example, the comparative study of animals reveals that form and function are closely correlated. Consider the long, thin, tongue-like proboscis of the sphinx moth (*Xanthopan morgani*) in **Figure 40.1**. The extended proboscis is a structural adaptation for feeding, serving as a straw through which the moth can suck nectar

from deep within tube-shaped flowers. Analyzing a biological structure, such as a sphinx moth's proboscis, gives us clues about what it does and how it functions. Anatomy is the study of the *structure* of an organism; physiology is the study of the *junctions* an organism performs. Natural selection can fit structure to function by selecting, over many generations, what works best among the available variations in a population. I

A feeding sphinx moth also illustrates an animal's need for fuel in the form of chemical energy. We will apply concepts of bioenergetics—how organisms obtain, process, and use their energy resources—as another theme throughout our comparative study of animals. One use of an animal's energy resources is to regulate its internal environment. In this chapter, we will begin to explore the concept of homeostasis, using the example of body temperature regulation.

Concept 40.1

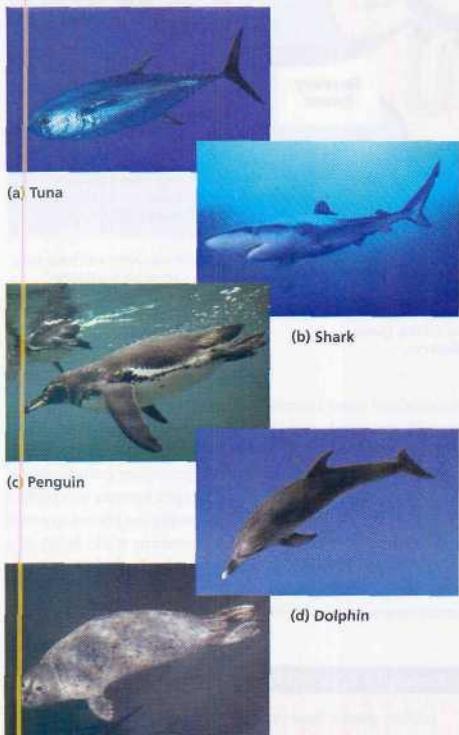

Physical laws and the environment constrain animal size and shape

An animal's size and shape, features that biologists often call "body plans" or "designs,"¹ are fundamental aspects of form and function that significantly affect the way an animal interacts with its environment. By using the terms *plan* and *design* here, we do not mean to imply that animal body forms are products of conscious invention. The body plan of an animal results from a pattern of development programmed by the genome, itself the product of millions of years of evolution. And the possibilities are not infinite—physical laws and the need to exchange materials with the environment place certain limits on the range of animal forms.

Physical Laws and Animal Form

Imagine seeing a winged serpent several meters long and weighing hundreds of kilograms flying through the air. Fortunately, you won't experience such a horrifying sight outside of a movie. Physical requirements constrain what natural selection can "invent," including the size and shape of flying animals. An animal's size and shape of a mythical dragon could not generate enough lift with its wings to get off the ground. This is just one example of how physical laws—in this case, the physics of flight—limit the evolution of an organism's form.

Consider another example: how the laws of hydrodynamics constrain the shapes that are possible for aquatic animals that swim very fast. Water is about a thousand times denser than air; thus, any bump on the body surface that causes drag would impede a swimmer even more than it would a runner or a flyer.

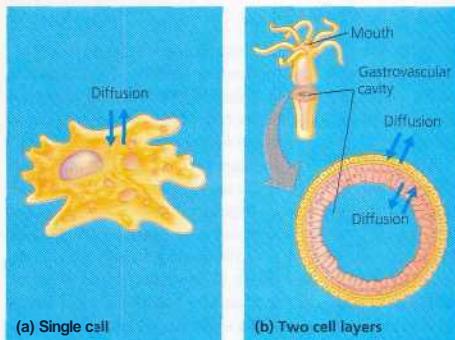

A. **Figure 40.2** Evolutionary convergence in fast swimmers.

Tuna and other fast ray-finned fishes can swim at speeds up to 80 km/hr. Sharks, penguins (birds), and aquatic mammals such as dolphins, seals, and whales are also fast swimmers. These animals all have the same streamlined body form: a fusiform shape, which means tapered on both ends (**Figure 40.2**). The fact that these speedy swimmers have similar shapes is an example of convergent evolution (see Chapter 25). Convergence occurs because natural selection shapes similar adaptations when diverse organisms face the same environmental challenge, such as the resistance of water to fast travel.

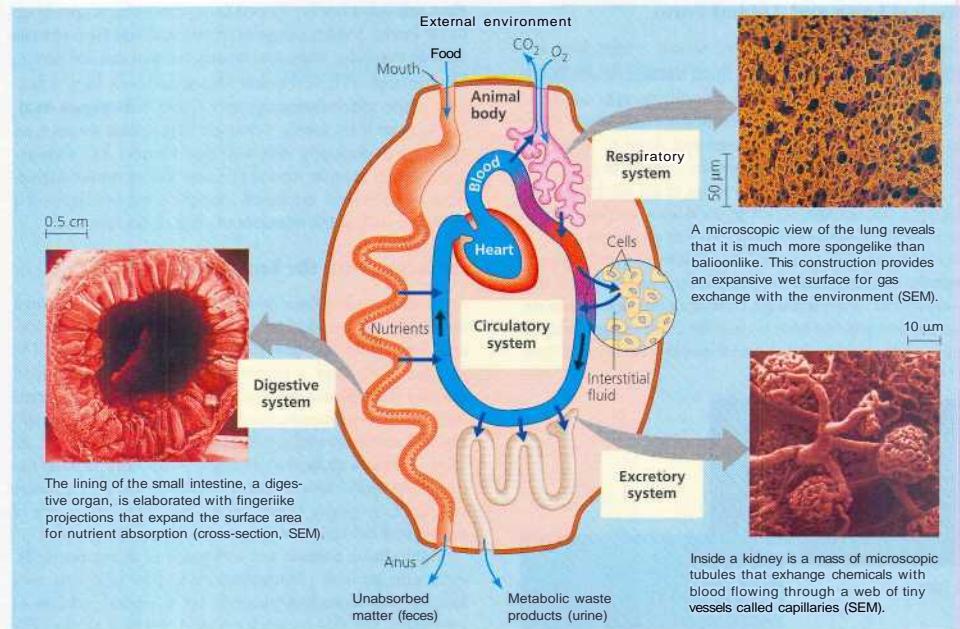

Exchange with the Environment

An animal's size and shape have a direct effect on how the animal exchanges energy and materials with its surroundings. An animal's body plan must allow all of its living cells to be bathed in an aqueous medium, a requirement for maintaining the fluid integrity of the plasma membranes. Exchange with the environment occurs as substances dissolved in the aqueous medium diffuse and are transported across the cells' plasma membranes. As shown in **Figure 40.3a**, a single-celled protist living in water has a sufficient surface area of plasma membrane to service its entire volume of cytoplasm. (Thus, surface-to-volume ratio is one of the physical constraints on the size of single-celled protists.)

Multicellular animals are composed of numerous cells, each with its own plasma membrane that functions as a loading and unloading platform for a modest volume of cytoplasm. But this organization only works if all the cells of the animal have access to a suitable aqueous environment. A hydra, which has a sac-like body plan, has a body wall only two cell layers thick (**Figure 40.3b**). Because its gastrovascular cavity opens to the exterior, both outer and inner layers of cells are

&. **Figure 40.3** Contact with the environment, (a) In unicellular protist, such as this amoeba, the entire surface area contacts the environment. (b) A hydra's body consists of two layers of cells. Because the aqueous environment can circulate in and out of the hydra's mouth, virtually every one of its cells directly contacts the environment and exchanges materials with it.

• **Figure 40.4 Internal exchange surfaces of complex animals.** This diagrammatic animal illustrates the logistics of chemical exchange with the environment by a mammal. Most animals have surfaces that are specialized for exchanging certain chemicals

with the surroundings. These exchange surfaces are usually internal, but are connected to the environment via openings on the body surface (the mouth, for example). The exchange surfaces are finely branched or folded, giving them a very large area. The digestive,

respiratory, and excretory systems all have such exchange surfaces. Chemicals transported across these surfaces are carried throughout the body by the circulatory system.

bathed in water. A flat body shape is another design that maximizes exposure to the surrounding medium. For instance, a parasitic tapeworm may be several meters long, but because it is very thin, most of its cells are bathed in the intestinal fluid of the worm's vertebrate host, the source of nutrients.

Two-layered sacs and flat shapes are designs that put a large surface area in contact with the environment, but these simple forms do not allow much complexity in internal organization. Most animals are more complex and made up of compact masses of cells; their outer surfaces are relatively small compared with their volumes. As an extreme comparison, the surface-to-volume ratio of a whale is hundreds of thousands of times smaller than that of a water flea (*Daphnia*), yet every cell in the whale must be bathed in fluid and have access to oxygen, nutrients, and other resources. Extensively folded or branched internal surfaces facilitate this exchange with the environment in whales and most other animals (Figure 40.4).

Despite the greater challenges of exchange with the environment, complex body forms have distinct benefits. For example,

a specialized outer covering can protect against predators; large muscles can enable rapid movement; and internal digestive organs can break down food gradually, controlling the release of stored energy. And because the cells' immediate environment is the internal body fluid, the animal's organ systems can control the composition of this solution, allowing the animal to maintain a relatively stable internal environment while living in a variable external environment. A complex body form is especially well suited for animals living on land, where the external environment may be highly variable.

Concept Check 40.1

- How does a large surface area contribute to the functions of the small intestine, the lungs, and the kidneys?

For suggested answers, see Appendix A.

Animal form and function are correlated at all levels of organization

As living things, animals exhibit hierarchical levels of organization, each with emergent properties (see Chapter 1). Most animals are composed of specialized cells organized into tissues that have different functions. Tissues are combined into functional units called organs, and groups of organs that work together form organ systems. For example, the digestive system consists of a stomach, small intestine, large intestine, and other organs, each composed of different kinds of tissues.

Tissue Structure and Function

Tissues are groups of cells with a common structure and function. Different types of tissues have different structures that are suited to their functions. For example, a tissue may be held together by a sticky extracellular matrix that coats the cells (see Figure 6.29) or weaves them together in a fabric of fibers. Indeed, the term tissue derives from a Latin word meaning "weave."

Tissues are classified into four main categories—epithelial tissue, connective tissue, muscle tissue, and nervous tissue—explored in **Figure 40.5**, on the next three pages.

Epithelial Tissue

Occurring in sheets of tightly packed cells, epithelial tissue covers the outside of the body and lines organs and cavities within the body. The cells of an epithelial tissue, or epithelium (plural, *epithelia*), are closely joined, with little material between them. In many epithelia, the cells are riveted together by tight junctions (see Figure 6.31). This tight packing enables the epithelium to function as a barrier against mechanical injury, microbes, and fluid loss. Some epithelia, called glandular epithelia, absorb or secrete chemical solutions. For example, the glandular epithelia that line the lumen (cavity) of the digestive and respiratory tracts form a mucous membrane; they secrete mucus that lubricates the surface and keeps it moist.

Two criteria for classifying epithelia are the number of cell layers and the shape of the cells on the exposed surface (see Figure 40.5). A simple epithelium has a single layer of cells, whereas a stratified epithelium has multiple tiers of cells. A "pseudostratified" epithelium is single-layered but appears stratified because the cells vary in length. The shape of the cells at the exposed surface may be cuboidal (like dice), columnar (like bricks standing on end), or squamous (like floor tiles).

Connective Tissue

Connective tissue functions mainly to bind and support other tissues. In contrast to epithelia, with their tightly packed cells,

connective tissues have a sparse population of cells scattered through an extracellular matrix. The matrix generally consists of a web of fibers embedded in a uniform foundation that may be liquid, jellylike, or solid. In most cases, the substances that make up the matrix are secreted by the cells of the connective tissue.

Connective tissue fibers, which are made of protein, are of three kinds: collagenous fibers, elastic fibers, and reticular fibers. Collagenous fibers are made of collagen, probably the most abundant protein in the animal kingdom. Collagenous fibers are nonelastic and do not tear easily when pulled lengthwise. If you pinch and pull some skin on the back of your hand, it is mainly collagen that keeps the flesh from tearing away from the bone. Elastic fibers are long threads made of a protein called elastin. Elastic fibers provide a rubbery quality that complements the nonelastic strength of collagenous fibers. When you release the skin on the back of your hand, elastic fibers quickly restore the skin to its original shape. Reticular fibers are very thin and branched. Composed of collagen and continuous with collagenous fibers, they form a tightly woven fabric that joins connective tissue to adjacent tissues.

The major types of connective tissue in vertebrates are loose connective tissue, adipose tissue, fibrous connective tissue, cartilage, bone, and blood (see Figure 40.5). Among the cells scattered in loose connective tissue, two types predominate: fibroblasts and macrophages. Fibroblasts secrete the protein ingredients of the extracellular fibers. Macrophages are amoeboid cells that roam the maze of fibers, engulfing foreign particles and the debris of dead cells by phagocytosis (see Chapter 6). You will learn more about the specific functions of those cells and various connective tissues later in this unit.

Muscle Tissue

Muscle tissue is composed of long cells called muscle fibers that are capable of contracting, usually when stimulated by nerve signals. Arranged in parallel within the cytoplasm of muscle fibers are large numbers of contracting units called myofibrils made of the proteins actin and myosin. (You will learn more about muscle contraction in Chapter 49.) Muscle is the most abundant tissue in most animals, and muscle contraction accounts for much of the energy-consuming cellular work in an active animal. In the vertebrate body, there are three types of muscle tissue: skeletal muscle, cardiac muscle, and smooth muscle (see Figure 40.5).

Nervous Tissue

Nervous tissue senses stimuli and transmits signals in the form of nerve impulses from one part of the animal to another. The functional unit of nervous tissue is the neuron, or nerve cell, which is uniquely specialized to transmit nerve impulses, as we discuss in detail in Chapter 48. In many animals, nervous tissue is concentrated in the brain, which functions as the control center that coordinates many of the animal's activities.

Exploring Structure and Function in Animal Tissues

EPITHELIAL TISSUE

Columnar epithelia, which have cells with relatively large cytoplasmic volumes, are often located where secretion or active absorption of substances is an important function.

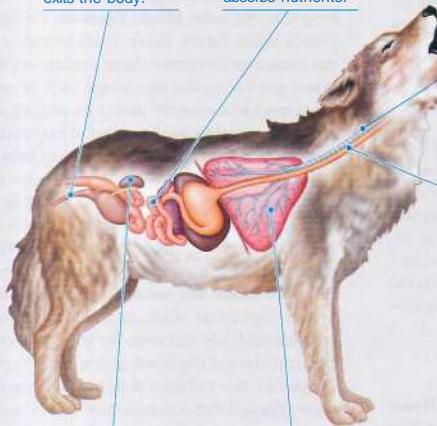

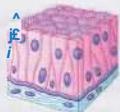

A stratified columnar epithelium lines the inner surface of the urethra, the tube through which urine exits the body.

A simple columnar epithelium lines the intestines. This epithelium secretes digestive juices and absorbs nutrients.

A pseudostratified ciliated columnar epithelium forms a mucous membrane that lines the nasal passages of many vertebrates. The beating cilia move the film of mucus along the surface. The ciliated epithelium of respiratory tubes helps keep lungs clean by trapping dust and other particles and sweeping them back up the trachea (windpipe).

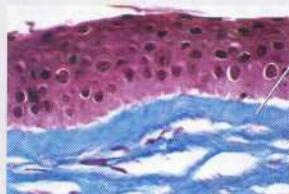

Cuboidal epithelia, with cells specialized for secretion, make up the epithelia of kidney tubules and many glands, including the thyroid gland and salivary glands. Glandular epithelia lining tubules in the thyroid gland secrete a hormone that regulates the body's rate of fuel consumption.

Simple squamous epithelia, which are thin and leaky, function in the exchange of material by diffusion. These epithelia line blood vessels and the air sacs of the lungs, where diffusion of nutrients and gases is critical.

Stratified squamous epithelia regenerate rapidly by cell division near the basement membrane (see below). The new cells are pushed to the free surface as replacements for cells that are continually sloughed off. This type of epithelium is commonly found on surfaces subject to abrasion, such as the outer skin and linings of the esophagus, anus, and vagina. The organization of this type of tissue ensures that abrasion affects the oldest (outermost) cells, while protecting the underlying tissues.

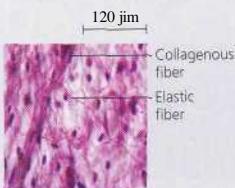

Basement membrane

The cells at the base of an epithelial layer are attached to a **basement membrane**, a dense mat of extracellular matrix. The free surface of the epithelium is exposed to air or fluid.

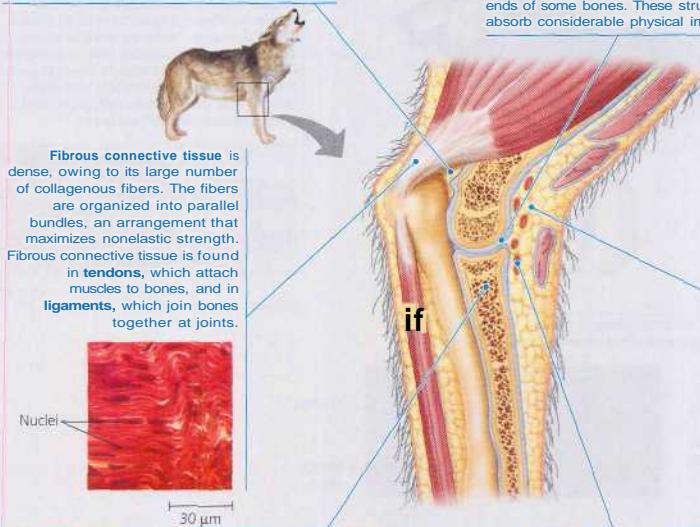

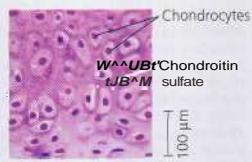

40 μm

CONNECTIVE TISSUE

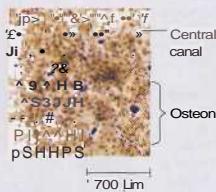

The most widespread connective tissue in the vertebrate body is **loose connective tissue**. It binds epithelia to underlying tissues and functions as "packing material," holding organs in place. Loose connective tissue gets its name from the loose weave of its fibers, which include all three fiber types: collagenous, elastic, and reticular. Fibroblasts and macrophages are scattered in the fibrous mesh.

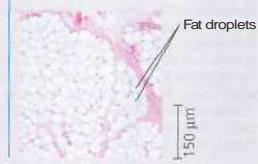

Cartilage has an abundance of collagenous fibers embedded in a rubbery matrix made of a protein-carbohydrate complex called chondroitin sulfate. Chondroitin sulfate and collagen are secreted by cells called **chondrocytes**. The composite of collagenous fibers and chondroitin sulfate makes cartilage a strong yet somewhat flexible support material. Many vertebrates have cartilaginous skeletons during the embryo stage, but most of the cartilage is replaced by bone as the embryo matures. Nevertheless, cartilage is retained in certain locations, such as the discs that act as cushions between vertebrae and the caps on the ends of some bones. These structures' flexibility allows them to absorb considerable physical impact without breaking.

The skeleton supporting the body of most vertebrates is made of **bone**, a mineralized connective tissue. Bone-forming cells called **osteoblasts** deposit a matrix of collagen. Calcium, magnesium, and phosphate ions combine and harden within the matrix into the mineral hydroxyapatite. The combination of hard mineral and flexible collagen makes bone harder than cartilage without being brittle. The microscopic structure of hard mammalian bone consists of repeating units called **osteons** (or Haversian systems). Each osteon has concentric layers of the mineralized matrix, which are deposited around a central canal containing blood vessels and nerves that service the bone.

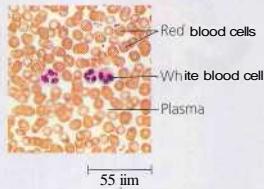

Adipose tissue is a specialized form of loose connective tissue that stores fat in adipose cells distributed throughout its matrix. Adipose tissue pads and insulates the body and stores fuel as fat molecules (see Figure 4.6). Each adipose cell contains a large fat droplet that swells when fat is stored and shrinks when the body uses fat as fuel.

Although **blood** functions differently from other connective tissues, it does meet the criterion of having an extensive extracellular matrix. In this case, the matrix is a liquid called plasma, consisting of water, salts, and a variety of dissolved proteins. Suspended in the plasma are two classes of blood cells, erythrocytes (red blood cells) and leukocytes (white blood cells), and cell fragments called platelets.

Red cells carry oxygen; white cells function in defense against viruses, bacteria, and other invaders; and platelets aid in blood clotting. The liquid matrix enables rapid transport of blood cells, nutrients, and wastes through the body.

Figure 40.5 (continued)

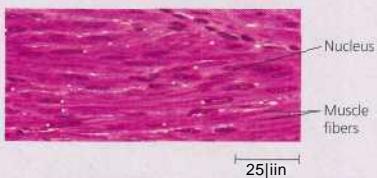

Exploring Structure and Function in Animal Tissues

MUSCLE TISSUE

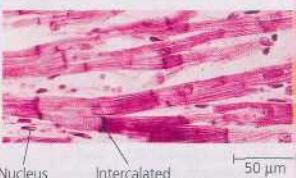

Attached to bones by tendons, skeletal muscle is responsible for voluntary movements of the body. Skeletal muscle consists of bundles of long cells called fibers; each fiber is a bundle of strands called myofibrils. The arrangement of contractile units, or sarcomeres, along the length of the fibers gives the cells a striped (striated) appearance under the microscope. For this reason, skeletal muscle is also called striated muscle. Adult mammals have a fixed number of muscle cells; building muscle does not increase the number of cells but rather enlarges those already present.

Smooth muscle, so named because it lacks striations, is found in the walls of the digestive tract, urinary bladder, arteries, and other internal organs. The cells are spindle-shaped. They contract more slowly than skeletal muscles but can remain contracted longer. Controlled by different kinds of nerves than those controlling skeletal muscles, smooth muscles are responsible for involuntary body activities, such as churning of the stomach or constriction of arteries.

Cardiac muscle forms the contractile wall of the heart. It is striated like skeletal muscle and has contractile properties similar to those of skeletal muscle. Unlike skeletal muscle, however, cardiac muscle carries out an unconscious task: contraction of the heart. Cardiac muscle fibers branch and interconnect via intercalated disks, which relay signals from cell to cell and help synchronize the heartbeat.

Nerve cells (neurons) are the basic units of the nervous system. A neuron consists of a cell body and two or more extensions, or processes, called dendrites and axons, which in certain neurons may be as long as a meter in some animals. Dendrites transmit impulses from their tips toward the rest of the neuron. Axons transmit impulses toward another neuron or toward an effector, a structure such as a muscle cell that carries out a body response. The long axons of some motor neurons enable quick responses by voluntary muscles.

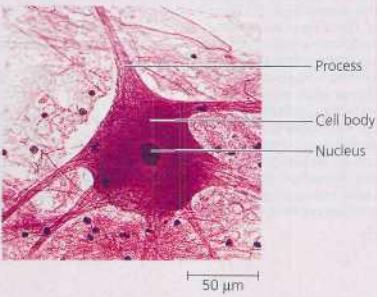

Table 40.1 Organ Systems: Their Main Components and Functions in Mammals

| Organ System | Main Components | Main Functions |
|----------------------|--|--|
| Digestive | Mouth, pharynx, esophagus, stomach, intestines, liver, pancreas, anus | Food processing (ingestion, digestion, absorption, elimination) |
| Circulatory | Heart, blood vessels, blood | Internal, distribution of materials |
| Respiratory | Lungs, trachea, other breathing tubes | Gas exchange (uptake of oxygen; disposal of carbon dioxide) |
| Immune and lymphatic | Bone marrow, lymph nodes, thymus, spleen, lymph vessels, white blood cells | Body defense (fighting infections and cancer) |
| Excretory | Kidneys, ureters, urinary bladder, urethra | Disposal of metabolic wastes; regulation of osmotic balance of blood |
| Endocrine | Pituitary, thyroid, pancreas, other hormone-secreting glands | Coordination of body activities (such as digestion, metabolism) |
| Reproductive | Ovaries, testes, and associated organs | Reproduction |
| Nervous | Brain, spinal cord, nerves, sensory organs | Coordination of body activities; detection of stimuli and formulation of responses to them |
| Integumentary | Skin and its derivatives (such as hair, claws, skin glands) | Protection against mechanical injury, infection, drying out; thermoregulation |
| Skeletal | Skeleton (bones, tendons, ligaments, cartilage) | Body support, protection of internal organs, movement |
| Muscular | Skeletal muscles | Movement, locomotion |

Organs and Organ Systems

In all but the simplest animals (sponges and some cnidarians), different tissues are organized into organs. In some organs, the tissues are arranged in layers. For example, the vertebrate stomach has four major tissue layers (**Figure 40.6**).

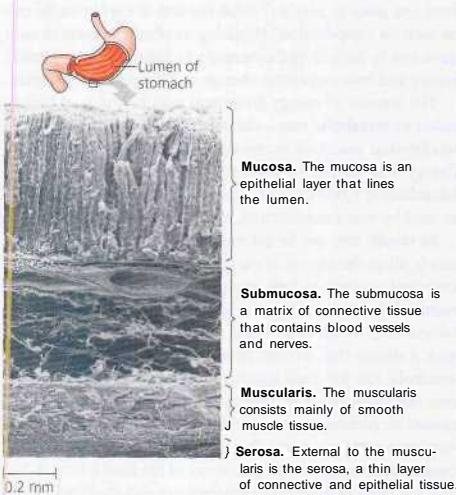

Figure 40.6 Tissue layers of the stomach, a digestive organ. The wall of the stomach and other tubular organs of the digestive system has four main tissue layers (SEM).

A thick epithelium lines the lumen and secretes mucus and digestive juices into it. Outside this layer is a zone of connective tissue, surrounded by a thick layer of smooth muscle. Yet another layer of connective tissue encases the entire stomach.

Many of the organs of vertebrates are suspended by sheets of connective tissue called mesenteries in moist or fluid-filled body cavities. Mammals have a thoracic cavity housing the lungs and heart that is separated from the lower abdominal cavity by a sheet of muscle called the diaphragm.

Representing a level of organization higher than organs, organ systems carry out the major body functions of most animals (**Table 40.1**). Each organ system consists of several organs and has specific functions, but the efforts of all systems must be coordinated for the animal to survive. For instance, nutrients absorbed from the digestive tract are distributed throughout the body by the circulatory system. But the heart, which pumps blood through the circulatory system, depends on nutrients absorbed by the digestive tract as well as on oxygen (O_2) obtained by the respiratory system. Any organism, whether single-celled or an assembly of organ systems, is a coordinated living whole greater than the sum of its parts.

Concept Check 40.2

- Describe how the epithelial tissue that lines the stomach lumen is well suited to its function.
- Suggest why a disease that damages connective tissue is likely to threaten most of the body's organs.
- How are muscle and nervous tissue interdependent?

For suggested answers, see Appendix A.

Concept 40.3

Animals use the chemical energy in food to sustain form and function

All organisms require chemical energy for growth, repair, physiological processes (including movement in the case of animals), regulation, and reproduction. As we have discussed in other chapters, organisms can be classified by how they obtain this energy. Autotrophs such as plants use light energy to build energy-rich organic molecules and then use those organic molecules for fuel. In contrast, heterotrophs such as animals must obtain their chemical energy from food, which contains organic molecules synthesized by other organisms.

Bioenergetics

The flow of energy through an animal—its bioenergetics—ultimately limits the animal's behavior, growth, and reproduction and determines how much food it needs. Studying an animal's bioenergetics tells us a great deal about the animal's adaptations.

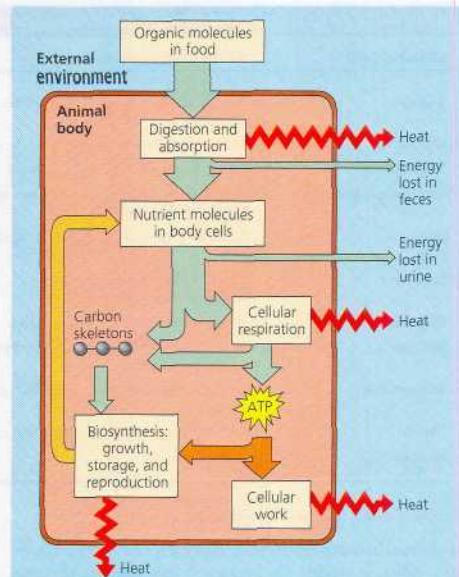

Energy Sources and Allocation

Animals harvest chemical energy from the food they eat. Food is digested by enzymatic hydrolysis (see Figure 5.2b), and energy-containing molecules are absorbed by body cells. Once absorbed, these energy-containing molecules have several possible fates. Most are used to generate ATP by the catabolic processes of cellular respiration and fermentation (see Chapter 9). The chemical energy of ATP powers cellular work, enabling cells, organs, and organ systems to perform the many functions that keep an animal alive. Because the production and use of ATP generate heat, an animal continuously gives off heat to its surroundings (heat balance is discussed in more detail later in this chapter).

After the energetic needs of staying alive are met, any remaining molecules from food can be used in biosynthesis, including body growth and repair, synthesis of storage material such as fat, and production of gametes (Figure 40.7). Biosynthesis requires both carbon skeletons for new structures and ATP to power their assembly. In some situations, biosynthetic products (such as body fat) can be broken down into fuel molecules for production of additional ATP, depending on the needs of the animal (see Figure 9.19).

Quantifying Energy Use

Understanding the bioenergetics of animals depends on the ability to quantify their energy needs. How much of the total energy an animal obtains from food does it need just to stay alive? How much energy must be expended to walk, run, swim, or fly

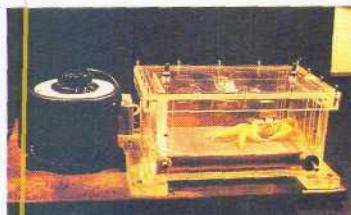

A Figure 40.7 Bioenergetics of an animal: an overview.

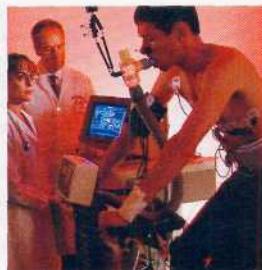

from one place to another? What fraction of energy intake can be used for reproduction? Physiologists obtain answers to soon questions by measuring the rates at which animals use chemical energy and how these rates change in different circumstances!

The amount of energy an animal uses in a unit of time is called its metabolic rate—the sum of all the energy-requiring biochemical reactions occurring over a given time interval! Energy is measured in calories (cal) or kilocalories (kcal). (A kilocalorie is 1,000 calories. The unit *Calorie*, with a capital C, as used by many nutritionists, is actually a kilocalorie.)

Metabolic rate can be determined in several ways. Because nearly all of the chemical energy used in cellular respiration eventually appears as heat, metabolic rate can be measured by monitoring an animal's rate of heat loss. Researchers can use a calorimeter, which is a closed, insulated chamber equipped with a device that records an animal's heat loss, to measure metabolic rate for small animals. A more indirect way to measure metabolic rate is to determine the amount of oxygen consumed or carbon dioxide produced by an animal's cellular respiration (Figure 40.8). Over long periods, the rate of food consumption and the energy content of the food (about 4.5–5 kcal per gram of protein or carbohydrate and about 9 kcal per gram of fat) can be used to estimate metabolic rate. However, this method must account for the energy stored in food that the animal cannot use (the energy lost in feces and urine).

(a) This photograph shows a ghost crab in a respirometer. Temperature is held constant in the chamber, with air of known O₂ concentration flowing through. The crab's metabolic rate is calculated from the difference between the amount of O₂ entering and the amount of O₂ leaving the respirometer. This crab is on a treadmill, running at a constant speed as measurements are made.

(b) Similarly, the metabolic rate of a man fitted with a breathing apparatus is being monitored while he works out on a stationary bike.

▲ Figure 40.8 Measuring metabolic rate.

Bioenergetic Strategies

An animal's metabolic rate is closely related to its bioenergetic "strategy." There are two basic bioenergetic strategies found in animals. Birds and mammals are mainly endothermic, meaning that their bodies are warmed mostly by heat generated by metabolism, and their body temperature is maintained within a relatively narrow range. Endothermy is a high-energy strategy that permits intense, long-duration activity over a wide range of environmental temperatures. In contrast, most fishes, amphibians, reptiles other than birds, and invertebrates are ectothermic, meaning that they gain their heat mostly from external sources. The ectothermic strategy requires much less energy than is needed by endotherms because of the high energy cost of heating (or cooling) an endothermic body. In general, endotherms have higher metabolic rates than ectotherms. You will read more about endothermic and ectothermic strategies later in this chapter.

Influences on Metabolic Rate

The metabolic rates of animals are affected by many factors besides whether the animal is an endotherm or an ectotherm. One of animal biology's most intriguing (but largely unanswered) questions has to do with the relationship between body size and metabolic rate.

Size and Metabolic Rate

By measuring the metabolic rates of many species of vertebrates and invertebrates, physiologists have shown that the amount of energy it takes to maintain each gram of body weight is inversely related to body size. Each gram of a mouse, for instance, requires about 20 times more calories than a gram of an elephant (even though the whole elephant, of

course, uses far more calories than the whole mouse). The higher metabolic rate of a smaller animal's tissues demands a proportionately greater rate of oxygen delivery. Correlated with its higher metabolic rate per gram, the smaller animal also has a higher breathing rate, blood volume (relative to its size), and heart rate (pulse), and it must eat much more food per unit of body mass.

The explanation for the inverse relationship between metabolic rate and size is still unclear. One hypothesis is that for endotherms, the smaller the animal, the greater the energy cost of maintaining a stable body temperature. In effect, the smaller an animal, the greater its surface-to-volume ratio and thus the greater the loss of heat to (or gain of heat from) the surroundings. Logical as this hypothesis seems, it cannot be the complete explanation, as it fails to explain the inverse relationship between metabolism and size in ectotherms, which do not use metabolic heat to maintain body temperature. Although this relationship has been extensively documented in both endotherms and ectotherms, researchers continue to search for its underlying causes.

Activity and Metabolic Rate

Every animal experiences a range of metabolic rates. A minimum rate powers the basic functions that support life, such as cell maintenance, breathing, and heartbeat. The metabolic rate of a nongrowing endotherm that is at rest, has an empty stomach, and is not experiencing stress is called the basal metabolic rate (BMR). The BMR for humans averages about 1,600–1,800 kcal per day for adult males and about 1,300–1,500 kcal per day for adult females. These BMRs are about equivalent to the energy requirement of a 75-watt light bulb.

In an ectotherm, body temperature changes with the temperature of the animal's surroundings, and so does metabolic rate. Unlike BMRs, which can be determined within a range of environmental temperatures, the minimum metabolic rate of an ectotherm must be determined at a specific temperature. The metabolic rate of a resting, fasting, nonstressed ectotherm at a particular temperature is called its standard metabolic rate (SMR).

For both ectotherms and endotherms, activity has a large effect on metabolic rate. Any behavior, even a person reading quietly at a desk or an insect extending its wings, consumes energy beyond the BMR or SMR. Maximum metabolic rates (the highest rates of ATP utilization) occur during peak activity, such as lifting heavy weights, sprinting, or high-speed swimming.

In general, an animal's maximum possible metabolic rate is inversely related to the duration of activity. **Figure 40.9** contrasts ectothermic and endothermic "strategies" for sustaining activity over different time intervals. Both an alligator (ectotherm) and a human (endotherm) are capable of very intense exercise in short spurts of a minute or less. During these "sprints" the ATP present in muscle cells and ATP generated anaerobically by glycolysis are sufficient to power the activity. Neither the ectotherm nor the endotherm can sustain their maximum metabolic rates and peak levels of activity over longer periods of exercise, though the endotherm has an advantage in such endurance tests. Sustained activity depends on the aerobic process of cellular respiration for ATP supply, and an endotherm's respiration rate is about ten times greater than an ectotherm's. Only a few ectotherms, such as migratory monarch butterflies or salmon, are capable of long-duration activities.

Between the extremes of BMR or SMR and maximum metabolic rate, many factors influence energy requirements, including age, sex, size, body and environmental temperatures, quality and quantity of food, activity level, oxygen availability, and hormonal balance. Time of day also plays a role. Birds, humans, and

many insects are usually active (and therefore have their higher metabolic rates) during daylight hours. In contrast, bats, mice, and many other mammals generally are active and have their highest metabolic rates at night or during the hours of dawn and dusk. Metabolic rates measured when animals are performing a variety of activities give a better idea of the energy costs of everyday life. For most terrestrial animals (both endotherms and ectotherms), the average daily rate of energy consumption is 2 to 4 times BMR or SMR. Humans in most developed countries have an unusually low average daily metabolic rate of about 1.5 times BMR—an indication of relatively sedentary lifestyles.

Energy Budgets

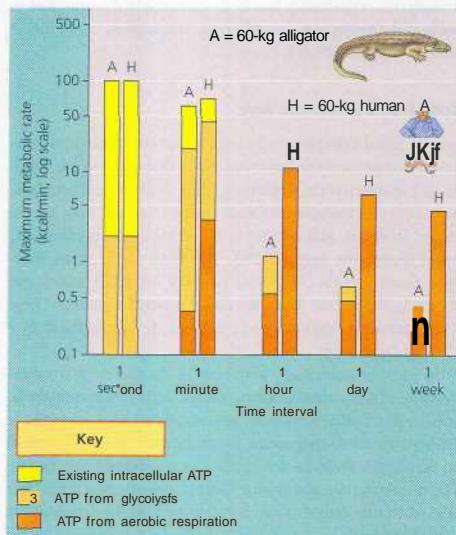

Different species of animals use the energy and materials in food in different ways, depending on their environment, behavior, size, and basic strategy of endothermy or ectothermy. For most animals, the majority of food is devoted to the production of ATP, and relatively little goes to growth or reproduction. However, the amount of energy used for BMR (or SMR), activity, and body temperature control varies considerably between species. For example, consider the typical energy "budgets" of four terrestrial vertebrates: a 25-g female deer mouse, a 4-kg female python, a 4-kg male Adélie penguin, and a 60-kg female human (**Figure 40.10**). We will assume that all of these animals reproduce during the year.

The female human spends a large fraction of her energy budget for BMR and relatively little for activity and body temperature regulation. The small amount of growth, about 1% of her annual energy budget, is equivalent to adding about 1 kg of body fat or 5–6 kg of other tissues. The cost of nine months of pregnancy and several months of breast-feeding amounts to only 5–8% of the mother's annual energy requirements.

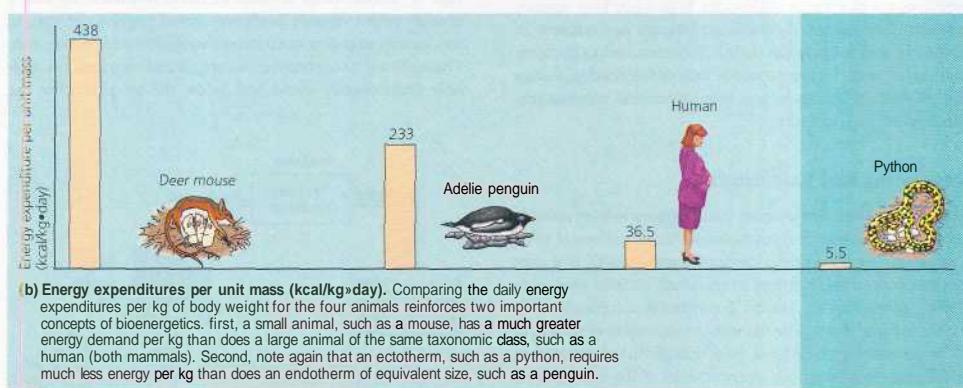

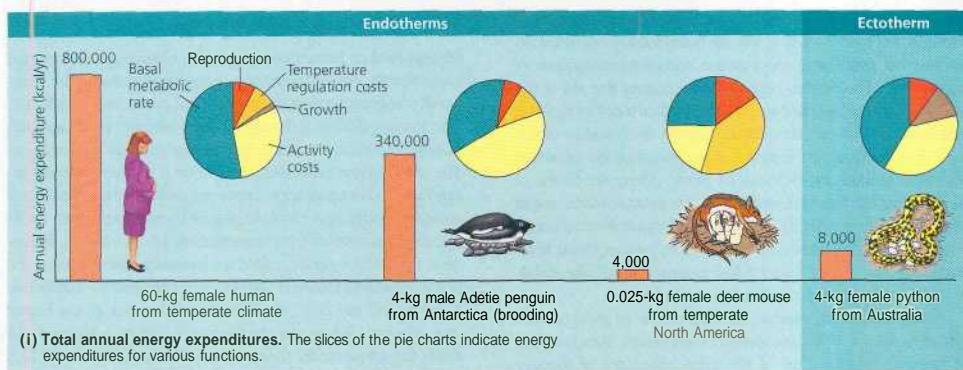

A male penguin spends a much larger fraction of his energy expenditures for activity because he swims to catch food. Because the penguin is well insulated and fairly large, he has relatively low costs of temperature regulation in spite of living in the cold antarctic environment. His reproductive costs, about 6% of annual energy expenditures, mainly come from incubating eggs (brooding) and bringing food to his chicks. Penguins, like most birds, do not grow once they are adults.

The female deer mouse spends a large fraction of her energy budget for temperature regulation. Because of the high surface-to-volume ratio that goes with small size, mice lose body heat rapidly and must constantly generate metabolic heat to maintain body temperature. Female deer mice spend about 12% of their energy budget on reproduction.

In contrast to these endothermic animals, the ectothermic python has no temperature regulation costs. Like most reptiles, she grows continuously throughout life. In the example in Figure 40.10, the snake added about 750 g of new body tissue. She also produced about 650 g of eggs. The python's economical ectothermic strategy is revealed by her very low energy expenditure per unit mass, which is only 1/4 of the

A Figure 40.9 Maximum metabolic rates over different time spans. The bars compare an ectotherm (alligator) and an endotherm (human) for their maximum potential metabolic rates and ATP sources over different durations of time. The human's basal metabolic rate (about 1.2 kcal/min) is much greater than the alligator's standard metabolic rate (about 0.04 kcal/min). The human's higher BMR partly contributes to his ability to sustain a higher maximum metabolic rate over a longer period.

A Figure 40.10 Energy budgets for four animals.

energy expended by the similarly-sized endothermic penguin (see Figure 40.10b).

Throughout our study of animal biology, we will encounter many other examples of how bioenergetics relates to the form and function of diverse animals.

Concept Check 40.3

- [If a mouse and a small lizard of the same mass (both at rest) were placed in respirometers under identical environmental conditions, which animal would consume oxygen at a higher rate? Explain.]
- [Why are alligators not capable of intense activity for periods of more than 1 hour?]
- [Which must eat a larger proportion of its weight in food each day: a house cat or an African lion? Explain.]

For suggested answers, see Appendix A.

Concept 40.4

Many animals regulate their internal environment within relatively narrow limits

More than a century ago, French physiologist Claude Bernard made the distinction between the external environment surrounding an animal and the internal environment in which the cells of the animal live. The internal environment of vertebrates is called the interstitial fluid (see Figure 40.4). This fluid, which fills the spaces between vertebrate cells, exchanges nutrients and wastes with blood contained in microscopic vessels called capillaries. Bernard also recognized that many animals tend to maintain relatively constant conditions in their internal environment, even when the external environment changes. A

pond-dwelling hydra is powerless to affect the temperature of the fluid that bathes its cells, but the human body can maintain its "internal pond" at a more-or-less constant temperature of about 37°C. The human body also can control the pH of the blood and interstitial fluid to within a tenth of a pH unit of 7.4, and it can regulate the amount of sugar in the blood so that it does not fluctuate for long from a concentration of about 90 mg of glucose per 100 mL of blood. There are times, of course, during the development of an animal when major changes in the internal environment are programmed to occur. For example, the balance of hormones in human blood is altered radically during puberty and pregnancy. Still, the stability of the internal environment is remarkable.

Today Bernard's "constant internal milieu" is incorporated into the concept of **homeostasis**, which means "steady state," or internal balance. One of the main objectives of modern physiology, and a theme of this unit, is to study how animals maintain homeostasis. Actually, the internal environment of an animal always fluctuates slightly. Homeostasis is a dynamic state, an interplay between outside factors that tend to change the internal environment and internal control mechanisms that oppose such changes.

Regulating and Conforming

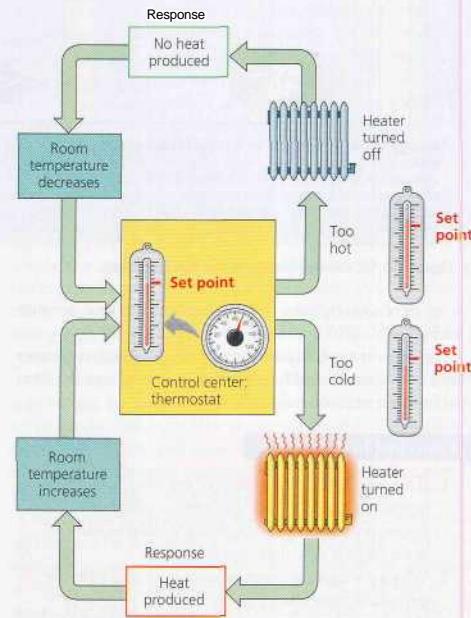

Regulating and conforming are two extremes in how^T animals cope with environmental fluctuations. An animal is said to be a **regulator** for a particular environmental variable if it uses internal control mechanisms to moderate internal change in the face of external fluctuation. For example, a freshwater fish is able to maintain a stable internal concentration of solutes in its blood and interstitial fluid, even though that concentration is different from the solute concentration of the water it lives in. The fish's anatomy and physiology enable it to moderate internal changes in solute concentration. (You will learn more about the mechanisms of this regulation in Chapter 44.)

An animal is said to be a **conformer** for a particular environmental variable if it allows its internal condition to vary with certain external changes. For example, many marine invertebrates, such as spider crabs of the genus *Hibinia*, live in environments where the solute concentration (salinity) is relatively stable. Unlike freshwater fishes, *Hibinia* does not regulate its internal solute concentration but rather conforms to the external environment.

Regulating and conforming represent extremes on a continuum, and no organism is a perfect regulator or conformer. Furthermore, an animal may maintain homeostasis while regulating some internal conditions and allowing others to conform to the environment. For example, even though a freshwater fish regulates its internal solute concentration, it allows its internal temperature to conform to the external water temperature. Next, we will explore in more detail the mechanisms that animals use in regulating certain aspects of their internal environment.

Mechanisms of Homeostasis

Mechanisms of homeostasis moderate changes in the internal environment. Any homeostatic control system has three functional components: a receptor, a control center, and an effector. The *receptor* detects a change in some variable of the animal's internal environment, such as a change in body temperature. The *control center* processes information it receives from the receptor and directs an appropriate response by the *effector*. Let's consider a nonliving example of how these components interact: the regulation of room temperature (Figure 40.11). In this case, the control center, called a thermostat, also contains the receptor (a thermometer). When room temperature falls below a "set point" say 20°C, the thermostat switches on the heater (the effector). When the thermometer detects a temperature above the set point, the thermostat switches off the heater. This type of control circuit is called **negative feedback**, because a change in the variable being monitored triggers the control mechanism to counteract further change in the same direction. Owing to a time lag between reception and response, the variable drifts slightly above and below the set point, but the

A Figure 40.11 A nonliving example of negative feedback: control of room temperature. Regulating room temperature depends on a control center that detects temperature change and activates mechanisms that reverse that change.

fluctuations are moderate. Negative-feedback mechanisms prevent small changes from becoming too large. Most homeostatic mechanisms in animals operate on this principle of negative feedback. In fact, your own body temperature is kept close to a set point of 37°C by the cooperation of several negative-feedback circuits, as you will read later.

In contrast to negative feedback, **positive feedback** involves a change in some variable that triggers mechanisms that amplify rather than reverse the change. During childbirth, for instance, the pressure of the baby's head against receptors near the opening of the uterus stimulates uterine contractions, which cause greater pressure against the uterine opening, heightening the contractions, which causes still greater pressure. Positive feedback brings childbirth to completion.

It is important not to overstate the concept of a constant internal environment. In fact, *regulated change* is essential to normal body functions. In some cases, the changes are cyclic, such as the changes in hormone levels responsible for the menstrual cycle in women (see Figure 46.13). In other cases, a regulated change is a reaction to a challenge to the body. For example, the human body reacts to certain infections by raising the set point for temperature to a slightly higher level, and the resulting fever helps fight the infection. Over the short term, homeostatic mechanisms keep body temperature close to a set point, whatever it is at that particular time. But over the longer term, homeostasis allows regulated change in the body's internal environment.

Internal regulation is expensive. Anyone who pays utility bills is aware of the energy costs for heating or cooling a home to maintain a comfortable interior temperature. Similarly, animals use a considerable portion of the energy from the food they eat to maintain favorable internal conditions. In the next section, we will explore in detail how different kinds of animals maintain relatively constant body temperatures.

SConcept 40.4

1. Does a regulator maintain a constant internal environment? Explain.
2. Describe the difference between negative feedback and positive feedback mechanisms.

For suggested answers, see Appendix A.

IConcept 40.5

Thermoregulation contributes to homeostasis and involves anatomy, physiology, and behavior

In this section, we will examine one example of how animal function work together in regulating the internal

environment—specifically, the regulation of body temperature. Other processes involved in maintaining homeostasis will be discussed in Chapter 44.

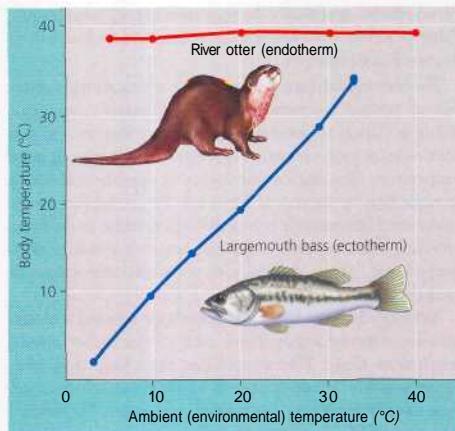

Thermoregulation is the process by which animals maintain an internal temperature within a tolerable range. This ability is critical to survival because most biochemical and physiological processes are very sensitive to changes in body temperature. The rates of most enzyme-mediated reactions increase two- to three-fold for every 10°C temperature increase until temperature is high enough to begin to denature proteins. The properties of membranes also change with temperature. These thermal effects dramatically influence animal functioning.

Although different species of animals are adapted to different environmental temperatures, each species has an optimal temperature range. Thermoregulation helps keep body temperature within that optimal range, enabling cells to function most effectively, even as the external temperature fluctuates.

Ectotherms and Endotherms

There are important **differences** in how various species manage their heat budgets. One way to classify the thermal characteristics of animals is to emphasize the role of metabolic heat in determining body temperature. As you learned earlier, **ectotherms** gain most of their heat from the environment. An ectotherm has such a low metabolic rate that the amount of heat it generates is too small to have much effect on body temperature. In contrast, **endotherms** can use metabolic heat to regulate their body temperature. In a cold environment, an endotherm's high metabolic rate generates enough heat to keep its body substantially warmer than its surroundings. Many endotherms, including humans, maintain high and very stable internal temperatures even as the temperature of their surroundings fluctuates. Many ectotherms can thermoregulate by behavioral means, such as basking in the sun or seeking out shade. But in general, ectotherms tolerate greater variation in internal temperature than do endotherms (Figure 40.12, on the next page). Most invertebrates, fishes, amphibians, lizards, snakes, and turtles are ectotherms. Mammals, birds and a few other reptiles, some fishes, and numerous insect species are endotherms.

It is important to note that animals are *not* classified as ectotherms or endotherms based on whether they have variable or constant body temperatures, a common misconception. As mentioned earlier, it is the source of heat used to maintain body temperature that distinguishes ectotherms from endotherms. A different set of terms is used to imply variable or constant body temperatures. The term *poikilotherm* refers to animals whose internal temperatures vary widely, and the term *homotherm* refers to animals that maintain relatively stable internal temperatures. However, as scientists have gained more knowledge of animal thermoregulatory mechanisms, these terms have largely fallen out of use. Many marine fishes and invertebrates, classified as poikilotherms, inhabit water

A Figure 40.12 The relationship between body temperature and environmental temperature in an aquatic endotherm and ectotherm. Using its high metabolic rate to generate heat, the river otter maintains a stable body temperature across a wide range of environmental temperatures. The largemouth bass, meanwhile, generates relatively little metabolic heat and conforms to the water temperature.

with such stable temperatures that their body temperature varies less than that of humans and other mammals. Furthermore, some mammals that were classified as homeotherms experience great variation in internal temperature. For example, a chipmunk sustains a high body temperature while it is active, but its temperature drops as hibernation begins. Because of such exceptions, the terms *ectotherm* and *endotherm* are generally preferred.

Another common misconception is the idea that ectotherms are "cold-blooded" and endotherms are "warm-blooded." Ectotherms do not necessarily have low body temperatures. In fact, when sitting in the sun, many ectothermic lizards have higher body temperatures than mammals. Thus, most biologists avoid the familiar terms *cold-blooded* and *warm-blooded* because they are so often misleading. It is also important to note that ectothermy and endothermy are not mutually exclusive thermoregulatory strategies. For example, a bird is an endotherm, but it may warm itself in the sun on a cold morning, much as an ectothermic lizard does.

Endothermy has several important advantages. Being able to generate a large amount of heat metabolically, along with other biochemical and physiological adaptations associated with endothermy (such as elaborate circulatory and respiratory systems), enables endotherms to perform vigorous activity for much longer than is possible for most ectotherms (see Figure 40.9). Sustained intense activity, such as long-distance running or powered (flapping) flight, is usually only feasible

for animals with an endothermic way of life. Endothermy also solves certain thermal problems of living on land, enabling terrestrial animals to maintain stable body temperatures in the face of environmental temperature fluctuations that are generally more severe than in aquatic habitats. For example, no ectotherm can be active in the below-freezing weather that prevails during winter over much of Earth's surface, but many endotherms function very well in these conditions. Most of the time, endothermic vertebrates—birds and mammals—are warmer than their surroundings, but these animals also have mechanisms for cooling the body in a hot environment, which enables them to withstand heat loads that are intolerable for most ectotherms. Endotherms are better buffered against external temperature fluctuations compared to ectotherms, but keep in mind that ectotherms can usually tolerate larger fluctuations in their internal temperatures.

Being endothermic is liberating, but it is also energetically expensive. For example, at 20°C, a human at rest has a metabolic rate of 1,300 to 1,800 kcal per day (BMR). In contrast a resting ectotherm of similar weight, such as an American alligator, has a metabolic rate of only about 60 kcal per day at 20°C (SMR). Thus, endotherms generally need to consume much more food than ectotherms of equivalent size—a serious disadvantage for endotherms if food supplies are limited. For this and other reasons, ectothermy is an extremely effective and successful strategy in most of Earth's environments, as shown by the abundance and diversity of ectothermic animals.

Modes of Heat Exchange

Whether it is an ectotherm or an endotherm, an organism, like any object, exchanges heat by four physical processes: conduction, convection, radiation, and evaporation. **Figure 40.13** distinguishes these processes, which account for the flow of heat within an organism and between an organism and its external environment. Note that heat is always transferred from an object of higher temperature to one of lower temperature.

Balancing Heat Loss and Gain

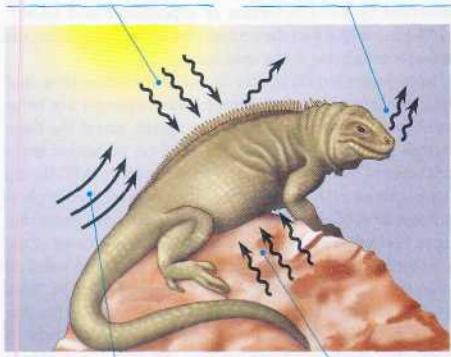

For endotherms and for those ectotherms that thermoregulate, the essence of thermoregulation is managing the heat budget so that rates of heat gain are equal to rates of heat loss. If the heat budget is unbalanced, the animal becomes either warmer or colder. Five general categories of adaptations help animals thermoregulate.

Insulation

A major thermoregulatory adaptation in mammals and birds is insulation (hair, feathers, or fat layers), which reduces the flow of heat between an animal and its environment and lowers the energy cost of keeping warm. In mammals, the insulating material is associated with the integumentary system,

Radiation is the emission of electromagnetic waves by all objects warmer than absolute zero. Radiation can transfer heat between objects that are not in direct contact, as when a lizard absorbs heat radiating from the sun.

Evaporation is the removal of heat from the surface of a liquid that is losing some of its molecules as gas. Evaporation of water from a lizard's moist surfaces that are exposed to the environment has a strong cooling effect.

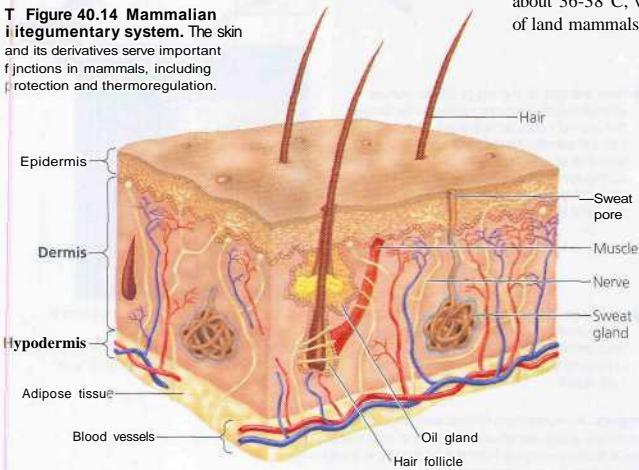

Convection is the transfer of heat by the movement of air or liquid past a surface, as when a breeze contributes to heat loss from a lizard's dry skin, or blood moves heat from the body core to the extremities.

Conduction is the direct transfer of thermal motion (heat) between molecules of objects in direct contact with each other, as when a lizard sits on a hot rock.

1 Figure 40.13 Heat exchange between an organism and its environment.

T Figure 40.14 Mammalian integumentary system. The skin and its derivatives serve important functions in mammals, including protection and thermoregulation.

the outer covering of the body, consisting of the skin, hair, and nails (claws or hooves in some species). Skin is a key organ of the integumentary system. In addition to functioning as a thermoregulatory organ by housing nerves, sweat glands, blood vessels, and hair follicles, the skin protects internal body parts from mechanical injury, infection, and drying out. The skin consists of two layers, the epidermis and the dermis, underlain by a tissue layer called the hypodermis (Figure 40.14). The epidermis is the outermost layer of skin and is composed mostly of dead epithelial cells that continually flake and fall off. New cells pushing up from lower layers replace the cells that are lost. The dermis supports the epidermis and contains hair follicles, oil and sweat glands, muscles, nerves, and blood vessels. The hypodermis contains adipose tissue, which includes fat-storing cells and blood vessels. Adipose tissue provides varying degrees of insulation, depending on the species.

The insulating power of a layer of fur or feathers mainly depends on how much still air the layer traps. (Hair loses most of its insulating power when wet.) Most land mammals and birds react to cold by raising their fur or feathers, thereby trapping a thicker layer of air. Humans rely more on a layer of fat just beneath the skin as insulation (see Figure 40.14); goose bumps are a vestige of hair raising inherited from our fury ancestors.

Marine mammals, such as whales and seals, have a very thick layer of insulating fat called blubber just under their skin. Marine mammals swim in water colder than their body core temperature, and many species spend at least part of the year in nearly freezing polar seas. The transfer of heat to water occurs 50 to 100 times more rapidly than heat transfer to air, and the skin temperature of a marine mammal is close to water temperature. Even so, the blubber insulation is so effective that marine mammals maintain body core temperatures of about 36–38°C, with metabolic rates about the same as those of land mammals of similar size.

Circulatory Adaptations

Many endotherms and some ectotherms can alter the amount of blood (and hence heat) flowing between the body core and the skin. Elevated blood flow in the skin normally results from vasodilation, an increase in the diameter of superficial blood vessels (those near the body surface) triggered by nerve signals that relax the muscles of the vessel walls, in endotherms, vasodilation usually warms the skin, increasing the transfer of body heat to a cool environment by radiation, conduction, and convection (see Figure 40.13). The reverse process, vasoconstriction, reduces blood flow and heat transfer by decreasing the diameter of superficial vessels.

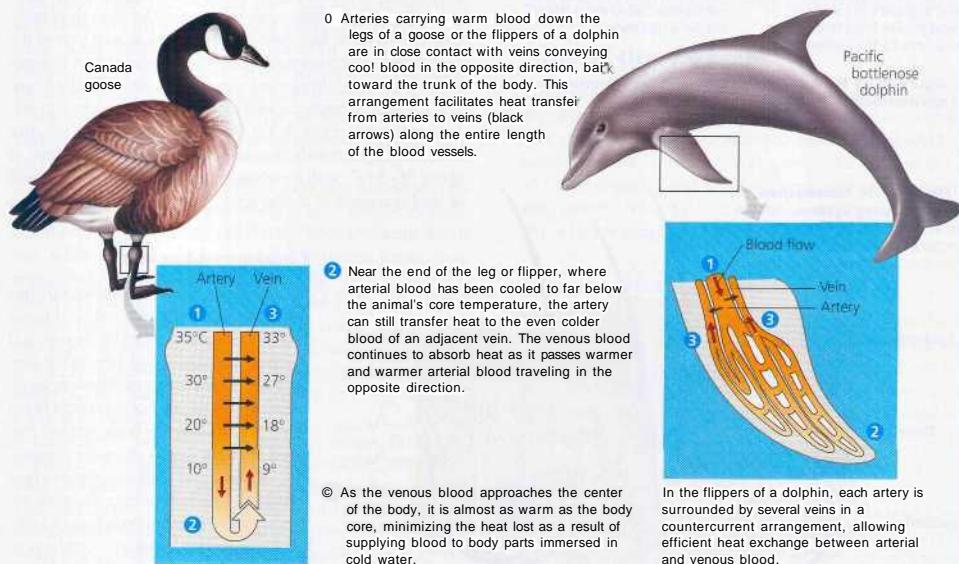

Another circulatory adaptation is an arrangement of blood vessels called a countercurrent heat exchanger that is important for reducing heat loss in many endotherms, including marine mammals and birds. **Figure 40.15** explores two examples of countercurrent heat exchangers. In some species, blood can either go through the heat exchanger or bypass it by way of other blood vessels. In this way, the relative amount of blood that flows through the two different paths may vary, adjusting the rate of heat loss as an animal's physiological state or environment changes.

Unlike most fishes, which are thermoconformers with internal body temperatures usually within 1–2°C of the surrounding water temperature, some specialized endothermic bony fishes and sharks have circulatory adaptations that retain metabolic heat in the body. These include large, powerful swimmers such as bluefin tuna and swordfish, as well as the great white shark. Large arteries convey most of the cold blood from the gills to tissues just under the skin. Branches deliver blood to the deep muscles, where the small vessels are arranged into a countercurrent heat exchanger (**Figure 40.16**). Endothermy enables the vigorous, sustained activity that is characteristic of these animals by keeping the main swimming

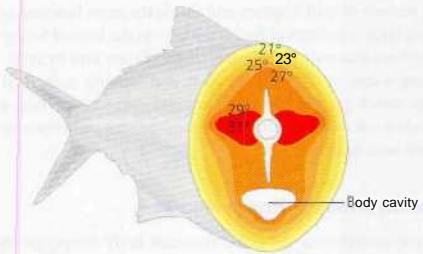

muscles several degrees warmer than the tissues near the animal's surface, which are about the same temperature as the surrounding water.

Some reptiles also have physiological adaptations that regulate heat loss. For example, in the marine iguana, which inhabits the Galapagos Islands (see Figure 22.1), body heat is conserved by vasoconstriction of superficial blood vessels, routing more blood to the central core of the body when the animal is swimming in the cold ocean.

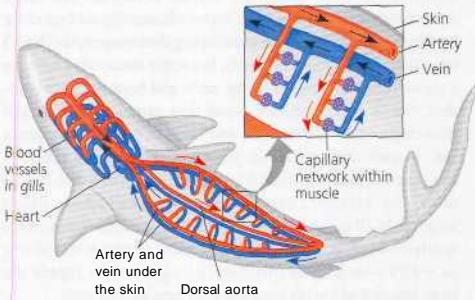

Many endothermic insects (bumblebees, honeybees, and some moths) have a countercurrent heat exchanger that helps maintain a high temperature in the thorax, where the flight muscles are located. For example, the heat exchanger keeps the thorax of certain winter-active moths at about 30°C during flight, even on cold, snowy nights when the external temperature may be subfreezing (**Figure 40.17**). In contrast, insects flying in hot weather run the risk of overheating because of the large amount of heat produced by working flight muscles. In some species, the countercurrent mechanism can be "shut down," allowing muscle-produced heat to be lost from the thorax to the abdomen, and from there to the environment. A bumblebee queen incubates her eggs this way: She generates

A Figure 40.15 Countercurrent heat exchangers. A countercurrent heat exchanger traps heat in the body core, thus reducing heat loss from the extremities, which are often immersed in cold water or in contact with ice or snow. In essence, heat in the arterial blood emerging from the body core is transferred directly to the returning venous blood instead of being lost to the environment.

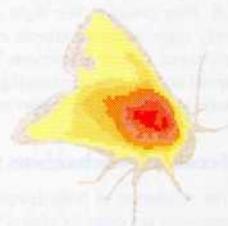

(a) Bluefin tuna. Unlike most fishes, the bluefin tuna maintains temperatures in its main swimming muscles that are much higher than the surrounding water (colors indicate swimming muscles cut in transverse section). These temperatures were recorded for a tuna in 19°C water.

(b) Great white shark. Like the bluefin tuna, the great white shark has a countercurrent heat exchanger in its swimming muscles that reduces the loss of metabolic heat. All bony fishes and sharks lose heat to the surrounding water when their blood passes through the gills. However, endothermic sharks have a small dorsal aorta, and as a result, relatively little cold blood from the gills goes directly to the core of the body. Instead, most of the blood leaving the gills is conveyed via large arteries just under the skin, keeping cool blood away from the body core. As shown in the enlargement, small arteries carrying cool blood inward from the large arteries under the skin are paralleled by small veins carrying warm blood outward from the inner body. This countercurrent flow retains heat in the muscles.

A Figure 40.16 Thermoregulation in large, active bony fishes and sharks.

► Figure 40.17 Internal temperature in the winter moth. This infrared map shows the moth's heat distribution immediately after a flight. Red in the thorax region indicates the highest temperature. Moving outward, the variously colored zones correspond to regions of increasingly cooler body temperatures.

A Figure 40.18 A terrestrial mammal bathing, an adaptation that enhances evaporative cooling.

heat by shivering her flight muscles and then transfers the heat to her abdomen, which she presses against her eggs.

Cooling by Evaporative Heat Loss

Many mammals and birds live in places where thermoregulation requires cooling as well as warming. If environmental temperature is above body temperature, animals gain heat from the environment as well as from metabolism, and evaporation is the only way to keep body temperature from rising rapidly. Terrestrial animals lose water by evaporation across the skin and when they breathe. Water absorbs considerable heat when it evaporates; it is 50 to 100 times more effective than air in transferring heat.

Some animals have adaptations that can greatly augment this cooling effect. Panting is important in birds and many mammals. Some birds have a pouch richly supplied with blood vessels in the floor of the mouth; fluttering the pouch increases evaporation. Pigeons, for example, can use evaporative cooling to keep body temperature close to 40°C in air temperatures as high as 60°C, as long as they have sufficient water. Sweating or bathing moistens the skin and enhances evaporative cooling (Figure 40.18). Many terrestrial mammals have sweat glands controlled by the nervous system (see Figure 40.14). Other mechanisms that promote evaporative cooling include spreading saliva on body surfaces, an adaptation of some kangaroos and rodents for combating severe heat stress. Some species of amphibians, such as bullfrogs, can vary the amount of mucus they secrete from their surface, a response that regulates evaporative cooling.

Behavioral Responses

Both endotherms and ectotherms use behavioral responses to control body temperature. Many ectotherms can maintain a very constant body temperature through relatively simple behaviors.

More extreme behavioral adaptations in some animals include hibernation or migration to a more suitable climate.

All amphibians and most reptiles other than birds are ectothermic. Therefore, these organisms control body temperature mainly by behavior. The optimal temperature range for amphibians varies substantially with the species. For example, certain closely related species of salamanders have average body temperatures ranging from 7° to 25°C. When exposed to air, most amphibians lose heat rapidly by evaporation from their moist body surfaces, making it difficult to keep sufficiently warm. However, by moving to a location where solar heat is available, an amphibian can maintain a satisfactory body temperature. And when the surroundings are too warm, amphibians seek cooler microenvironments, such as shaded areas.

Like amphibians, reptiles other than birds thermoregulate mainly by behavior. When cold, they seek warm places, orienting themselves toward heat sources and expanding the body surface exposed to a heat source. When hot, they move to cool areas or turn in another direction. Many reptiles keep their body temperatures very stable over the course of a day by shuttling back and forth between warm and cool spots.

Many terrestrial invertebrates can adjust internal temperature by the same behavioral mechanisms used by vertebrate ectotherms. The desert locust, for example, must reach a certain temperature to become active, and on cold days it orients in a direction that maximizes the absorption of sunlight. Other terrestrial invertebrates have certain postures that enable them to maximize or minimize their absorption of heat from the sun (**Figure 40.19**).

Honeybees use thermoregulatory mechanism that depends on social behavior. In cold weather, they increase heat production and huddle together, thereby retaining heat. They maintain a relatively constant temperature by changing the density of the huddling. Individuals move between the cooler outer edges of the cluster and the warmer center, thus circulating and distributing the heat. Even when huddling, honeybees must expend considerable energy to keep warm during

< Figure 40.19 Thermoregulatory behavior in a dragonfly. This dragonfly's "obelisk" posture is an adaptation that minimizes the amount of body surface exposed to the sun. This posture helps reduce heat gain by radiation.

long periods of cold weather, and this is the main function of storing large quantities of fuel in the hive in the form of honey. Honeybees also control the temperature of their hive by transporting water to it in hot weather and fanning with their wings, which promotes evaporation and convection. Thus, a honeybee colony uses many of the mechanisms of thermoregulation seen in single organisms.

Adjusting Metabolic Heat Production

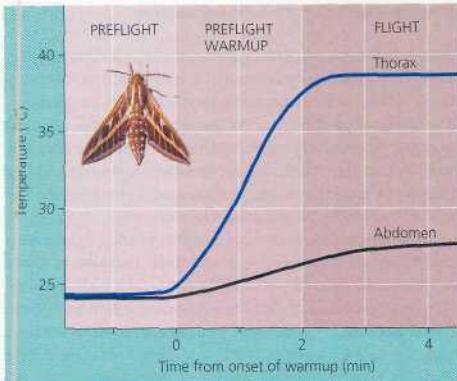

Because endotherms generally maintain body temperatures considerably warmer than the environment, they must counteract constant heat loss. Endotherms can vary heat production to match changing rates of heat loss. For example, heat production is increased by such muscle activity as moving or shivering. In some mammals, certain hormones can cause mitochondria to increase their metabolic activity and produce heat instead of ATE. This nonshivering thermogenesis (NST) takes place throughout the body, but some mammals also have a tissue called brown fat in the neck and between the shoulders that is specialized for rapid heat production. Through shivering and NST, mammals and birds in cold environments can increase their metabolic heat production by as much as five to ten times the minimal levels that occur in warm conditions. For example, small birds called chickadees, which weigh only 20 g, can remain active and hold body temperature nearly constant at 40°C in environmental temperatures as low as -40°C—as long as they have enough food to supply the large amount of energy necessary for heat production.

A few large reptiles become endothermic in particular circumstances. For example, female pythons that are incubating eggs increase their metabolic rate by shivering, generating enough heat to keep their body (and egg) temperatures 5–7°C warmer than the surrounding air for weeks at a time. This temporary endothermy consumes considerable energy. Researchers continue to debate whether certain groups of dinosaurs were endothermic (see Chapter 34).

As mentioned earlier, many species of flying insects, such as bees and moths, are endothermic—the smallest of all endotherms. The capacity of such endothermic insects to elevate body temperature depends on powerful flight muscles, which generate large amounts of heat when operating. Many endothermic insects use shivering to warm up before taking off. They contract their flight muscles in synchrony, so that only slight wing movements occur but considerable heat is produced. Chemical reactions, and hence cellular respiration speed up in the warmed-up flight "motors," enabling these insects to fly even on cold days or at night (**Figure 40.20**).

Feedback Mechanisms in Thermoregulation

The regulation of body temperature in humans and other mammals is a complex system facilitated by feedback mecha-

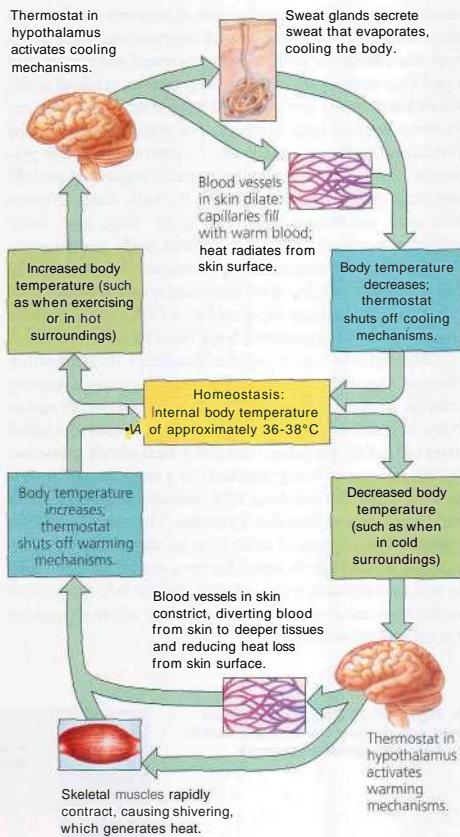

i Figure 40.20 Preflight warmup in the hawkmoth. The hawkmoth (*Manduca sexta*) is one of many insect species that use a shivering-like mechanism for preflight warmup of thoracic flight muscles. Warming up helps these muscles produce enough power to let the animal take off. Once airborne, flight muscle activity maintains a high thoracic temperature.

riisms (see Figure 40.11). Nerve cells that control thermoregulation, as well as those that control many other aspects of homeostasis, are concentrated in a region of the brain called the hypothalamus (discussed in detail in Chapter 48). The hypothalamus contains a group of nerve cells that functions as a thermostat, responding to changes in body temperature above or below a set point (actually above or below a normal range) by activating mechanisms that promote heat loss or gain (Figure 40.21). Nerve cells that sense temperature are in the skin, in the hypothalamus itself, and in several other body regions. Warm receptors signal the hypothalamic thermostat when temperatures increase; cold receptors signal temperature decrease. At body temperatures below the normal range, the thermostat inhibits heat loss mechanisms and activates heat-saving ones such as vasoconstriction of superficial vessels and erection of fur, while stimulating heat-generating mechanisms (shivering and nonshivering thermogenesis). In response to elevated body temperature, the thermostat shuts down heat retention mechanisms and promotes body cooling by vasodilation, sweating, or panting. The thermostat can also respond to external temperature (sensed as skin temperature) even without changes in body core temperature.

Adjustment to Changing Temperatures

Many animals can adjust to a new range of environmental temperatures over a period of days or weeks, a physiological response called acclimatization. Both ectotherms and endotherms acclimatize, but in different ways. In birds and mammals, acclimatization often includes adjusting the amount of insulation—by growing a thicker coat of fur in the

A Figure 40.21 The thermostat function of the hypothalamus in human thermoregulation.

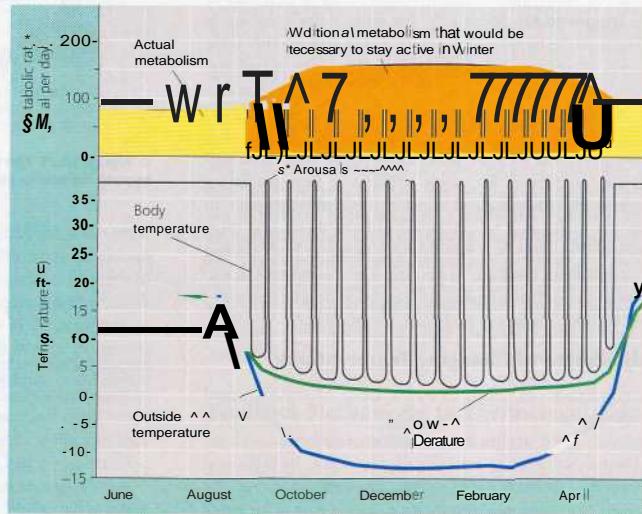

winter and shedding it in the summer, for example—and sometimes varying the capacity for metabolic heat production in different seasons. These changes help endotherms keep a constant body temperature in both warm and cold seasons. Acclimatization in ectotherms involves compensating for changes in temperature. These adjustments can strongly affect physiology and temperature tolerance. For example, summer-acclimatized bullhead catfish can survive water temperatures up to 36°C but cannot function in cold water; after winter acclimatization, they can easily tolerate cold water, but a temperature above 28°C is lethal.

Acclimatization responses in ectotherms often include adjustments at the cellular level. Cells may increase the production of

certain enzymes or produce variants of enzymes that have the same function but different optimal temperatures. Membranes may also change the proportions of saturated and unsaturated lipids they contain, which helps keep membranes fluid at different temperatures (see Figure 7.5). Some ectotherms that experience subzero body temperatures protect themselves by producing "antifreeze" compounds (cryoprotectants) that prevent ice formation in the cells. In arctic regions or on cold mountain peaks, cryoprotectants in the body fluids let overwintering **ectotherms**, such as some frogs and many arthropods and their eggs, withstand body temperatures considerably below zero. Cryoprotectants are also found in certain species of fishes from arctic and antarctic seas, where water temperatures can be as cold as -1.8°C , well below the freezing point of unprotected body fluids (about -0.7°C).

Cells can often make rapid adjustments to temperature changes. For example, mammalian cells grown in laboratory cultures respond to a marked increase in temperature and to other forms of severe stress by accumulating molecules called **stress-induced proteins**, including **heat-shock proteins**. Within minutes of being "shocked" by a rapid change in temperature from 37°C to about 43°C , cultured mammalian cells begin synthesizing heat-shock proteins. These molecules help maintain the integrity of other proteins that would be denatured by severe heat. Found in bacteria, yeasts, and plant cells as well as in animals, stress-induced proteins help prevent cell death when an organism is challenged by severe changes in the cellular environment.

> Figure 40.22 Body temperature and metabolism during hibernation in Belding's ground squirrels.

Torpor and Energy Conservation

Despite their many adaptations for homeostasis, animals may occasionally encounter conditions that severely challenge their abilities to balance heat, energy, and materials budgets. For example, at certain seasons of the year (or certain times of day), temperatures may be extremely hot or cold, or food may be unavailable. An adaptation that enables animals to save energy while avoiding difficult and dangerous conditions is **torpor**, a physiological state in which activity is low and metabolism decreases.

Hibernation is long-term torpor that is an adaptation to winter cold and food scarcity. When vertebrate endotherms (birds and mammals) enter torpor or hibernation, their body temperatures decline—in effect, their body's thermostat is turned down. The temperature reduction may be dramatic: Some hibernating mammals cool to as low as 1.2°C , and a few even drop slightly below 0°C in a supercooled (unfrozen) state. The resulting energy savings due to lower metabolic rate and less heat production are huge; metabolic rates during hibernation can be several hundred times lower than if the animal attempted to maintain normal body temperatures of $36\text{--}38^{\circ}\text{C}$. This allows hibernators to survive for very long periods on limited supplies of energy stored in the body tissues or as food cached in a burrow.

Certain ground squirrels are favorite research models for biologists studying the physiology of hibernation (Figure 40.22). For example, a Belding's ground squirrel (*Spermophilus beldingi*) living in the high mountains of California is active only during spring and summer, when it maintains a body

temperature of about 37°C and a metabolic rate of about 85 kcal per day. In September, the squirrel retreats to a safe burrow where it spends the next eight months hibernating. For most of the hibernation season, the squirrel's body temperature is only slightly above burrow temperature (which may be close to freezing), and its metabolic rate is extremely low (see Figure 40.22). Every week or two it arouses for a few hours, using metabolic heat to warm up to about 37°C (these periodic arousals may be needed for maintenance functions that require high body temperature). In late spring, when outside temperature is climbing, the squirrel resumes normal endothermy. By hibernating, fielding ground squirrels avoid severe cold and greatly reduce the amount of energy they need to survive the winter, when their normal food of grasses and seeds is not available. Instead of having to spend 150 kcal per day to maintain normal body temperatures in winter weather, a squirrel in its burrow spends an average of only 5–8 kcal per day and can live on stored fat—without eating—for the entire hibernation season.

Estivation, or summer torpor, also characterized by slow metabolism and inactivity, enables animals to survive long periods of high temperatures and scarce water supplies. Hibernation and estivation are often triggered by seasonal changes in the length of daylight. As the days shorten, some hibernators prepare for winter by storing food in their burrows; other species eat huge quantities of food. For example, ground squirrels double their weight in a month of gorging.

Many small mammals and birds exhibit a daily torpor that seems to be adapted to their feeding patterns. For instance, most bats and shrews feed at night and go into torpor during daylight hours. Chickadees and hummingbirds feed during the day and often go into torpor on cold nights; the body

temperature of chickadees drops as much as 10°C at night, and that of hummingbirds can fall 25–30°C. All endotherms that use daily torpor are relatively small; when active, they have high metabolic rates and thus very high rates of energy consumption. During hours when they cannot feed, torpor enables them to survive on stored energy.

An animal's daily cycle of activity and torpor appears to be a built-in rhythm controlled by its biological clock (see Chapter 48). Even if food is made available to a shrew all day, it still goes through its daily torpor. The need for sleep in humans and the slight drop in body temperature that accompanies it may be an evolutionary remnant of a more pronounced daily torpor in our early mammalian ancestors.

Having examined some general principles of animal biology, we are now ready to compare how diverse animals perform such activities as digestion, circulation, gas exchange, excretion of wastes, reproduction, and coordination—the topics of the next several chapters.

Concept Check 40.5

1. Can ectotherms have stable body temperatures? Explain.
2. What mode of heat exchange is involved in "wind chill," when the air feels colder than the actual temperature?
3. Some birds in tropical dry forests periodically go into torpor, especially in the dry season. Explain.

For suggested answers, see Appendix A.

Chapter 40 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 40.1

Physical laws and the environment constrain animal size and shape

- **Physical Laws and Animal Form** (p. 821) The ability to perform certain actions, such as flying, depends on an animal's size and shape. Evolutionary convergence reflects different species' independent adaptation to a similar environmental challenge.
- **Exchange with the Environment** (pp. 821–822) Each cell of a multicellular animal must have access to an aqueous environment. Simple two-layered sacs and flat shapes maximize exposure to the surrounding medium. More complex body plans have highly folded internal surfaces specialized for exchanging materials.

Concept 40.2

Animal form and function are correlated at all levels of organization

- Animals are composed of cells. Groups of cells with a common structure and function make up tissues. Different tissues make up organs, which together make up organ systems (p. 823).
- **Tissue Structure and Function** (pp. 823–826) Epithelial tissue covers the outside of the body and lines internal organs and cavities. Connective tissues bind and support other tissues. Muscle tissue contracts in response to nerve signals. Nervous tissue transmits nerve signals throughout the animal.
Activity *Overview of Animal Tissues*
Activity *Epithelial Tissue*
Activity *Connective Tissue*
Activity *Muscle Tissue*
Activity *Nervous Tissue*
- **Organs and Organ Systems** (p. 827) The body functions as a whole, greater than the sum of its parts, because the activities of all tissues, organs, and organ systems are coordinated.

Concept 40.3

Animals use the chemical energy in food to sustain form and function

- **Bioenergetics** (pp. 828-829) Animals obtain chemical energy from food, most of which is converted to ATP for cellular work. An animal's metabolic rate is the total amount of energy it uses in a unit of time. Metabolic rates for birds and mammals, which maintain a fairly constant body temperature using metabolic heat (the endothermic strategy), are generally higher than those for most fishes, non-bird reptiles, amphibians, and invertebrates that rely mostly on external sources of heat for maintaining body temperature (the ectothermic strategy).
- **Influences on Metabolic Rate** (pp. 829-830) Metabolic rate per gram is inversely related to body size among similar animals. Activity increases metabolic rate above the BMR (endotherms) or SMR (ectotherms) of an animal. In general, endotherms can sustain high levels of activity longer than ectotherms can.
- **Investigation How Does Temperature Affect Metabolic Rate in Daphnia?**
- **Energy Budgets** (pp. 830-831) An animal's use of energy is partitioned to BMR (or SMR), activity, homeostasis (such as temperature regulation), growth, and reproduction.

Concept 40.4

Many animals regulate their internal environment within relatively narrow limits

- Homeostasis describes an animal's internal steady state. It is a balance between external changes and the animal's internal control mechanisms that oppose the changes (pp. 831-832).
- **Regulating and Conforming** (p. 832) Animals cope with environmental fluctuations by regulating certain internal changes while allowing others to conform to external changes.
- **Mechanisms of Homeostasis** (pp. 832-833) The interstitial fluid surrounding an animal's cells is usually very different from the external environment. Homeostatic mechanisms moderate changes in the internal environment and usually involve negative feedback. These mechanisms enable regulated change.

Activity Regulation; Negative and Positive Feedback

Concept 40.5

Thermoregulation contributes to homeostasis and involves anatomy, physiology, and behavior

- An animal maintains its internal temperature within a tolerable range by the process of thermoregulation (p. 833).
- **Ectotherms and Endotherms** (pp. 833-834) Most invertebrates, fishes, amphibians, and non-bird reptiles are ectotherms. Birds and mammals are endotherms. Endothermy, which is more energetically expensive than ectothermy, buffers animals' internal temperatures against external fluctuations and enables the animals to maintain a high level of aerobic metabolism.
- **Modes of Heat Exchange** (pp. 834-835) Conduction, convection, radiation, and evaporation account for heat gain or loss.
- **Balancing Heat Loss and Gain** (pp. 834-839) Thermoregulation involves physiological and behavioral adjustments that balance heat gain and loss. Insulation, vasodilation, vasoconstriction, and countercurrent heat exchangers alter the rate of heat exchange. Panting, sweating, and bathing increase evaporation, cooling the body. Both ectotherms and endotherms adjust the rate of heat exchange with their surroundings by behavioral responses. Some animals can even adjust their rate of metabolic heat production.

• **Feedback Mechanisms in Thermoregulation** (pp. 838-839)

Mammals regulate their body temperature by a complex negative-feedback mechanism that involves several organ systems, including the nervous, circulatory, and integumentary systems.

• **Adjustment to Changing Temperatures** (pp. 839-840)

Acclimation enables ectotherms and endotherms to adjust to changing environmental temperatures over days or weeks. Acclimation may involve cellular adjustments or, in the case of birds and mammals, adjustments of insulation and metabolic heat production.

• **Torpor and Energy Conservation** (pp. 840-841) Torpor conserves energy during environmental extremes. Animals may enter torpor in winter (hibernation), summer (estivation), or during sleep periods (daily torpor). Torpor involves a decrease in metabolic, heart, and respiratory rates and enables the animal to temporarily withstand unfavorable temperatures or lack of food and water.

TESTING YOUR KNOWLEDGE

Evolution Connection

The biologist C. Bergmann noted that mammals and birds living at higher latitudes are on average larger and bulkier than related species found at lower latitudes. This observation, sometimes called Bergmann's rule, has exceptions, but appears to hold true in most cases. Suggest an evolutionary hypothesis for this "rule."

Scientific Inquiry

Eastern tent caterpillars (*Malacosoma americanum*) live in sizable groups in silk nests, or tents, which they construct in cherry trees. They are among the first insects to become active in the spring, emerging very early in the season—a time when daily temperature fluctuates from freezing to very hot. Observing a colony over the course of a day, you observe striking differences in group behavior: Early in the morning, the black caterpillars rest in a tightly packed group on the east-facing surface of the tent. In midafternoon, the group is found on the tent undersurface, each caterpillar individually hanging from the tent by just a few of its legs. Propose a hypothesis to explain this behavior. How could you test your hypothesis?

Investigation How Does Temperature Affect Metabolic Rate in Daphnia?

Science, Technology, and Society

Medical researchers are investigating the possibilities of artificial substitutes for various human tissues. Examples are a liquid that could serve as "artificial blood" and a fabric that could temporarily serve as artificial skin for victims of serious burns. In what other situations might artificial blood or skin be useful? What characteristics would these substitutes need in order to function effectively in the body? Why do real tissues work better? Why not use the real things if they work better? Can you think of other artificial tissues that might be useful? What problems do you anticipate in developing and applying them?

41

Animal Nutrition

A Figure 41.1 Modern humans foraging at a farmer's market.

Key Concepts

- 41.1 Homeostatic mechanisms manage an animal's energy budget
- 41.2 An animal's diet must supply carbon skeletons and essential nutrients
- 41.3 The main stages of food processing are ingestion, digestion, absorption, and elimination
- 41.4 Each organ of the mammalian digestive system has specialized food-processing functions
- 41.5 Evolutionary adaptations of vertebrate digestive systems are often associated with diet

Overview

The Need to Feed

Every mealtime is a reminder that we are heterotrophs dependent on a regular supply of food (Figure 41.1). All animals eat other organisms—dead or alive, whole or by the piece. In general, animals fit into one of three dietary categories. Herbivores, such as gorillas, cattle, hares, and many snails, eat mainly autotrophs (plants and algae). Carnivores, such as sharks, hawks, spiders, and snakes, eat other animals. Omnivores regularly consume animals as well as plant or algal matter. Omnivorous animals include cockroaches, crows, bears, raccoons, and humans, who evolved as hunters, scavengers, and gatherers.

The terms *herbivore*, *carnivore*, and *omnivore* represent the kinds of food an animal *usually* eats and the adaptations enabling it to obtain and process that food. However, keep in mind that most animals are opportunistic feeders, eating

foods that are outside their main dietary category when their usual foods aren't available. For example, cattle and deer, which are herbivores, may occasionally eat small animals, such as insects and worms, or bird eggs, along with grass and other plants. Most carnivores obtain some nutrients from plant materials that remain in the digestive tract of the prey they eat. And all animals consume prokaryotes along with their other types of food.

Regardless of what and how an animal eats, an adequate diet must satisfy three nutritional needs: fuel (chemical energy) for all the cellular work of the body; the organic raw materials animals use in biosynthesis (carbon skeletons to make many of their own molecules); and essential nutrients, substances such as vitamins that the animal cannot make for itself from *any* raw material and therefore must obtain in food in prefabricated form. In this chapter, we will examine the nutritional requirements of animals and explore some of the diverse adaptations for obtaining and processing food. You can begin with Figure 41.2, which surveys four main mechanisms by which animals feed.

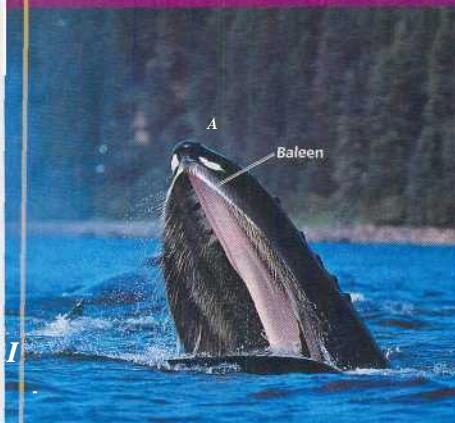

Concept 41.1

Homeostatic mechanisms manage an animal's energy budget

The theme of bioenergetics is integral to our study of nutrition. As we discussed in Chapter 40, the flow of energy into and out of an animal's body can be viewed as a "budget," with the production of ATP accounting for the largest fraction by far of most animals' energy budgets. This ATP powers basal (resting) metabolism, various activities, and in endotherms, thermoregulation.

Exploring Four Main Feeding Mechanisms of Animals

SUSPENSION FEEDERS

Many species of aquatic animals are suspension feeders, which sift small food particles from the water. For example, this humpback whale uses comb-like plates called baleen attached to its upper jaw to strain small invertebrates and fish from enormous volumes of water. Among other suspension feeders, clams and oysters use their gills to trap tiny morsels. Cilia sweep the food particles in a film of mucus to mouth.

SUBSTRATE FEEDERS

Substrate feeders are animals that live in or on their food source, eating their way through the food. This leaf miner caterpillar has eaten a hole in the mesophyll of an oak leaf, leaving a dark trail of wastes in its wake. Other substrate feeders include maggots (fly larvae), which burrow into animal carcasses.

FLUID FEEDERS

Fluid feeders suck nutrient-rich fluid from a living host. This mosquito has pierced the skin of us human host with hollow, needle-like mouthparts and is filling its digestive tract with a blood meal (colorized SEM). Similarly, aphids are fluid feeders that tap the phloem sap of plants. In contrast to such parasitic fluid feeders, which harm their hosts, some fluid feeders actually benefit their hosts. For example, hummingbirds and bees move pollen between flowers as they fluid-feed on nectar.

BULK FEEDERS

Most animals are bulk feeders, which eat relatively large pieces of food. Their adaptations include such diverse utensils as tentacles, pincers, claws, poisonous fangs, jaws, and teeth that kill their prey or tear off pieces of meat or vegetation. In this amazing scene, a rock python is beginning to ingest a gazelle it has captured and

killed. Snakes cannot chew their food into pieces and must swallow it whole—even if the prey is much bigger than the diameter of the snake. After swallowing its prey, which may take more than an hour, the python will spend two weeks or more in a quiet place digesting its meal.

Nearly all of an animal's ATP generation is based on the oxidation of energy-rich organic molecules—carbohydrates, proteins, and fats—in cellular respiration. The monomers of any of these substances can be used as fuel, though most animals "burn" proteins only after exhausting their supply of carbohydrates and fats. Fats are especially rich in energy; the oxidation of a gram of fat liberates about twice the energy liberated from a gram of carbohydrate or protein.

Glucose Regulation as an Example of Homeostasis

When an animal takes in more calories than it needs to produce ATP, the excess can be used for biosynthesis. If the animal isn't growing in size or reproducing, the body tends to store the surplus in energy depots. In humans, the liver and muscle cells store energy in the form of glycogen, a polymer made up of many glucose units (see Figure 5.6b). Glucose is a major fuel for cells, and its metabolism, regulated by

hormone action, provides an important example of homeostasis (Figure 41.3). If the body's glycogen depots are full and caloric intake still exceeds caloric expenditure, the excess is usually stored as fat.

When fewer calories are taken in than are expended—perhaps because of sustained heavy exercise or lack of food—fuel is taken out of storage depots and oxidized. This may cause an animal to lose weight. The human body generally expends liver glycogen first and then draws on muscle, glycogen and fat. Most healthy people, even if they are not obese, have enough stored fat to sustain them through several weeks of starvation (an average human's energy needs can be fueled by the oxidation of only 0.3 kg of fat per day).

Caloric Imbalance

Severe problems occur if the energy budget remains out of balance for long periods. If the diet of a human or other animal is chronically deficient in calories, undernourishment results. In this condition, the stores of glycogen and fat are used up, the body begins breaking down its own proteins for fuel, muscles begin to decrease in size, and the brain can become protein-deficient. If energy intake remains less than energy expenditures, death will eventually result. Even if a seriously undernourished person survives, some of the damage may be irreversible. Because a diet of a single staple such as rice or corn (maize) can often provide sufficient calories, undernourishment is generally common only where drought,

When blood glucose levels rise, a gland called the pancreas secretes insulin, a hormone, into the blood.

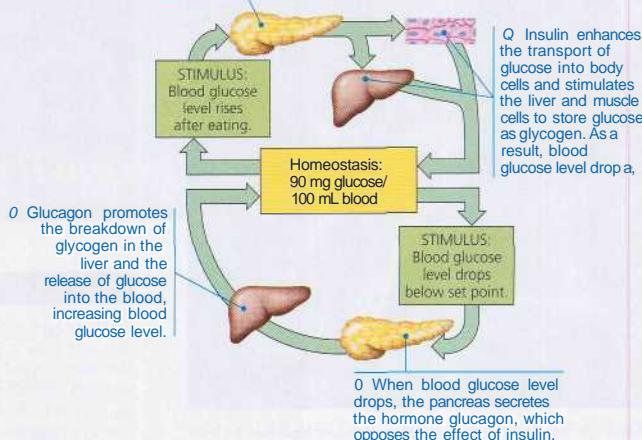

Figure 41.3 Homeostatic regulation of cellular fuel. After a meal is digested, glucose and other nutrients are absorbed into the blood from the digestive tract. The human body regulates the use and storage of glucose, a major cellular fuel. Notice that these regulatory loops are examples of the feedback control we introduced in Chapter 40.

war, or some other crisis has severely disrupted the food supply. Another cause of undernourishment is anorexia nervosa, an eating disorder in which sufferers (who are most often female) compulsively starve themselves to lose weight.

Detrimental effects also result from excessive food intake. In the United States and other affluent nations, overnourishment, or obesity, is an increasingly common problem. The human body hoards fat (Figure 41.4); it tends to store any excess fat molecules obtained from food instead of using them for fuel. In contrast, when a person eats an excess of carbohydrates, the body tends to increase its rate of carbohydrate oxidation. Thus, the amount of fat in the diet can have a more direct effect on weight gain than the amount of dietary carbohydrate.

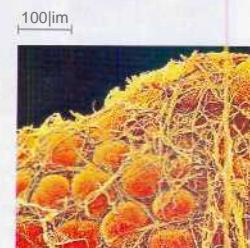

Figure 41.4 Fat cells from the abdomen of a human. Strands of connective tissue (yellow) hold the fat-storing adipose cells in place (colorized SEM).

Obesity as a Human Health Problem

The World Health Organization now recognizes obesity as a major global health problem. The increased availability of fattening foods in many countries combines with more sedentary lifestyles to put excess pounds on bodies. In the United States, the percentage of obese (very overweight) people has doubled to 30% in the past two decades, and another 35% are overweight. Weight problems often begin at a young age; 15% of children and adolescents in the U.S. are overweight.

Obesity contributes to a number of health problems, including the most common type of diabetes, cancer of the colon and breasts, and cardiovascular disease that can lead to heart attacks and strokes. The overall estimate is that obesity is a factor in about 300,000 deaths per year in the U.S. alone.

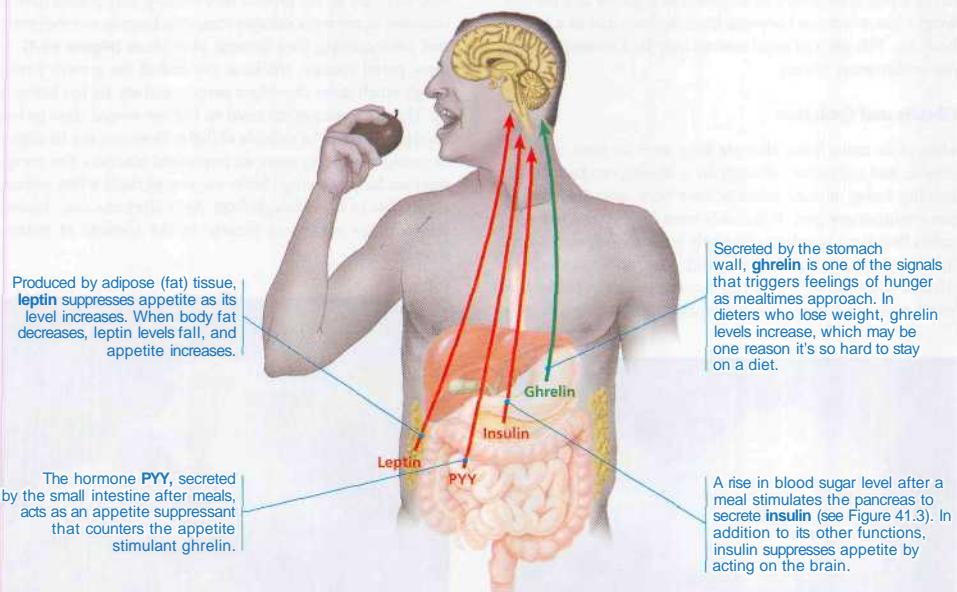

The obesity epidemic has stimulated an increase in research on the causes and possible treatments for weight-control problems. Researchers have already discovered several of the mechanisms that help regulate body weight. Over the long term, these homeostatic mechanisms are feedback circuits that control the body's storage and metabolism of fat.

And several of the chemical signals called hormones regulate both long-term and short-term appetite by affecting a "satiation center" in the brain (**Figure 41.5**).

Inheritance is a major factor in obesity. Most of the weight-regulating hormones are polypeptides (proteins), and researchers have identified dozens of the genes that code for these hormones. This hereditary connection helps explain why certain people have to struggle so hard to control their weight, while others are seemingly able to eat and eat without gaining a pound.

As researchers continue to study the genes and signaling pathways that regulate weight, there is reason to be somewhat optimistic that obese people who have inherited defects in these weight-controlling mechanisms may someday be treated with a new generation of drugs. But so far, the diversity of defects in the complex systems that regulate weight have made it difficult to develop treatments that are widely useful and free from serious side effects.

The complexity of weight control in humans is evident from studies of the hormone leptin, one of the key long-term appetite regulators in mammals. Leptin is produced by adipose

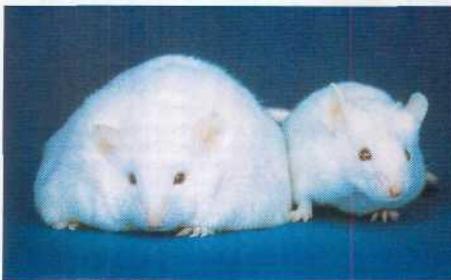

» **Figure 41.5 A few of the appetite-regulating hormones.** Secreted by various organs and tissues, the hormones reach the brain via the bloodstream. The hormones act on a region of the brain that in turn controls the "satiation center," which generates the nervous impulses that make us feel either hungry or sated ("full"). A green arrow indicates an appetite stimulant; red arrows represent appetite suppressants.

(fat) cells. As adipose tissue increases, leptin levels in the blood rise, which normally cues the brain to suppress appetite (see Figure 41.5). This is one of the feedback mechanisms that keeps most people from becoming obese in spite of access to an abundance of food. Conversely, loss of body fat decreases leptin levels, signaling the brain to increase appetite. Mice that inherit a defect in the gene for leptin become very obese (**Figure 41.6**). Researchers found that they could treat these obese mice by injecting leptin.

The discovery of the leptin-deficiency mutation in mice made front-page news and initially generated much excitement among obesity researchers, as humans also have a leptin gene. And indeed, obese children who have inherited a mutant form of the leptin gene *do* lose weight after leptin treatments. However, relatively few obese people have such defects in leptin production. In fact, most obese humans have an abnormally *high* level of leptin, which, after all, is produced by adipose tissue. For some reason, the brain's satiety center does not respond to the high leptin levels in many obese people. One hypothesis is that in humans, perhaps in contrast to many other mammals, the leptin system's primary function may not be preventing weight gain. Rather, the main function of the leptin system may be to stimulate appetite and prevent weight loss when the hormone level declines due to a loss of body fat. This physiological nuance may be a consequence of our evolutionary history.

Obesity and Evolution

Most of us crave foods that are fatty such as fries, burgers, cheese, and ice cream. Though fat hoarding can be a health liability today, it may actually have been advantageous in our evolutionary past. It has only been for the past few centuries that large numbers of people have had access to a reliable supply of high-calorie food. Our ancestors on the African savanna were gatherer-hunters who probably survived mainly on seeds and other plant products, a diet only

A Figure 41.6 A ravenous rodent. The obese mouse on the left has a defect in a gene that normally produces leptin, an appetite-suppressing hormone.

occasionally supplemented by hunting game or scavenging meat from animals killed by other predators. In such a feast-or-famine existence, natural selection may have favored those individuals with a physiology that induced them to gorge on rich, fatty foods on those rare occasions when such treats were abundantly available. Such individuals with genes promoting the storage of high-energy molecules during feasts may have been more likely than their thinner friends to survive famines. So perhaps our present-day taste for fats, which contributes to the obesity epidemic, is partly an evolutionary vestige of less nutritious times. Of course, most of us today only "gather and hunt" in grocery stores and food courts.

What seems to us to be excessive body fat may actually be beneficial in certain animal species. For example, seabirds called petrels must fly long distances to find food. Most of the food petrel parents bring to their chicks is very rich in lipids. This minimizes the weight of the food the parents must carry during their long foraging trips (recall that fat has twice as many calories per gram as other fuels). However, in addition to energy, growing baby petrels need lots of protein for building new tissues. There is relatively little protein in their oily diet, so to get all the protein they need, young petrels have to consume many more calories than they burn in metabolism—and consequently they become very obese (**Figure 41.7**). In some petrel species, chicks at the end of the growth period weigh much more than their parents and are far too heavy to fly. These fat youngsters need to fast for several days to lose enough weight to be capable of flight. However, the fat deposits in young petrels do serve an important function; the energy reserves help growing chicks survive periods when parents are unable to find enough food. As is often the case, biological oddities seem less bizarre in the context of natural selection.

A Figure 41.7 A plump petrel. Too heavy to fly, this petrel chick (right) will have to lose weight before it takes wing. In the meantime, its stored fat provides energy during times when its parent fails to bring enough food.

Concept Check 41.1

1. In what sense is a stable body weight a matter of caloric bookkeeping?
2. Explain how it is possible for someone to become obese even if his or her intake of dietary fat is relatively low compared to carbohydrate intake.
3. After reviewing Figure 41.5, explain how the hormones PYY and leptin complement each other in regulating body weight.

For suggested answers, see Appendix A.

(Concept 41.2)

An animal's diet must supply carbon skeletons and essential nutrients

In addition to providing fuel for ATP production, an animal's diet must also supply all the raw materials needed for biosynthesis. To build the complex molecules it needs to grow, maintain itself, and reproduce, an animal must obtain organic precursors (carbon skeletons) from its food. Given a source of organic carbon (such as sugar) and a source of organic nitrogen (usually amino acids from the digestion of protein), animals can fabricate a great variety of organic molecules—carbohydrates, proteins, and lipids.

▲ **Figure 41.8** Obtaining essential nutrients. A caribou, an arctic herbivore, chews on discarded antlers from another animal. Antlers and skeletal bones contain calcium phosphate, and osteophagia ("bone eating") is common among herbivores living where soils and plants are deficient in phosphorus. Animals require phosphorus as a mineral nutrient to make ATP, nucleic acids, phospholipids, and bones.

Besides fuel and carbon skeletons, an animal's diet must also supply essential nutrients. These are materials that must be obtained in preassembled form because the animal's cells cannot make them from any raw material. Some of these materials are essential for all animals, but others are needed only by certain species. For instance, ascorbic acid (vitamin C) is an essential nutrient for humans and other primates, guinea pigs, and some birds and snakes, but not for most other animals.

An animal whose diet is missing one or more essential nutrients is said to be malnourished (recall that *undernourished* refers to caloric deficiency). For example, cattle and other herbivorous animals may suffer mineral deficiencies if they graze on plants growing in soil lacking key minerals (Figure 41.8). Malnutrition is much more common than undernutrition in human populations, and it is even possible for an overnourished (obese) individual to be malnourished.

There are four classes of essential nutrients: essential amino acids, essential fatty acids, vitamins, and minerals.

Essential Amino Acids

Animals require 20 amino acids to make proteins, and most animal species can synthesize about half of these, as long as their diet includes organic nitrogen. The remaining ones, the essential amino acids, must be obtained from food in pre-fabricated form. Eight amino acids are essential in the adult human diet (arginine, histidine, is also essential for infants); the same amino acids are essential for most animals.

A diet that provides insufficient amounts of one or more essential amino acids causes a form of malnutrition known as protein deficiency (Figure 41.9). This is the most common type of malnutrition among humans. The victims are usually children, who, if they survive infancy, are likely to be retarded in physical and perhaps mental development. In one variation

▲ **Figure 41.9** Kwashiorkor (a protein deficiency) in a Haitian boy. The swelling (edema) of the belly is an osmotic effect: The ability of the blood to take up water from the body cavity by osmosis is reduced because of the deficiency of blood proteins (solutes).

of protein malnutrition, called *kwashiorkor*; the diet provides enough calories but is severely deficient in protein (see Figure 41.9). The syndrome is called kwashiorkor for a Ghanaian word meaning "rejected one," a reference to cases where the malnutrition begins when a child is weaned from the mothers milk.

The most reliable sources of essential amino acids are meat, eggs, cheese, and other animal products. The proteins in animal products are "complete," which means that they provide all the essential amino acids in their proper proportions. Most plant proteins are "incomplete," being deficient in one or more essential amino acids. Corn (maize), for example, is deficient in the amino acid lysine. People forced by economic necessity or other circumstances to obtain nearly all their calories from

corn would show symptoms of protein deficiency, as would those who were to eat only rice, wheat, or potatoes. This problem can be avoided by eating a combination of plant foods that complement one another to supply all essential amino acids (Figure 41.10). Most cultures have, by trial and error, developed balanced diets that prevent protein deficiency.

Some animals have adaptations that help them through periods when their bodies demand extraordinary amounts of protein. For example, penguins can use their muscle protein as a source of amino acids to make new proteins when they replace their feathers after molting (Figure 41.11).

Essential Fatty Acids

Animals can synthesize most of the fatty acids they need. The essential fatty acids, the ones they cannot make, are certain unsaturated fatty acids (fatty acids having double bonds; see Figure 5.12). In humans, for example, linoleic acid must be present in the diet. This essential fatty acid is required to make some of the phospholipids found in membranes. The diets of humans and other animals generally furnish ample quantities of essential fatty acids, and thus deficiencies are rare.

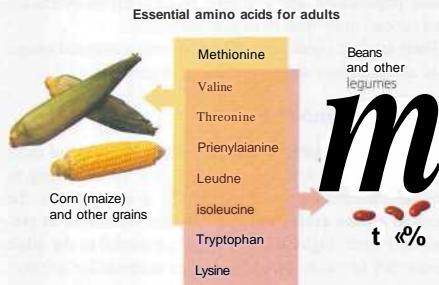

Vitamins

Vitamins are organic molecules required in the diet in amounts that are quite small compared with the relatively large required quantities of essential amino acids and fatty acids. Tiny amounts of vitamins may suffice—from about 0.01 to 100 mg per day, depending on the vitamin. However, vitamin deficiencies can cause severe problems.

So far, 13 vitamins essential to humans have been identified. They have extremely diverse physiological functions. Vitamins are grouped into two categories: water-soluble vitamins and fat-soluble vitamins (Table 41.1). The water-soluble vitamins include the B complex, which consists of several compounds that generally function as coenzymes in key metabolic processes. Vitamin C, also water-soluble, is required for the production of connective tissue. Excesses of water-soluble vitamins are excreted in urine, and moderate overdoses of these vitamins are probably harmless.

The fat-soluble vitamins are A, D, E, and K. They have a wide variety of functions. Vitamin A is incorporated into visual pigments of the eye. Vitamin D aids in calcium absorption and bone formation. The function of vitamin E is not yet fully understood, but (along with vitamin C) it seems to protect the phospholipids in membranes from oxidation (you have probably encountered advertisements for dietary supplements containing vitamin E as an "antioxidant"). Vitamin K is required for blood clotting. Excesses of fat-soluble vitamins are not excreted but are deposited in body fat, so overconsumption may result in an accumulation of these compounds to toxic levels.

The subject of vitamin dosage has aroused heated scientific and popular debate. Some think that it is sufficient to meet

A Figure 41.10 Essential amino acids from a vegetarian diet. An adult human can obtain all essential amino acids by eating a meal of corn and beans.

A Figure 41.11 Storing protein for growth. Penguins, such as this Adelie from Antarctica, must make an abundance of new protein when they molt (grow new feathers). Because of the temporary loss of their insulating coat of feathers, penguins cannot swim—or feed—when molting. What is the source of amino acids for production of feather protein? Before molting, a penguin greatly increases its muscle mass. The penguin then breaks down the extra muscle protein, which supplies the amino acids for growing new feathers.

Tafoie 41.1 Vitamin Requirements of Humans

| Vitamin | Major Dietary Sources | Some Major Functions in the Body | Possible Symptoms of Deficiency or Extreme Excess |
|--|--|---|---|
| Water-Soluble Vitamins | | | |
| Thiamin B ⁶ (thiamine) | Pork, legumes, peanuts, whole grains | Coenzyme used in removing CO ₂ from organic compounds | Beriberi (nerve disorders, emaciation, anemia) |
| Vitamin B ₂ (riboflavin) | Dairy products, meats, enriched grains, vegetables | Component of coenzymes FAD and FMN | Skin lesions such as cracks at corners of mouth |
| Niacin | Nuts, meats, grains | Component of coenzymes NAD ⁺ and NADP ⁺ | Skin and gastrointestinal lesions, nervous disorders Liver damage |
| Vitamin B ₆ (pyridoxine) | Meats, vegetables, whole grains | Coenzyme used in amino acid metabolism | Irritability, convulsions, muscular twitching, anemia Unstable gait, numb feet, poor coordination |
| α,γ-dihydroxy-β,β-dimethylbutyric acid | Most foods; meats, dairy products, whole grains, etc. | Component of coenzyme A | Fatigue, numbness, tingling of hands and feet |
| Folic acid (folacin) | Green vegetables, oranges, nuts, legumes, whole grains | Coenzyme in nucleic acid and amino acid metabolism | Anemia, gastrointestinal problems May mask deficiency of vitamin B₁₂ |
| Vitamin B ₁₂ | Meats, eggs, dairy products | Coenzyme in nucleic acid metabolism; maturation of red blood cells | Anemia, nervous system disorders |
| Biotin | Legumes, other vegetables, meats | Coenzyme in synthesis of fat, glycogen, and amino acids | Scaly skin inflammation, neuromuscular disorders |
| Vitamin C (ascorbic acid) | Fruits and vegetables, especially citrus fruits, broccoli, cabbage, tomatoes, green peppers | Used in collagen synthesis (such as for bone, cartilage, gums); antioxidant; aids in detoxification; improves iron absorption | Scurvy (degeneration of skin, teeth, blood vessels), weakness, delayed wound healing, impaired immunity Gastrointestinal upset |
| Fat-Soluble Vitamins | | | |
| Vitamin A (retinol) | Provitamin A (beta-carotene) in deep green and orange vegetables and fruits; retinol in dairy products | Component of visual pigments; maintenance of epithelial tissues; antioxidant; helps prevent damage to cell membranes | Vision problems; dry, scaling skin Headache, irritability, vomiting, hair loss, blurred vision, liver and bone damage |
| Vitamin D | Dairy products, egg yolk (also made in human skin in presence of sunlight) | Aids in absorption and use of calcium and phosphorus; promotes bone growth | Rickets (bone deformities) in children, bone softening in adults Brain, cardiovascular, and kidney damage |
| Vitamin E (tocopherol) | Vegetable oils, nuts, seeds | Antioxidant; helps prevent damage to cell membranes | None well documented in humans; possibly anemia |
| Vitamin K (phylloquinone) | Green vegetables, tea (also made by colon bacteria) | Important in blood clotting | Defective blood clotting Liver damage and anemia |

recommended daily allowances (RDAs), the nutrient intakes proposed by nutritionists to maintain health. Others think that RDAs are set too low for some vitamins, and a fraction of those people think, probably mistakenly, that *massive* doses of vitamins confer health benefits. Research is far from complete, and debate continues, especially over optimal doses of vitamins C and E. At this time, all that can be said with any certainty is that people who eat a balanced diet are not likely to develop symptoms of vitamin deficiency.

Minerals

Minerals are simple inorganic nutrients, usually required in small amounts—from less than 1 mg to about 2,500 mg per

day (**Table 41.2**, on the next page). As with vitamins, mineral requirements vary in different animal species. Humans and other vertebrates require relatively large quantities of calcium and phosphorus for the construction and maintenance of bone. Calcium is also necessary for the normal functioning of nerves and muscles, and phosphorus is also an ingredient of ATP and nucleic acids. Iron is a component of the cytochromes that function in cellular respiration (see Figure 9.13) and of hemoglobin, the oxygen-binding protein of red blood cells. Magnesium, iron, zinc, copper, manganese, selenium, and molybdenum are cofactors built into the structure of certain enzymes; magnesium, for example, is present in enzymes that split ATP. Vertebrates need iodine to make thyroid hormones, which regulate metabolic rate. Sodium,

Table 41.2 Mineral Requirements of Humans

| Mineral | Major Dietary Sources | Some Major Functions in the Body | Possible Symptoms of Deficiency* |
|-----------------|--|--|--|
| Calcium (Ca) | Dairy products, dark green vegetables, legumes | Bone and tooth formation, blood clotting, nerve and muscle function | Retarded growth, possibly loss of bone mass |
| Phosphorus (P) | Dairy products, meats, grains | Bone and tooth formation, acid-base balance, nucleotide synthesis | Weakness, loss of minerals from bone, calcium loss |
| Sulfur (S) | Proteins from many sources | Component of certain amino acids | Symptoms of protein deficiency |
| Potassium (K) | Meats, dairy products, many fruits and vegetables, grains | Acid-base balance, water balance, nerve function | Muscular weakness, paralysis, nausea, heart failure |
| Chlorine (Cl) | Table salt | Acid-base balance, formation of gastric juice, nerve function, osmotic balance | Muscle cramps, reduced appetite |
| Sodium (Na) | Table salt | Acid-base balance, water balance, nerve function | Muscle cramps, reduced appetite |
| Magnesium (Mg) | Whole grains, green leafy vegetables | Cofactor; ATP bioenergetics | Nervous system disturbances |
| Iron (Fe) | Meats, eggs, legumes, whole grains, green leafy vegetables | Component of hemoglobin and of electron carriers in energy metabolism; enzyme cofactor | Iron-deficiency anemia, weakness, impaired immunity |
| Fluorine (F) | | Maintenance of tooth (and probably bone) structure | Higher frequency of tooth decay |
| Zinc (Zn) | Drinking water, tea, seafood | Component of certain digestive enzymes and other proteins | Growth failure, scaly skin inflammation, reproductive failure, impaired immunity |
| Copper (Cu) | Seafood, nuts, legumes, organ meats | Enzyme cofactor in iron metabolism, melanin synthesis, electron transport | Anemia, bone and cardiovascular changes |
| Manganese (Mn) | Nuts, grains, vegetables, fruits, tea | Enzyme cofactor | Abnormal bone and cartilage |
| Iodine (I) | Seafood, dairy products, iodized salt | Component of thyroid hormones | Goiter (enlarged thyroid) |
| Cobalt (Co) | Meals and dairy products | Component of vitamin B ₁₂ | None, except as B ₁₂ deficiency |
| Selenium (Se) | Seafood, meals, whole grains | Enzyme cofactor; antioxidant functioning in close association with vitamin E | Muscle pain, possibly heart muscle deterioration |
| Chromium (Cr) | Brewer's yeast, liver, seafood, meats, some vegetables | Involved in glucose and energy metabolism | Impaired glucose metabolism |
| Molybdenum (Mo) | Legumes, grains, some vegetables | Enzyme cofactor | Disorder in excretion of nitrogen-containing compounds |

*All of these minerals are also harmful when consumed in excess.

potassium, and chlorine are important in nerve functioning and also in maintaining the osmotic balance between cells and the interstitial fluid.

Most people ingest far more salt (sodium chloride) than they need. For example, the average U.S. citizen eats enough salt to provide about 20 times the required amount of sodium. Much of this salt is hidden in packaged, prepared foods, even those that may not taste salty. Ingesting an excess of salt or several other minerals can upset homeostatic balance and cause toxic side effects. For example, too much sodium is associated with high blood pressure, and excess iron can cause liver damage.

In the next section, we will shift our attention from nutritional requirements to how animals process their food.

Concept Check 41.2

1. Contrast undernutrition with malnutrition.
2. Explain how a balanced vegetarian diet can provide all of the essential amino acids.
3. Compare and contrast vitamins with minerals.

For suggested answers, see Appendix A.

The main stages of food processing are ingestion, digestion, absorption, and elimination

We began our study of nutrition by surveying the diverse feeding mechanisms that have evolved among animals (see Figure 41.2). But ingestion, the act of eating, is only the first stage of food processing. Organic material in food consists largely of proteins, fats, and carbohydrates in the form of starch and other polysaccharides. Animals cannot use these large molecules directly for two reasons. First, polymers are too large to pass through membranes and enter the cells of the animal. Second, the macromolecules that make up an animal are not identical to those of its food. In building their macromolecules, however, all organisms use common monomers. For example, soybeans, fruit flies, and humans all assemble their proteins from the same 20 amino acids.

Digestion, the second stage of food processing, is the process of breaking food down into molecules small enough for the body to absorb (Figure 41.12). Digestion cleaves macromolecules into their component monomers, which the animal then uses to make its own molecules or as fuel for ATP production. Polysaccharides and disaccharides are split into simple sugars, fats are digested to glycerol and fatty acids, proteins are split into amino acids, and nucleic acids are cleaved into nucleotides.

Recall from Chapter 5 that a cell makes a macromolecule by linking together monomers; it does so by removing a molecule of water for each new covalent bond formed. Digestion reverses this process by breaking bonds with the addition of water (see Figure 5.2). This splitting process is called enzymatic hydrolysis. A variety of hydrolytic enzymes catalyze the digestion of each of the classes of macromolecules found in food. This chemical digestion is usually preceded by mechanical fragmentation of the food—by chewing, for instance. Breaking food into smaller pieces increases the surface area exposed to digestive juices containing hydrolytic enzymes.

The last two stages of food processing occur after the food is digested. In the third stage, **absorption**, the animal's cells take up (absorb) small molecules such as amino acids and simple sugars from the digestive compartment. And finally, elimination occurs, as undigested material passes out of the digestive compartment (see Figure 41.12).

Digestive Compartments

How do animals apply their digestive processes to food without digesting their own cells and tissues? Alter all, digestive enzymes hydrolyze the same biological materials (such as proteins, lipids, and carbohydrates) that animals are made of, and it is obviously important to avoid digesting oneself! Most animals reduce the risk of self-digestion by processing food in specialized compartments.

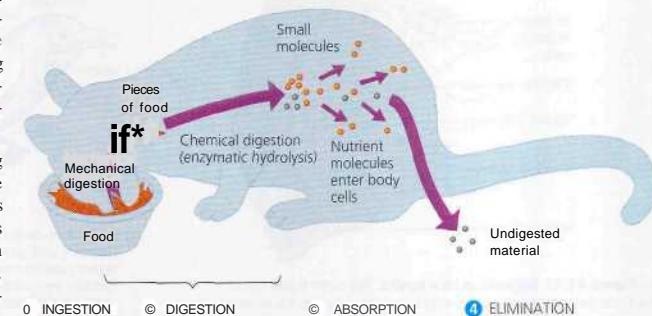

Intracellular Digestion

Food vacuoles—cellular organelles in which hydrolytic enzymes break down food without digesting the cell's own cytoplasm—are the simplest digestive compartments. This digestion within a cell, called intracellular digestion, begins after a cell engulfs food by phagocytosis or pinocytosis (see Figure 7.20). Newly formed food vacuoles fuse with lysosomes, which are organelles containing hydrolytic enzymes. This mixes the food with the enzymes, allowing digestion to occur safely within a compartment that is enclosed by a protective membrane. Sponges are unusual among animals in that they digest their food entirely by the intracellular mechanism (see Figure 33.4).

Extracellular Digestion

In most animals, at least some hydrolysis occurs by extracellular digestion, the breakdown of food outside cells. Extracellular digestion occurs within compartments that are continuous with the outside of the animal's body. Having an extracellular cavity for digestion enables an animal to devour much larger prey than can be ingested by phagocytosis and digested intracellularly.

Many animals with relatively simple body plans have a digestive sac with a single opening. This pouch, called a

► Figure 41.12 The four stages of food processing.

gastrovascular cavity, functions in both digestion and distribution of nutrients throughout the body (hence the *vascular* part of the term). The cnidarians called hydras provide a good example of how a gastrovascular cavity works. Hydras are carnivores that sting prey with specialized organelles called nematocysts and then use tentacles to stuff the food through their mouth into their gastrovascular cavity (Figure 41.13). Specialized gland cells of the gastrodermis, the tissue layer that lines the cavity, then secrete digestive enzymes that break the soft tissues of the prey into tiny pieces. Other gastrodermal cells, called nutritive muscular cells, engulf these food particles, and most of the actual hydrolysis of macromolecules occurs intracellularly, as in sponges. After a hydra has digested its meal, undigested materials remaining in the gastrovascular cavity, such as the exoskeletons of small crustaceans, are eliminated through the single opening, which functions in the

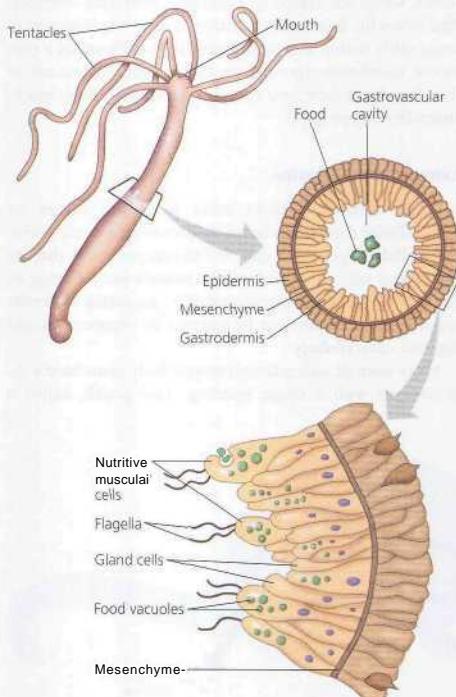

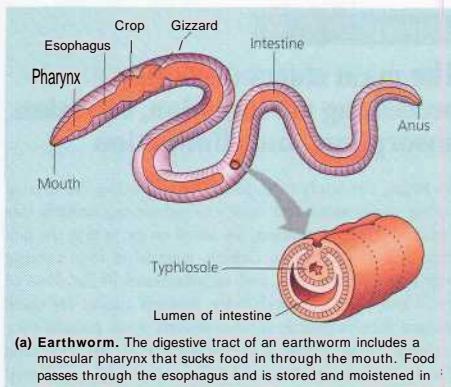

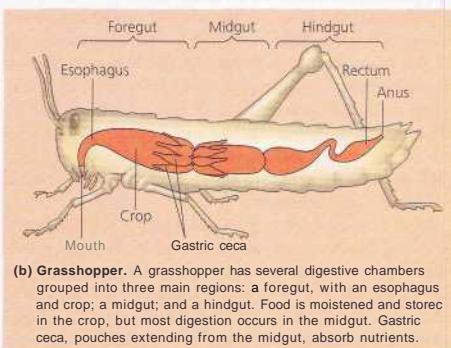

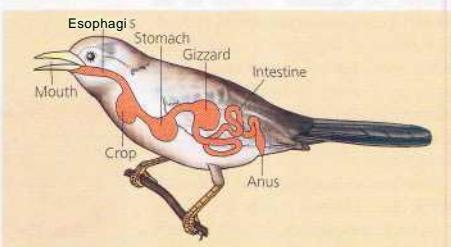

Figure 41.13 Digestion in a hydra. The outer epidermis of the hydra has protective and sensory functions, whereas the inner gastrodermis is specialized for digestion. Digestion begins in the gastrovascular cavity and is completed intracellularly after small food particles are engulfed by the gastrodermal cells.

(a) Earthworm. The digestive tract of an earthworm includes a muscular pharynx that sucks food in through the mouth. Food passes through the esophagus and is stored and moistened in the crop. The muscular gizzard, which contains small bits of sand and gravel, pulverizes the food. Digestion and absorption occur in the intestine, which has a dorsal fold, the typhlosole, that increases the surface area for nutrient absorption.

(b) Grasshopper. A grasshopper has several digestive chambers grouped into three main regions: a foregut, with an esophagus and crop; a midgut; and a hindgut. Food is moistened and stored in the crop, but most digestion occurs in the midgut. Gastric ceca, pouches extending from the midgut, absorb nutrients.

(c) Bird. Many birds have three separate chambers—the crop, stomach, and gizzard—where food is pulverized and churned before passing into the intestine. A bird's crop and gizzard function very much like those of an earthworm. In most birds, chemical digestion and absorption of nutrients occur in the intestine.

A Figure 41.14 Variation in alimentary canals.

dual role of mouth and anus. Many flatworms also have a gastrovascular cavity with a single opening (see Figure 33.10).

In contrast to cnidarians and flatworms, most animals—including nematodes, annelids, molluscs, arthropods, echinoderms, and chordates—have a digestive tube extending between two openings, a mouth and an anus. Such a tube is called a complete digestive tract or an alimentary canal. Because food moves along the canal in a single direction, the tube can be organized into specialized regions that carry out digestion and nutrient absorption in a stepwise fashion (Figure 41.14). Another advantage of a complete digestive tract is the ability to ingest additional food before earlier meals are completely digested—which may be difficult or inefficient for animals with gastrovascular cavities.

Concept Check 41.3

- What is the main anatomical distinction between a gastrovascular cavity and an alimentary canal?
- Why are nutrients from a recently ingested meal not really "inside" your body prior to the absorption stage of food processing?

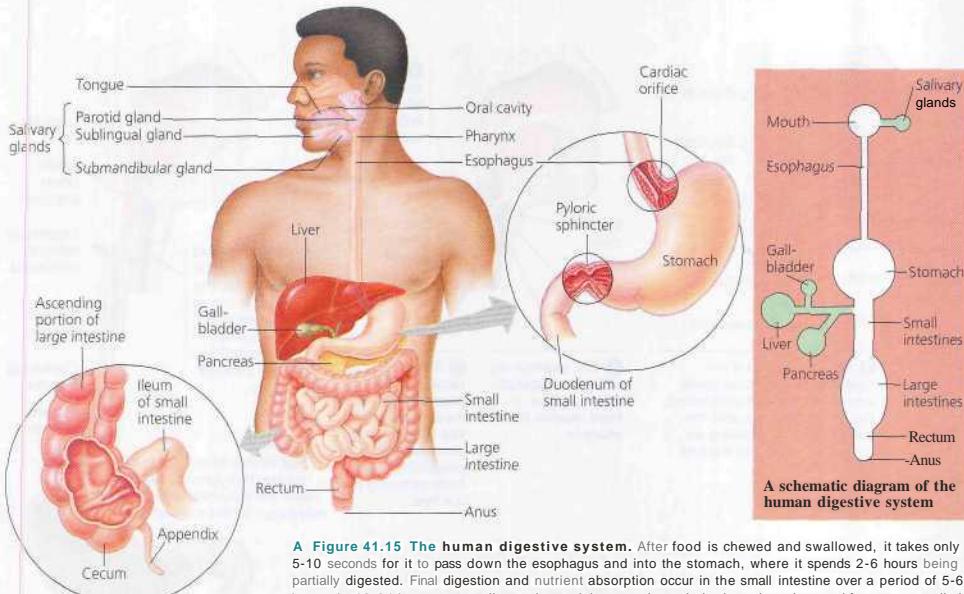

For suggested answers, see Appendix A.

41.4

Each organ of the mammalian digestive system has specialized food-processing functions

The general principles of food processing are similar for a diversity of animals, so we can use the digestive system of mammals as a representative example. The mammalian digestive system consists of the alimentary canal and various accessory glands that secrete digestive juices into the canal through ducts (Figure 41.15). Peristalsis, rhythmic waves of contraction by smooth muscles in the wall of the canal, pushes the food along the tract. At some of the junctions between specialized segments of the digestive tube, the muscular layer is modified into ringlike valves called sphincters, which close off the tube like drawstrings, regulating the passage of material between chambers of the canal. The accessory glands of the mammalian digestive system are three pairs of salivary glands, the pancreas, the liver, and the gallbladder, which stores a digestive juice.

Using the human digestive system as a model, let's now follow a meal through the alimentary canal, examining in more

A. Figure 41.15 The human digestive system. After food is chewed and swallowed, it takes only 5–10 seconds for it to pass down the esophagus and into the stomach, where it spends 2–6 hours being partially digested. Final digestion and nutrient absorption occur in the small intestine over a period of 5–6 hours. In 12–24 hours, any undigested material passes through the large intestine, and feces are expelled through the anus.

detail what happens to the food in each of the processing stations along the way (see Figure 41.15).

The Oral Cavity, Pharynx, and Esophagus

Both physical and chemical digestion of food begin in the mouth. During chewing, teeth of various shapes cut, smash, and grind food, making it easier to swallow and increasing its surface area. The presence of food in the oral cavity triggers a nervous reflex that causes the salivary glands to deliver saliva through ducts to the oral cavity. Even before food is actually in the mouth, salivation may occur in anticipation because of learned associations between eating and the time of day, cooking odors, or other stimuli. Humans secrete more than a liter of saliva each day.

Saliva contains a slippery glycoprotein (carbohydrate-protein complex) called mucus, which protects the lining of the mouth from abrasion and lubricates food for easier swallowing. Saliva also contains buffers that help prevent tooth decay by neutralizing acid in the mouth. Antibacterial agents in saliva kill many of the bacteria that enter the mouth with food.

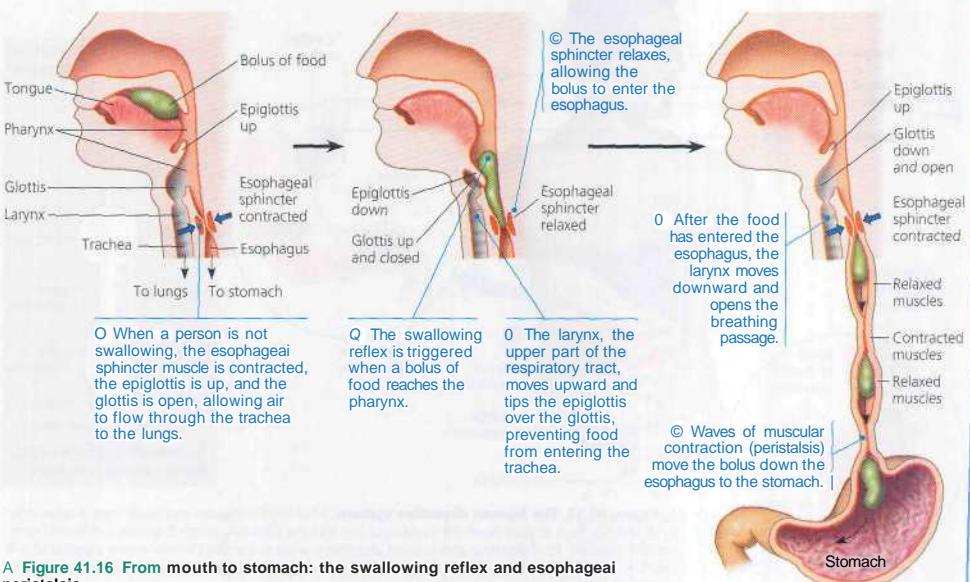

Chemical digestion of carbohydrates, a main source of chemical energy, begins in the oral cavity. Saliva contains salivary amylase, an enzyme that hydrolyzes starch (a glucose polymer from plants) and glycogen (a glucose polymer

from animals). The main products of this enzyme's action are smaller polysaccharides and the disaccharide maltose.

The tongue tastes food, manipulates it during chewing, and helps shape the food into a ball called a bolus. During swallowing, the tongue pushes a bolus to the back of the oral cavity and into the pharynx.

The region we call our throat is the pharynx, a junction that opens to both the esophagus and the windpipe (trachea). When we swallow, the top of the windpipe moves up so that its opening, the glottis, is blocked by a cartilaginous flap, the epiglottis. You can see this motion in the bobbing of the "Adam's apple" during swallowing. This tightly controlled mechanism normally ensures that a bolus is guided into the entrance of the esophagus (Figure 41.16, steps 1-4). Food or liquids may go "down the wrong pipe" because the swallowing reflex didn't close the opening of the windpipe in time. The resulting blockage of airflow (choking) stimulates vigorous coughing, which usually expels the material. If it is not expelled quickly, the lack of airflow to the lungs can be fatal.

The esophagus conducts food from the pharynx down to the stomach by peristalsis (see Figure 41.16, step 6). The muscles at the very top of the esophagus are striated (voluntary). Thus, the act of swallowing begins voluntarily, but then the involuntary waves of contraction by smooth muscles in the rest of the esophagus take over.

A. Figure 41.16 From mouth to stomach: the swallowing reflex and esophageal peristalsis.

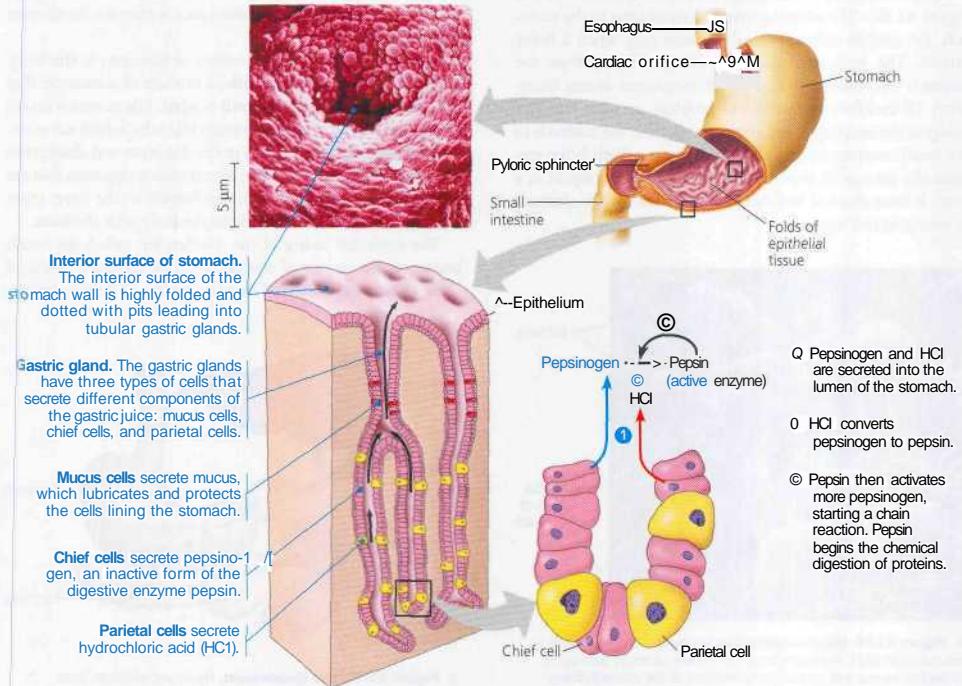

THE Stomach

The **stomach** stores food and performs preliminary steps of digestion. This large organ is located in the upper abdominal cavity, just below the diaphragm. With accordionlike folds and a very elastic wall, the stomach can stretch to accommodate about 2 L of food and fluid. It is because the stomach can store an entire meal that we do not need to eat constantly. Besides storing food, the stomach performs important digestive functions; it secretes a digestive fluid called **gastric juice** and mixes this secretion with the food by the churning action of the smooth muscles in the stomach wall.

Gastric juice is secreted by the epithelium lining numerous deep pits in the stomach wall. With a high concentration of hydrochloric acid, gastric juice has a pH of about 2—acidic enough to dissolve iron nails. One function of the acid is to disrupt the extracellular matrix that binds cells together in meat and plant material. The acid also kills most bacteria that are swallowed with food. Also present in gastric juice is **pepsin**, an enzyme that begins the hydrolysis of proteins. Pepsin breaks

peptide bonds adjacent to specific amino acids, cleaving proteins into smaller polypeptides, which are later digested completely to amino acids in the small intestine. Pepsin is one of the few enzymes that works best in a strongly acidic environment. The low pH of gastric juice denatures (unfolds) the proteins in food, increasing exposure of their peptide bonds to pepsin.

What prevents pepsin from destroying the cells of the stomach wall? First, pepsin is secreted in an *inactive* form called **pepsinogen** by specialized cells called chief cells located in gastric pits (Figure 41.17). Other cells, called parietal cells, also in the pits, secrete hydrochloric acid. The acid converts pepsinogen to active pepsin by removing a small portion of the molecule and exposing its active site. Because different cells secrete the acid and pepsinogen, the two ingredients do not mix—and pepsinogen is not activated—until they enter the lumen (cavity) of the stomach. Activation of pepsinogen is an example of positive feedback: Once some pepsinogen is activated by acid, activation occurs at an increasingly rapid rate because pepsin itself can activate additional molecules of pepsinogen. Many other digestive enzymes are also secreted in inactive

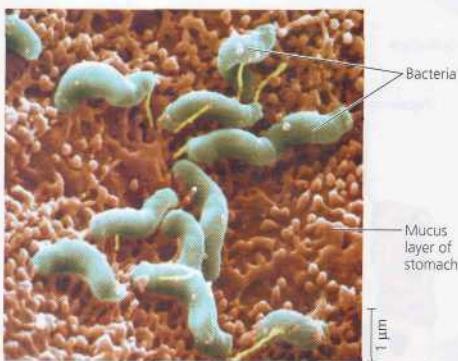

A Figure 41.17 The stomach and its secretions. The micrograph (colorized SEM) shows a gastric pit on the interior surface of the stomach, through which digestive juices are secreted.

forms that become active within the lumen of the digestive tract

The stomach's second defense against self-digestion is a coating of mucus, secreted by the epithelial cells of the stomach lining. Still, the epithelium is constantly eroded, and mitosis generates enough cells to completely replace the stomach lining every three days. Gastric ulcers, lesions in this lining, are caused mainly by the acid-tolerant bacterium *Helicobacter pylori* (Figure 41.18). Though treatable with antibiotics, gastric ulcers may worsen if pepsin and acid destroy the lining faster than it can regenerate.

About every 20 seconds, the stomach contents are mixed by the churning action of smooth muscles. You may feel hunger pangs when your empty stomach churns. (Sensations of hunger are also associated with brain centers that monitor the blood's nutritional status and levels of the appetite-controlling hormones discussed earlier in this chapter.) As a result of mixing and enzyme action, what begins in the stomach as a recently swallowed meal becomes a nutrient-rich broth known as **acid chyme**.

Most of the time, the stomach is closed off at both ends (see Figure 41.15). The opening from the esophagus to the stomach, the cardiac orifice, normally dilates only when a bolus arrives. The occasional backflow of acid chyme from the stomach into the lower end of the esophagus causes heartburn. (If backflow is a persistent problem, an ulcer may develop in the esophagus.) At the opening from the stomach to the small intestine is the **pyloric sphincter**, which helps regulate the passage of chyme into the intestine, one squirt at a time. It takes about 2 to 6 hours after a meal for the stomach to empty in this way.

A Figure 41.18 Ulcer-causing bacteria. The bacteria visible in this colorized SEM, *Helicobacter pylori*, initiate ulcers by destroying protective mucus and causing inflammation of the stomach lining. Then the acidic gastric juice can attack the stomach tissue. In severe ulcers, the erosion can produce a hole in the stomach wall and cause life-threatening internal bleeding and infection.

The Small Intestine

With a length of more than 6 m in humans, the sm, **small intestine** is the longest section of the alimentary canal (its name refers to its small diameter, compared with that of the large intestine). Most of the enzymatic hydrolysis of food macromolecules and most of the absorption of nutrients into the blood occur in the small intestine.

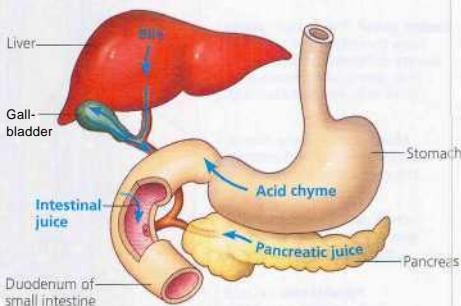

Enzymatic Action in the Small Intestine

The first 25 cm or so of the small intestine is called the **duodenum**. It is here that acid chyme from the stomach mixes with digestive juices from the pancreas, liver, gallbladder, and gland cells of the intestinal wall itself (Figure 41.19).

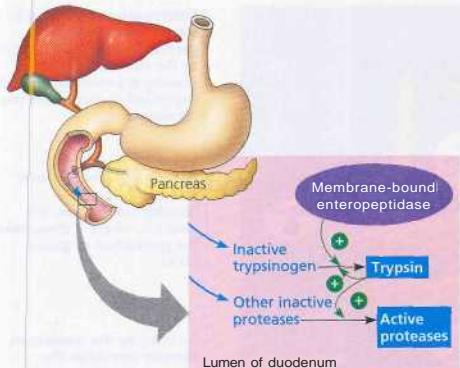

The pancreas produces several hydrolytic enzymes and an alkaline solution rich in bicarbonate. The bicarbonate acts as a buffer, offsetting the acidity of chyme from the stomach. The pancreatic enzymes include protein-digesting enzymes (proteases) that are secreted into the duodenum in inactive form. In a chain reaction similar to the activation of pepsin in the stomach, the pancreatic proteases are activated once they are safely located in the extracellular space within the duodenum (Figure 41.20).

The liver performs a wide variety of functions in the body, including the production of **bile**, a mixture of substances that is stored in the gallbladder until needed. Bile contains no digestive enzymes, but it does contain bile salts, which act as detergents (emulsifiers) that aid in the digestion and absorption of fats (see Figure 41.24). Bile also contains pigments that are by-products of red blood cell destruction in the liver; these bile pigments are eliminated from the body with the feces.

The epithelial lining of the duodenum, called the brush border, is the source of several digestive enzymes. Some of these enzymes are secreted into the lumen of the duodenum,

A Figure 41.19 The duodenum. Hydrolytic enzymes from accessory glands mix with acid chyme in the duodenum, continuing the digestion process. Note that bile is produced in the liver but stored in the gallbladder, which releases bile into the duodenum as needed.

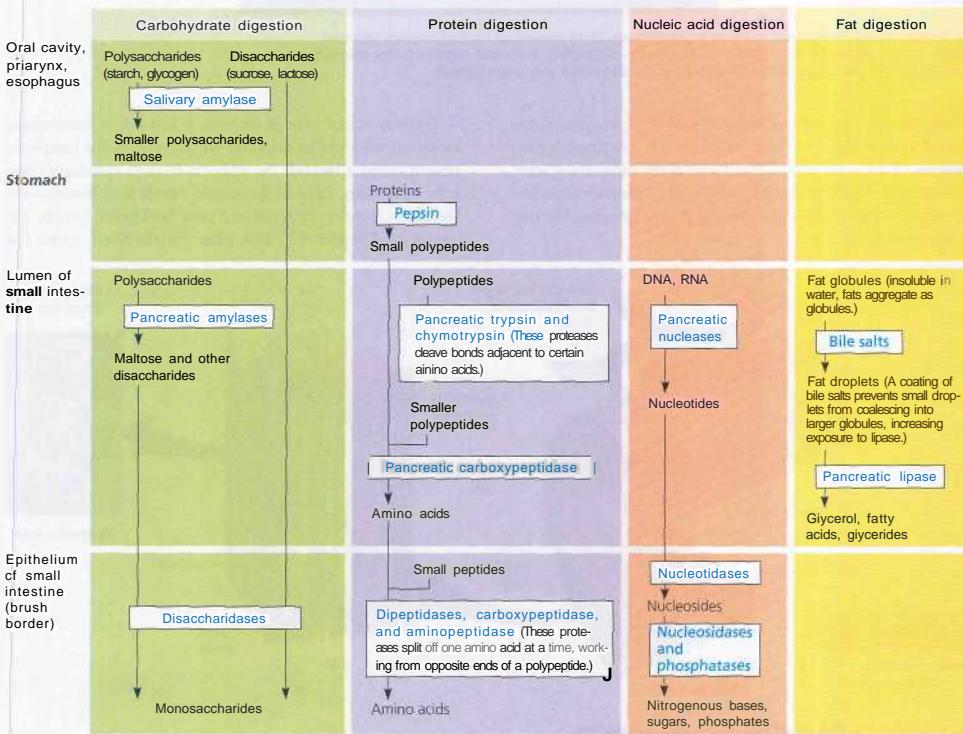

A Figure 41.20 Protease activation. The pancreas secretes inactive proteases into the duodenum. An enzyme called enteropeptidase, which is bound to the intestinal epithelium, converts trypsinogen to trypsin. Trypsin then activates other proteases. (© indicates activation.)

but other digestive enzymes are actually bound to the surface of epithelial cells.

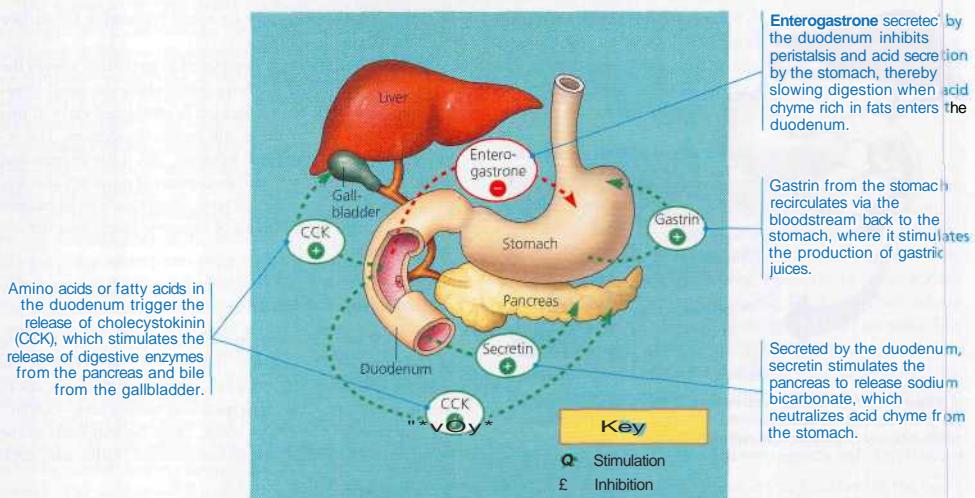

Enzymatic digestion is completed as peristalsis moves the mixture of chyme and digestive juices along the small intestine (Figure 41.21). Most digestion is completed early in this journey, while the chyme is still in the duodenum. The remaining regions of the small intestine, called the *jejunum* and *ileum*, function mainly in the absorption of nutrients and water. Figure 41.22, on the next page, diagrams how hormones help coordinate the secretion of digestive juices into the alimentary canal.

Absorption of Nutrients

To enter the body nutrients in the lumen must cross the lining of the digestive tract. A few nutrients are absorbed in the stomach and large intestine, but most absorption occurs in the small intestine. This organ has a huge surface area— 300 m^2 , roughly the size of a tennis court. Large circular folds in the lining bear fingerlike projections called *villi*, and each

B Figure 41.21 Flowchart of enzymatic digestion in the human digestive system.

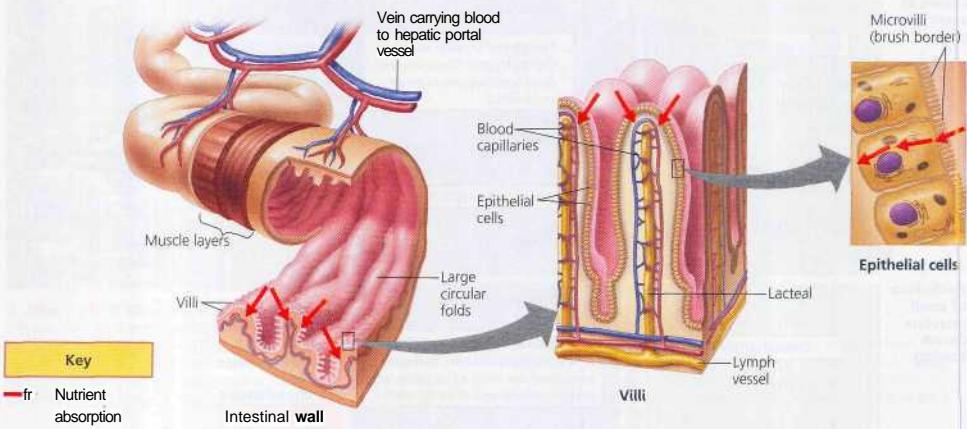

Amino acids or fatty acids in the duodenum trigger the release of cholecystokinin (CCK), which stimulates the release of digestive enzymes from the pancreas and bile from the gallbladder.

A Figure 41.22 Hormonal control of digestion. Many animals go for long intervals between meals and do not need their digestive systems to run continuously. Hormones released by the stomach and duodenum help ensure that digestive secretions are present only when needed.

epithelial cell of a villus has many microscopic appendages called **microvilli** that are exposed to the intestinal lumen (**Figure 41.23**). (The microvilli's shape is the basis of the term *brush border* for the intestinal epithelium.) This enormous microvillar surface is an adaptation that greatly increases the rate of nutrient absorption.

Penetrating the core of each villus is a net of microscopic blood vessels (capillaries) and a small vessel of the lymphatic system called a **lacteal**. (In addition to their circulatory system, vertebrates have an associated network of vessels—the lymphatic system—that carries a clear fluid called lymph, discussed in Chapter 43.) Nutrients are absorbed across the

A Figure 41.23 The structure of the small intestine.

int stinal epithelium and then across the unicellular epithelium of the capillaries or lacteals. Only these two single layers of epithelial cells separate nutrients in the lumen of the intestine from the bloodstream.

In some cases, transport of nutrients across the epithelial cells is passive. The simple sugar fructose, for example, apparently moves by diffusion down its concentration gradient from the lumen of the intestine into the epithelial cells and

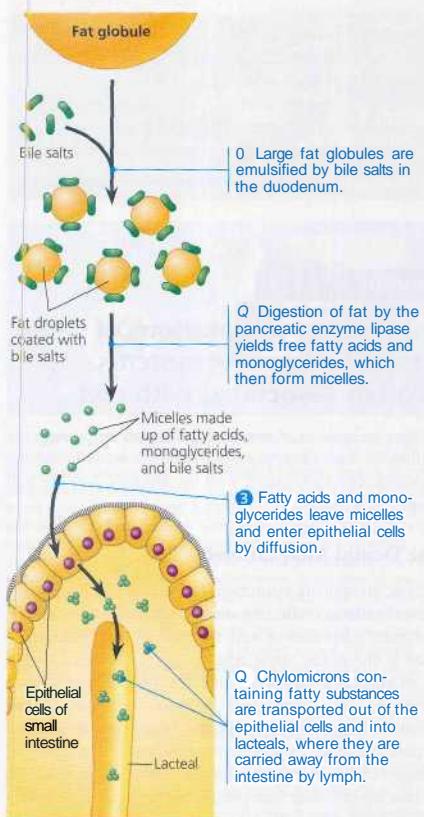

Figure 41.24 **Digestion and absorption of fats.** Hydrolysis of fats is a digestive challenge because fat molecules are insoluble in water. However, bile salts from the gallbladder secreted into the duodenum coat tiny fat droplets and keep them from coalescing, a process called emulsification. Because the droplets are small, a large surface area of fat is exposed to lipase. Once the fat molecules have been hydrolyzed, they form micelles, which enable the fatty substances to diffuse into the epithelial lining of the small intestine. From the epithelial cells, they can be absorbed into the circulatory system.

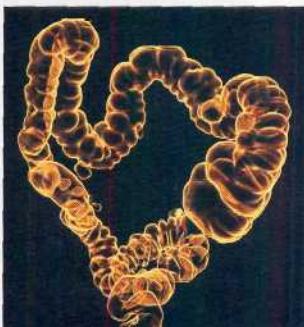

then into capillaries. Other nutrients, including amino acids, small peptides, vitamins, and glucose and several other simple sugars, are pumped against concentration gradients by the epithelial membranes. This active transport allows the intestine to absorb a much higher proportion of the nutrients in the intestine than would be possible with passive diffusion.

Amino acids and sugars pass through the epithelium, enter capillaries, and are carried away from the intestine by the bloodstream. After glycerol and fatty acids are absorbed by epithelial cells, they are recombined into fats within those cells. The fats are then mixed with cholesterol and coated with proteins, forming small globules called chylomicrons, most of which are transported by exocytosis out of the epithelial cells and into lacteals (**Figure 41.24**). The lacteals converge into the larger vessels of the lymphatic system. Lymph, containing chylomicrons, eventually drains from the lymphatic system into large veins that return blood to the heart.

In contrast to the lacteals, the capillaries and veins that drain nutrients away from the villi all converge into the hepatic portal vein, a blood vessel that leads directly to the liver. This ensures that the liver—which has the metabolic versatility to interconvert various organic molecules—has first access to amino acids and sugars absorbed after a meal is digested. Therefore, blood that leaves the liver may have a very different balance of these nutrients than the blood that entered via the hepatic portal vein. For example, the liver helps regulate the level of glucose molecules in the blood, and blood exiting the liver usually has a glucose concentration very close to 0.1%, regardless of the carbohydrate content of a meal (see Figure 41.3). “From the liver, blood travels to the heart, which pumps the blood and the nutrients it contains to all parts of the body.”

The Large Intestine

The large intestine, or colon (**Figure 41.25**), is connected to the small intestine at a T-shaped junction, where a sphincter

*** Figure 41.25** **Digital image of a human colon.** This image was produced by integrating two-dimensional sectional views of the large intestine.

(a muscular valve) controls the movement of material. One arm of the T is a pouch called the cecum (see Figure 41.15). Compared to many other mammals, humans have a relatively small cecum. The human cecum has a fingerlike extension, the appendix, which is dispensable. (Lymphoid tissue in the appendix makes a minor contribution to body defense.) The main branch of the human colon is about 1.5 m long.

A major function of the colon is to recover water that has entered the alimentary canal as the solvent of the various digestive juices. About 7 L of fluid are secreted into the lumen of the digestive tract each day, which is much more liquid than most people drink. Most of this water is reabsorbed when nutrients are absorbed in the small intestine. The colon reclaims much of the remaining water that was not absorbed in the small intestine. Together, the small intestine and colon reabsorb about 90% of the water that enters the alimentary canal.

The wastes of the digestive tract, the feces, become more solid as they are moved along the colon by peristalsis. The movement is sluggish, and it generally takes about 12 to 24 hours for material to travel the length of the organ. If the lining of the colon is irritated—by a viral or bacterial infection, for instance—less water than normal may be reabsorbed, resulting in diarrhea. The opposite problem, constipation, occurs when peristalsis moves the feces along the colon too slowly. An excess of water is reabsorbed, and the feces become compacted.

Living in the large intestine is a rich flora of mostly harmless bacteria. One of the common inhabitants of the human colon is *Escherichia coli*, a favorite research organism of molecular biologists (see Chapter 18). The presence of *E. coli* in lakes and streams is an indication of contamination by untreated sewage. Intestinal bacteria live on unabsorbed organic material. As by-products of their metabolism, many colon bacteria generate gases, including methane and hydrogen sulfide. Some of the bacteria produce vitamins, including biotin, folic acid, vitamin K, and several B vitamins. These vitamins, absorbed into the blood, supplement our dietary intake of vitamins.

Feces contain masses of bacteria, as well as cellulose and other undigested materials. Although cellulose fibers have no caloric value to humans, their presence in the diet helps move food along the digestive tract.

The terminal portion of the colon is called the rectum, where feces are stored until they can be eliminated. Between the rectum and the anus are two sphincters, one involuntary and the other voluntary. One or more times each day, strong contractions of the colon create an urge to defecate.

We have now followed a meal from one opening (the mouth) of the alimentary canal to the other (the anus). In the last section of this chapter, we'll see how some of the digestive adaptations of animals may have evolved.

Concept Check 41.4

- In the weightless environment of space, how does food swallowed by an astronaut reach the stomach?
- Describe two key digestive functions of the hydrochloric acid in gastric juice.
- What materials are mixed within the duodenum during digestion of a meal?
- How is the structure of the brush border (epithelium) of the small intestine adapted to its function of nutrient absorption?
- Explain why treatment of a chronic infection, with antibiotics for an extended period of time may cause vitamin K deficiency.
- After reviewing Figure 41.22, explain how the pancreas times its secretion of digestive juice to mix with a partially digested meal in the duodenum.

For suggested answers, see Appendix A.

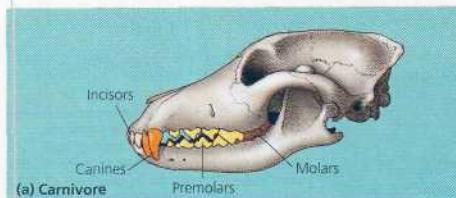

Concept 41.5

Evolutionary adaptations of vertebrate digestive systems are often associated with diet

The digestive systems of mammals and other vertebrates are variations on a common plan, but there are many intriguing adaptations, often associated with the animal's diet. We will examine just a few.

Some Dental Adaptations

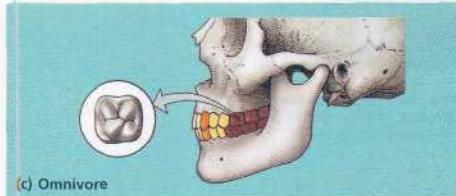

Dentition, an animal's assortment of teeth, is one example of structural variation reflecting diet. Particularly in mammals, evolutionary adaptation of teeth for processing different kinds of food is one of the major reasons this vertebrate class has been so successful. Compare the dentition of carnivorous, herbivorous, and omnivorous mammals in Figure 41.26. Nonmammalian vertebrates generally have less specialized dentition, but there are interesting exceptions. For example, poisonous snakes, such as rattlesnakes, have fangs, modified teeth that inject venom into prey. Some fangs are hollow, like syringes, while others drip the poison along grooves on the surfaces of the teeth. All snakes have another important anatomical adaptation associated with feeding: They swallow their prey whole, with no chewing, and the lower jaw is loosely hinged to the skull by an elastic ligament that permits the mouth and throat to open very wide for swallowing impressively large prey (once again, witness the astonishing episode recorded in Figure 41.2).

(a) Carnivore

(b) Herbivore

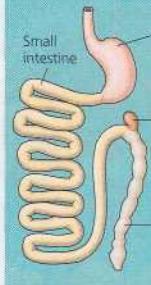

(c) Omnivore

A Figure 41.26 Dentition and diet. (a) Carnivores, such as members of the dog and cat families, generally have pointed incisors and canines that can be used to kill prey and rip or cut away pieces of flesh. The jagged premolars and molars crush and shred food. (b) In contrast, herbivorous mammals, such as horses and deer, usually have teeth with broad, ridged surfaces that grind tough plant material. The incisors and canines are generally modified for biting off pieces of vegetation. In some herbivorous mammals, canines are absent. (c) Humans, being omnivores adapted for eating both vegetation and meat, have a relatively unspecialized dentition. The permanent (adult) set of teeth is 32 in number. Beginning at the midline of the upper and lower jaw are two bladelike incisors for biting, a pointed canine for tearing, two premolars for grinding, and three molars for crushing.

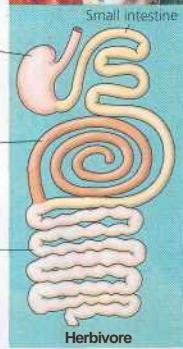

Stomach and Intestinal Adaptations

Large, expandable stomachs are common in carnivores, which may go for a long time between meals and therefore must eat as much as they can when they do catch prey. For example, a 200-kg African lion can consume 40 kg of meat in one meal.

The length of the vertebrate digestive system is also correlated with diet. In general, herbivores and omnivores have longer alimentary canals relative to their body size than carnivores (Figure 41.27). Vegetation is more difficult to digest than meat because it contains cell walls. A longer tract furnishes more time for digestion and more surface area for the absorption of nutrients.

Carnivore

Herbivore

A Figure 41.27 The digestive tracts of a carnivore (coyote) and herbivore (koala) compared. Although these two mammals are about the same size, the koala's intestines are much longer, an adaptation that enhances processing of fibrous, protein-poor eucalyptus leaves from which it obtains virtually all its food and water. Extensive chewing chops the leaves into very small pieces, increasing exposure of the food to digestive juices. The koala's cecum—at 2 m, the longest of any animal of equivalent size—functions as a fermentation chamber where symbiotic bacteria convert the shredded leaves into a more nutritious diet.

Symbiotic Adaptations

Herbivorous animals face a nutritional challenge: Much of the chemical energy in their diets is contained in the cellulose of plant cell walls, but animals do not produce enzymes that hydrolyze cellulose. Many vertebrates (as well as termites, whose wood diets are largely cellulose) solve this problem by housing large populations of symbiotic bacteria and protists in fermentation chambers in their alimentary canals. These microorganisms *do* have enzymes that can digest cellulose to simple sugars and other compounds that the animal can absorb. In many cases, the microorganisms can also use the sugars from digested cellulose along with minerals to make a variety of nutrients essential to the animal, such as vitamins and amino acids.

The location of symbiotic microbes in the digestive tracts of herbivores varies, depending on the type of animal. The hoatzin, an herbivorous bird that lives in South American rain forests, has a large, muscular crop (an esophageal pouch) that houses symbiotic microorganisms. Hard ridges in the wall of the crop grind plant leaves into small fragments, and the microorganisms break down cellulose. Many herbivorous mammals, including horses, house

O Rumen. When the cow first chews and swallows a mouthful of grass, boluses (green arrows) enter the rumen.

O Abomasum. The cud, containing great numbers of microorganisms, finally passes to the abomasum for digestion by the cow's own enzymes (black arrows).

O Omasum. The cow then reswallows the cud (blue arrows), which moves to the omasum, where water is removed.

O Reticulum. Some boluses also enter the reticulum. In both the rumen and the reticulum, symbiotic prokaryotes and protists (mainly ciliates) go to work on the cellulose-rich meal. As by-products of their metabolism, the microorganisms secrete fatty acids. The cow periodically regurgitates and rechews the cud (red arrows), which further breaks down the fibers, making them more accessible to further microbial action.

A Figure 41.28 Ruminant digestion. The stomach of a ruminant has four chambers. Because of the microbial action in the chambers, the diet from which a ruminant actually absorbs its nutrients is much richer than the grass the animal originally ate. In fact, a ruminant eating grass or hay obtains many of its nutrients by digesting the symbiotic microorganisms, which reproduce rapidly enough in the rumen to maintain a stable population.

symbiotic microorganisms in a large cecum, the pouch where the small and large intestines connect. The symbiotic bacteria of rabbits and some rodents live in the large intestine as well as in the cecum. Since most nutrients are absorbed in the small intestine, nourishing by-products of fermentation by bacteria in the large intestine are initially lost with the feces. Rabbits and rodents recover these nutrients by eating some of their feces and passing the food through the alimentary canal a second time. (The familiar rabbit "pellets," which are not reingested, are the feces eliminated after food has passed through the digestive tract twice.) The koala, an Australian marsupial, also has an enlarged cecum, where symbiotic bacteria ferment finely shredded eucalyptus leaves (see Figure 41.27). The most elaborate adaptations for an herbivorous diet have evolved in the animals called **ruminants**, which include deer, cattle, and sheep (**Figure 41.28**).

In the next chapter, we will see that obtaining food, digesting it, and absorbing nutrients are only parts of a larger story.

Provisioning the body also involves distributing nutrients to cells throughout the body (circulation) and exchanging respiratory gases with the environment.

Concept Check 41.5

- Explain how human dentition is adapted for an omnivorous diet.
- Compared with an adult frog, a tadpole (frog larva) has a much longer intestine relative to its body size. What does this suggest about the diets of these two stages in a frog's life history?
- "Chewing its cud" is a common expression about cattle. What is the cud, and what role does it play in bovine nutrition?

For suggested answers, see Appendix A.

Chapter 41 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

- An animal's diet must supply chemical energy, organic raw materials, and essential nutrients. Herbivores mainly eat plants, carnivores mainly eat other animals, and omnivores regularly eat both plant and animal matter. Many aquatic animals are suspension feeders, sifting small particles from the water. Substrate feeders tunnel through their food, eating as they go. Fluid feeders suck nutrient-rich fluids from a living host. Most animals are bulk feeders, eating relatively large pieces of food (pp. 844–845).

Concept 41.1

Homeostatic mechanisms manage an animal's energy budget

- **Glucose Regulation as an Example of Homeostasis** (pp. 846) Animals store excess calories as glycogen in the liver and muscles and as fat. These energy stores can be tapped when an animal is in need of ATP. Blood glucose level is maintained within a relatively narrow range by a negative feedback mechanism.
- **Caloric Imbalance** (pp. 846–848) Undernourished animals have diets deficient in calories. Overnourished (obese) animals consume more calories than they need. Obesity is a serious health problem worldwide and especially in the United States, where lack of exercise and fattening foods make an unhealthy combination. Obesity is also strongly influenced by genes. The problem of maintaining healthy weight partly stems from our evolutionary past, when fat hoarding was a means of survival.

Jui animal's diet most supply carbon skeletons and essential nutrients

- Carbon skeletons are required in biosynthesis. Essential nutrients must be supplied in preassembled form. Malnourished animals are missing one or more essential nutrients in their diet, a condition more common than undernourishment in human populations (p. 849).
- **Essential Amino Acids** (pp. 849–850) Animals require 20 amino acids and can synthesize about half of them from the other molecules they obtain from their diet. Essential amino acids are those an animal cannot make. An animal whose diet is lacking one or more essential amino acids will become malnourished and suffer protein deficiency.
- **Essential Fatty Acids** (p. 850) Essential fatty acids, which an animal cannot make, are unsaturated, meaning that they have double bonds. Deficiencies in essential fatty acids are rare.
- **Vitamins** (pp. 850–851) Vitamins are organic molecules required in small amounts. They are either water-soluble or fat-soluble.
- **Minerals** (pp. 851–852) Minerals are inorganic nutrients, usually required in small amounts.

Concept 41.3

The main stages of food processing are ingestion, digestion, absorption, and elimination

- Food processing in animals involves ingestion (the act of eating), digestion (enzymatic breakdown of the macromolecules of food into their monomers), absorption (the uptake of nutrients by body cells), and elimination (the passage of undigested materials out of the body in feces) (p. 853).
- **Digestive Compartments** (pp. 853–855) In intracellular digestion, food particles are engulfed by endocytosis and digested within food vacuoles. Most animals use extracellular digestion, with enzymatic hydrolysis occurring outside cells in a gastrovascular cavity or alimentary canal.

Concept 41.4

Each organ of the mammalian digestive system has specialized food-processing functions

- The mammalian digestive system is composed of the alimentary canal and accessory glands that secrete digestive juices into the canal (pp. 855–856).
- **The Oral Cavity, Pharynx, and Esophagus** (p. 856) Food is lubricated and digestion begins in the oral cavity, where teeth chew food into smaller particles that are exposed to salivary amylase, initiating the breakdown of glucose polymers. The pharynx is the intersection leading to the trachea and esophagus. The esophagus conducts food from the pharynx to the stomach by involuntary peristaltic waves.
- **The Stomach** (pp. 857–858) The stomach stores food and secretes gastric juice, which converts a meal to acid chyme. Gastric juice includes hydrochloric acid and the enzyme pepsin.
- **The Small Intestine** (pp. 838–861) The small intestine is the major organ of digestion and absorption. Acid chyme from the stomach mixes in the duodenum with intestinal juice, bile, and pancreatic juice. Diverse enzymes complete the hydrolysis of food molecules to monomers, which are absorbed into the blood across the lining of the small intestine. Hormones help regulate digestive juice secretions.
- **The Large Intestine** (pp. 861–862) The large intestine (colon) aids the small intestine in reabsorbing water and houses bacteria, some of which synthesize vitamins. Feces pass through the rectum and out the anus.

Activity Digestive System Function

Investigation *What Role Does Amylase Play in Digestion?*

Activity Hormonal Control of Digestion

Concept 41.5

Evolutionary adaptations of vertebrate digestive systems are often associated with diet

- **Some Dental Adaptations** (pp. 862–863) A mammal's dentition is generally correlated with its diet. In particular, mammals have specialized dentition that best enables them to ingest their usual diet.
- **Stomach and Intestinal Adaptations** (p. 863) Herbivores generally have longer alimentary canals than carnivores, reflecting the longer time needed to digest vegetation.

- **Symbiotic Adaptations** (pp. 863-864) Many herbivorous animals have fermentation chambers where symbiotic micro-organisms digest cellulose.

TESTING YOUR KNOWLEDGE

Evolution Connection

The human esophagus and trachea share a common passage leading from the mouth and nasal passages, a "design" that occasionally contributes to death by choking. After reviewing vertebrate evolution in Chapter 34, explain the historical (evolutionary) basis for this "imperfect" anatomy.

Scientific Inquiry

Design a controlled experiment to test the hypothesis that human salivary amylase digests starch faster at 37°C (human body temperature) than it does at either 20°C (approximate room temperature) or 43°C (110°F). Your only materials and equipment are a source of human saliva, distilled water, starch, an iodine reagent that stains starch dark purple, beakers, and several water baths that can be maintained at constant temperatures. How would you interpret the results if (a) the rate of enzyme activity were highest at 37°C; or (b) the rate of enzyme activity were highest at 43°C?

Investigation *What Role Does Amylase Play in Digestion?*

Biological Inquiry: A Workbook of Investigative Cases *Explore several mammalian mechanisms for starch digestion in the case "Galloper's Gut."*

Science, Technology, and Society

The media report numerous claims and counterclaims about the benefits and dangers of certain foods. Just a few examples are debates about vitamin doses, advocacy of diets enriched in certain food molecules such as carbohydrates or proteins, much discussion about low-carbohydrate diets, and publicity about new products such as cholesterol-lowering margarine. Have you modified your eating habits on the basis of nutritional information disseminated by the media? Why or why not? How should a person evaluate whether such nutritional claims are valid?

42

Circulation and Gas Exchange

A Figure 42.1 The gills of a salmon, which exchange gases between the blood and the environment.

IKey Concepts

- 42.1 Circulatory systems reflect phylogeny
- 42.2 Double circulation in mammals depends on the anatomy and pumping cycle of the heart
- 42.3 Physical principles govern blood circulation
- 4•2.4 Blood is a connective tissue with cells suspended in plasma
- 4•2.5 Gas exchange occurs across specialized respiratory surfaces
- i 4•2.6 Breathing ventilates the lungs
- 4•2.7 Respiratory pigments bind and transport gases

Overview

Trading with the Environment

Every organism must exchange materials and energy with its environment, and this exchange ultimately occurs at the cellular level. Cells live in aqueous surroundings; the resources they need, such as nutrients and oxygen, move across the plasma membrane into the cytoplasm, and metabolic wastes, such as carbon dioxide, move out of the cell. In unicellular organisms, these exchanges occur directly with the external environment. For most of the cells making up multicellular organisms, however, direct exchange with the environment is not possible. This constraint is associated with the evolution of physiological systems specialized for material transport and exchange.

The feathery gills of a salmon (Figure 42.1) present an expansive surface area to the outside environment. Networks of tiny blood vessels (capillaries) lie close to the outside surfaces of the gills. Oxygen dissolved in the surrounding water diffuses

across the thin epithelium covering the gills and into the blood, while carbon dioxide diffuses out into the water.

Salmon and most other animals have organ systems specialized for exchanging materials with the environment, and most also have an internal transport system that conveys fluid (blood or interstitial fluid) throughout the body (see Figure 40.4).

In this chapter, we will explore mechanisms of internal transport in animals. We will also examine a key example of chemical transfer between animals and their environment; the exchange of the gases oxygen (O_2) and carbon dioxide (CO_2), a process essential to cellular respiration and bioenergetics.

Concept 42.1

Circulatory systems reflect phylogeny

Diffusion alone is not adequate for transporting substances over long distances in animals—for example, for moving glucose from the digestive tract and oxygen from the lungs to the brain of a mammal. Diffusion is inefficient over distances of more than a few millimeters, because the time it takes for a substance to diffuse from one place to another is proportional to the square of the distance. For example, if it takes 1 second for a given quantity of glucose to diffuse 100 μm , it will take 100 seconds for the same quantity to diffuse 1 mm and almost 3 hours to diffuse 1 cm. The circulatory system solves this problem by ensuring that no substance must diffuse very far to enter or leave a cell. By rapidly transporting fluid in bulk throughout the body, the circulatory system functionally connects the aqueous environment of the body cells to the organs that exchange gases, absorb nutrients, and dispose of wastes. In the lungs of a mammal, for example, oxygen from inhaled air diffuses'

across a thin epithelium and into the blood, while carbon dioxide diffuses in the opposite direction. Bulk fluid movement in the circulatory system, powered by the heart, then quickly carries the oxygen-rich blood to all parts of the body. As the blood streams through the body tissues within capillaries, chemicals are transported between the blood and the interstitial fluid that directly bathes the cells.

Internal transport and gas exchange are functionally related in most animal phyla, and so in this chapter we will focus on both the circulatory and respiratory systems. We will also highlight the role of these two organ systems in maintaining homeostasis (see Chapter 40)—for example, in regulating the interstitial fluids content of nutrients and wastes. First, let's look at circulation in invertebrate animals.

Invertebrate Circulation

The wide range of invertebrate body size and form is paralleled by diversity in circulatory systems. The different selective pressures of various environments have also led to evolutionary modification of circulatory systems among invertebrates.

Gastrovascular Cavities

Owing to the simplicity of their body plan, hydras and other cnidarians do not require a true circulatory system. In these animals, a body wall only two cells thick encloses a central gastrovascular cavity which serves both in digestion and in distribution of substances throughout the body (see Figure 41.13). The fluid inside the cavity is continuous with the water outside through a single opening; thus, both the inner and outer tissue layers are bathed by fluid. Thin branches of a hydra's gastrovascular cavity extend into the animal's tentacles, and some cnidarians, such as jellies, have even more elaborate gastrovascular cavities (Figure 42.2). Since digestion begins in the cavity, only the cells of the inner layer have direct

access to nutrients, but the nutrients have to diffuse only a short distance to reach the cells of the outer layer.

Planarians and most other flatworms also have gastrovascular cavities that exchange materials with the environment through a single opening (see Figure 33.10). The flat shape of the body and the branching of the gastrovascular cavity throughout the animal ensure that all cells are bathed by a suitable medium and that diffusion distances are short.

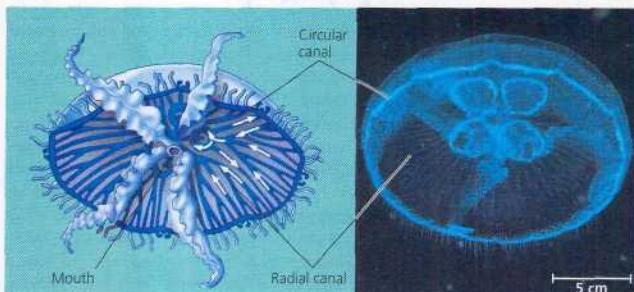

Open and Closed Circulatory Systems

For animals with many cell layers, gastrovascular cavities are insufficient for internal transport because diffusion distances are too great for adequate exchange of nutrients and wastes. In such animals, two types of circulatory systems that overcome the limitations of diffusion have evolved: open and closed. Both have three basic components: a circulatory fluid (blood), a set of tubes (blood vessels) through which the blood moves through the body, and a muscular pump (the heart). The heart powers circulation by using metabolic energy to elevate the hydrostatic pressure of the blood, which then flows down a pressure gradient through its circuit and back to the heart. This blood pressure is the motive force for fluid movement in the circulatory system.

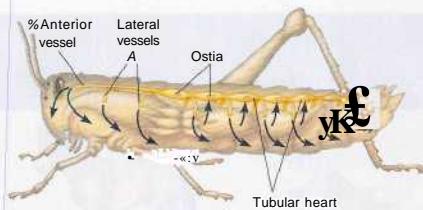

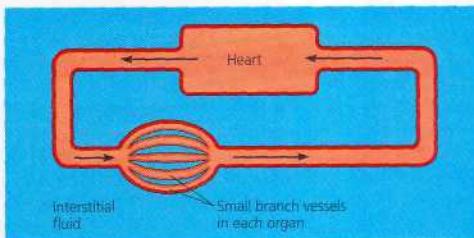

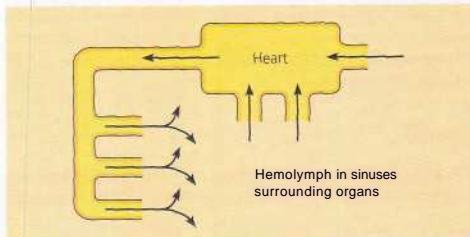

In insects, other arthropods, and most molluscs, blood bathes the organs directly in an open circulatory system (Figure 42.3a). There is no distinction between blood and interstitial fluid, and this general body fluid is more correctly termed hemolymph. One or more hearts pump the hemolymph into an interconnected system of sinuses, which are spaces surrounding the organs. Here, chemical exchange occurs between the hemolymph and body cells. In insects and other arthropods, the heart is an elongated tube located dorsally. When the heart contracts, it pumps hemolymph through vessels out into sinuses. When the heart relaxes, it draws hemolymph into the circulatory system through pores called ostia. Body movements that squeeze the sinuses help circulate the hemolymph.

In a closed circulatory system, blood is confined to vessels and is distinct from the interstitial fluid (Figure 42.3b). One or more hearts pump blood into large vessels that branch into smaller ones, coursing through the organs. Here, materials are exchanged by diffusion between the blood and the interstitial fluid bathing the cells. Earthworms, squids, octopuses, and all vertebrates have closed circulatory systems.

The fact that open and closed circulatory systems are each widespread among animals suggests that both offer advantages. For example, the lower hydrostatic

A Figure 42.2 Internal transport in the cnidarian *Aurelia*. The animal is viewed here from its underside (oral surface). The mouth leads to an elaborate gastrovascular cavity that has branches radiating to and from a circular canal. Ciliated cells lining the canals circulate fluid in the directions indicated by the arrows.

(a) **An open circulatory system.** In an open circulatory system, such as that of a grasshopper, blood and interstitial fluid are the same, and this fluid is called hemolymph. The heart pumps hemolymph through vessels into sinuses, where materials are exchanged between the hemolymph and cells. Hemolymph returns to the heart through ostia, which are equipped with valves that close when the heart contracts.

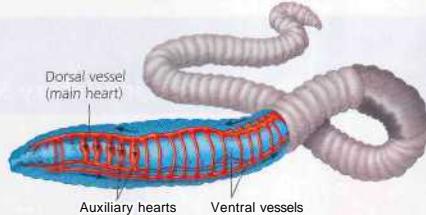

4. Figure 42.3 Open and closed circulatory systems.

Pressures associated with open circulatory systems make them less costly than closed systems in terms of energy expenditure. Furthermore, because they lack an extensive system of blood vessels, open systems require less energy to build and maintain. And in some invertebrates, open circulatory systems serve a variety of other functions. For example, in molluscs and reshelly molted aquatic arthropods, the open circulatory system functions as a hydrostatic skeleton in supporting the body.

What advantages might be associated with closed circulatory systems? Closed systems, with their higher blood pressure, are more effective at transporting circulatory fluids to meet the high metabolic demands of the tissues and cells of larger and more active animals. For instance, among the molluscs, only the large and active squids and octopuses have closed circulatory systems. And although all arthropods have open circulatory systems, the larger crustaceans, such as the lobsters and crabs, have a more developed system of arteries and veins as well as an accessory pumping organ that helps maintain blood pressure. Closed circulatory systems are most highly developed in the vertebrates.

Survey of Vertebrate Circulation

Humans and other vertebrates have a closed circulatory system, often called the **cardiovascular system**. Generally, the

(b) **A closed circulatory system.** Closed circulatory systems circulate blood entirely within vessels, distinct from the interstitial fluid. Chemical exchange occurs between the blood and the interstitial fluid, and between the interstitial fluid and body cells. In an earthworm, three major vessels branch into smaller vessels that supply blood to the various organs. The dorsal vessel functions as the main heart, pumping blood forward by peristalsis. Near the worm's anterior end, five pairs of vessels loop around the digestive tract and function as auxiliary hearts, propelling blood ventrally.

vertebrate heart has one or two **atria** (singular, *atrium*), the chambers that receive blood returning to the heart, and one or two **ventricles**, the chambers that pump blood out of the heart.

Arteries, veins, and capillaries are the three main kinds of blood vessels, which in the human body have a total length of about 100,000 km. Arteries carry blood away from the heart to organs throughout the body. Within organs, arteries branch into arterioles, small vessels that convey blood to the capillaries.

Capillaries are microscopic vessels with very thin, porous walls. Networks of these vessels, called **capillary beds**, infiltrate each tissue. Across the thin walls of capillaries, chemicals, including dissolved gases, are exchanged by diffusion between blood and the interstitial fluid around the tissue cells.

At their "downstream" end, capillaries converge into **venules**, and venules converge into veins. Generally speaking, veins return blood to the heart. Notice that arteries and veins are distinguished by the *direction* in which they carry blood, not by the characteristics of the blood they contain. All arteries carry blood from the heart *toward* capillaries, and veins return blood to the heart *from* capillaries. A significant exception is the hepatic portal vein that carries blood from capillary beds in the digestive system to capillary beds in the liver. Blood flowing from the liver passes into the hepatic vein, which conducts blood to the heart.

The cardiovascular systems of different vertebrate taxa are variations of this general scheme, modified by natural selection. Metabolic rate (see Chapter 40) is an important factor in the evolution of cardiovascular systems. In general, animals with higher metabolic rates have more complex circulatory systems and more powerful hearts than animals with lower metabolic rates. Similarly, within an animal, the complexity and number of blood vessels in a particular organ are correlated with that organ's metabolic requirements. Perhaps

the most fundamental differences in cardiovascular adaptations between animals are associated with gill breathing in most aquatic vertebrates compared with lung breathing in terrestrial vertebrates.

Fishes

A fish heart has two main chambers, one ventricle and one atrium (**Figure 42.4**). Blood pumped from the ventricle travels

Figure 42.4
Exploring Vertebrate Circulatory Systems

FISHES

Fishes have a two-chambered heart and a single circuit of blood flow.

AMPHIBIANS

Amphibians have a three-chambered heart and two circuits of blood flow: pulmocutaneous and systemic. Some mixing of oxygen-rich and oxygen-poor blood occurs in the single ventricle.

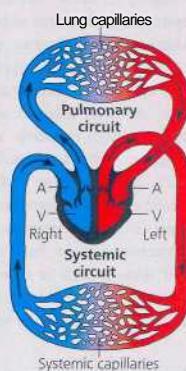

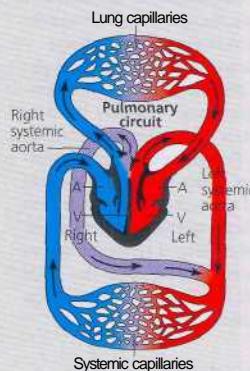

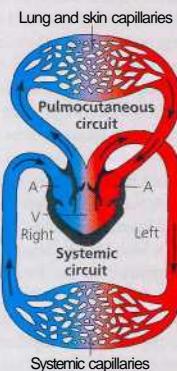

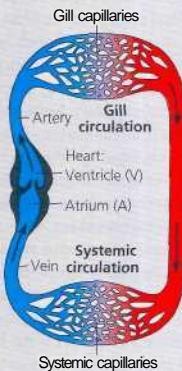

REPTILES (EXCEPT BIRDS)

Reptiles other than birds have a three-chambered heart and two circuits of blood flow. However, a septum partially divides the single ventricle, further reducing mixing of oxygen-rich and oxygen-poor blood.

MAMMALS AND BIRDS

Mammals and birds have a four-chambered heart that completely segregates oxygen-rich and oxygen-poor blood. (The major vessels near the heart are slightly different in birds, but the pattern of double circulation is essentially the same as depicted here.)

Systemic circuits include all body tissues. Note that circulatory systems are depicted as if the animal is facing you: with the right side of the heart shown at the left and vice-versa.

fins to the gills (the **gill circulation**), where it picks up oxygen (P_i) and disposes of carbon dioxide (CO_2) across capillary walls. The gill capillaries converge into a vessel that carries oxygen-rich blood to capillary beds throughout all other parts of the body (the **systemic circulation**). Blood then returns in veins to the atrium of the heart. Notice that in a fish, blood must pass through two capillary beds during each circuit. When blood flows through a capillary bed, blood pressure—the motive force for circulation—drops substantially (for reasons we will explain shortly). Therefore, oxygen-rich blood leaving the gills flows to the systemic circulation quite slowly (although the process is aided by body movements during swimming). This constrains the delivery of O_2 to body tissues and hence the maximum aerobic metabolic rate of fishes.

Amphibians

Frogs and other amphibians have a three-chambered heart, with two atria and one ventricle (see Figure 42.4). The ventricle pumps blood into a forked artery that splits the ventricles output into the **pulmocutaneous circuit** and the **systemic circuit**. The pulmocutaneous circuit leads to capillaries in the gas exchange organs (the lungs and skin in a frog), where the blood picks up O_2 and releases CO_2 before returning to the heart's left atrium. Most of the returning oxygen-rich blood is pumped into the systemic circuit, which supplies all organs and then returns oxygen-poor blood to the right atrium via the veins. In the ventricle of the frog, there is some mixing of oxygen-rich blood that has returned from the lungs with oxygen-poor blood that has returned from the rest of the body. However, a ridge within the ventricle diverts most of the oxygen-rich blood from the left atrium into the systemic circuit and most of the oxygen-poor blood from the right atrium into the pulmocutaneous circuit.

This organization, called **double circulation**, provides a vigorous flow of blood to the brain, muscles, and other organs because the blood is pumped a second time after it loses pressure in the capillary beds of the lungs or skin. This contrasts sharply with single circulation in fishes, in which blood flows directly from the respiratory organs (gills) to other organs under reduced pressure.

Reptiles (Except Birds)

Reptiles have double circulation with a **pulmonary circuit** (lungs) and a systemic circuit (see Figure 42.4). Turtles, snakes, and lizards have a three-chambered heart, although the ventricle is partially divided by a septum, which results in even less mixing of oxygen-rich and oxygen-poor blood than in amphibians. In the crocodilians, a septum divides the ventricle completely into separate right and left chambers. All reptiles except birds have two arteries leading from the heart to the systemic circuit, and arterial valves allow them to divert most of their blood from the pulmonary circuit to the systemic circuit.

Mammals and Birds

In all mammals and birds, the ventricle is completely divided into separate right and left chambers (see Figure 42.4). The left side of the heart receives and pumps **only** oxygen-rich blood, while the right side receives and pumps only oxygen-poor blood. Oxygen delivery is enhanced because there is no mixing of oxygen-rich and oxygen-poor blood, and double circulation restores pressure to the systemic circuit after blood has passed through the lung capillaries.

A powerful four-chambered heart was an essential adaptation in support of the endothermic way of life characteristic of mammals and birds. Endotherms use about ten times as much energy as equal-sized ectotherms; therefore, their circulatory systems need to deliver about ten times as much fuel and O_2 to their tissues (and remove ten times as much CO_2 and other wastes). This large traffic of substances is made possible by separate and independent systemic and pulmonary circulations and by large, powerful hearts that pump the necessary volume of blood. As we discussed in Chapter 25, mammals and birds descended from different reptilian ancestors, and their four-chambered hearts evolved independently—an example of convergent evolution.

Concept Check 42.1

- What fundamental physical constraint necessitates a circulatory system in large organisms?
- What is one advantage of a closed circulatory system? What is a disadvantage?
- What are two physiological advantages of separate respiratory (pulmocutaneous or pulmonary) and systemic circuits over a single circuit as seen in fishes, which combines gill and systemic circulation?

For suggested answers, see Appendix A.

Concept 42.2

Double circulation in mammals depends on the anatomy and pumping cycle of the heart

Because heart disease is such a significant and widespread health problem in human populations, scientists have studied the human circulatory system in much greater detail than any other. Its structure and function can serve as a model for exploring mammalian circulation in general.

Mammalian Circulation: The Pathway

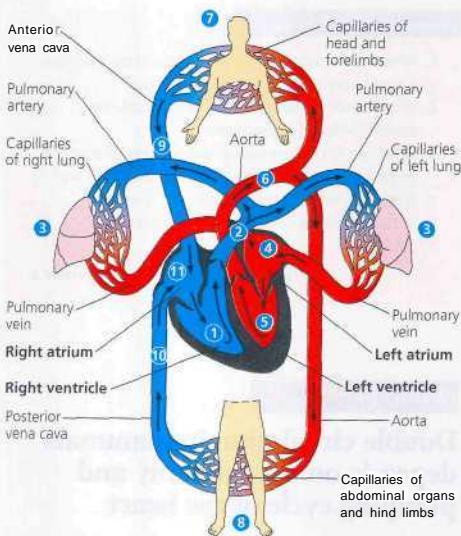

As you read this detailed discussion of blood flow through the mammalian cardiovascular system, refer to **Figure 42.5**, which has numbers keyed to the circled numbers in the text. Beginning our tour with the pulmonary (lung) circuit, O the right ventricle pumps blood to the lungs via ① the pulmonary arteries. As the blood flows through ② capillary beds in the left and right lungs, it loads O₂ and unloads CO₂. Oxygen-rich blood returns from the lungs via the pulmonary veins to ③ the left atrium of the heart. Next, the oxygen-rich blood flows into ④ the left ventricle as the ventricle opens and the atrium contracts. The left ventricle pumps the oxygen-rich blood out to body tissues through the systemic circuit. Blood leaves the left ventricle via ⑤ the aorta, which conveys blood to arteries leading throughout the body. The first branches from the aorta are the coronary arteries (not shown), which supply blood to the heart muscle itself. Then come branches leading to capillary beds ⑥ in the head and arms (forelimbs). The aorta continues in a posterior direction, supplying oxygen-rich blood to arteries leading to ⑦ capillaries and capillary beds in the abdominal organs and legs. Within the capillaries, O₂ and CO₂ diffuse along their concentration gradients,

with O₂ moving from the blood to the tissues and CO₂ produced by cellular respiration diffusing into the bloodstream. Capillaries rejoin, forming venules, which convey blood to veins. Oxygen-poor blood from the head, neck, and forelimbs is channeled into a large vein called ⑧ the anterior (or superior) vena cava. Another large vein called ⑨ the posterior (or inferior) vena cava drains blood from the trunk and hind limbs. The two venae cavae empty their blood into ⑩ the right atrium, from which the oxygen-poor blood flows into ⑪ the right ventricle.

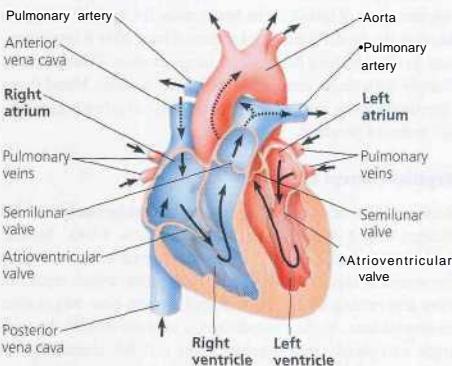

The Mammalian Heart: A Closer Look

A closer look at the mammalian heart (using the human heart as an example) provides a better understanding of how double circulation works (**Figure 42.6**). Located beneath the breastbone (sternum), the human heart is about the size of a clenched fist and consists mostly of cardiac muscle (see **Figure 40.5**). The two atria have relatively thin walls and serve as collection chambers for blood returning to the heart, most of which flows into the ventricles as they relax. Contraction of the atria completes filling of the ventricles. The ventricles have thicker walls and contract much more strongly than the atria—especially the left ventricle, which must pump blood to all body organs through the systemic circuit.

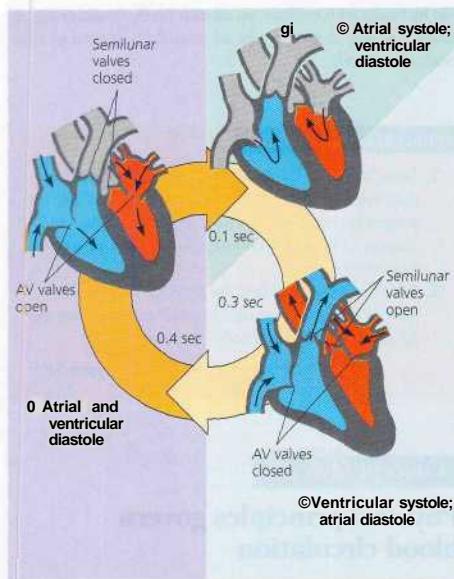

The heart contracts and relaxes in a rhythmic cycle. When it contracts, it pumps blood; when it relaxes, its chambers fill with blood. The cardiac cycle refers to one complete sequence of pumping and filling. The contraction phase of the cycle is called systole, and the relaxation phase is diastole (**Figure 42.7**). The volume of blood per minute that the left

A Figure 42.5 The mammalian cardiovascular system: an overview. Note that the dual circuits operate simultaneously, not in the serial fashion that the numbering in the diagram suggests. The two ventricles pump almost in unison; while some blood is traveling in the pulmonary circuit, the rest of the blood is flowing in the systemic circuit.

A Figure 42.6 The mammalian heart: a closer look. Notice the valves, which prevent backflow of blood within the heart, and the relative thickness of the walls of the heart chambers.

A Figure 42.7 The cardiac cycle. For an adult human at rest with a pulse of about 75 beats per minute, one complete cardiac cycle takes about 0.8 second. ① During a relaxation phase (atria and ventricles in diastole), blood returning from the large veins flows into the atria and ventricles. ② A brief period of atrial systole then forces all remaining blood out of the atria into the ventricles. ③ During the remainder of the cycle, ventricular systole pumps blood into the large arteries. Note that seven-eighths of the time—all but 0.1 second of the cardiac cycle—the atria are relaxed and are filling with blood returning via the veins.

ventricle pumps into the systemic circuit is called **cardiac output**. Cardiac output depends on two factors: the rate of contraction, or **heart rate** (number of beats per minute); and **stroke volume**, the amount of blood pumped by the left ventricle in each contraction. The average stroke volume in humans is about 75 mL. A person with this stroke volume and a heart rate at rest of 70 beats per minute has a cardiac output of 5.25 L/min—about equivalent to the total volume of blood in the human body. Cardiac output can increase as much as about fivefold during heavy exercise. This is equivalent to pumping an amount of blood matching an average person's body mass every 2–3 minutes.

Four valves in the heart, each consisting of flaps made of connective tissue, prevent backflow and keep blood moving in the correct direction (see Figure 42.6). Between each atrium and ventricle is an **atrioventricular (AV) valve**. The AV valves are anchored by strong fibers that prevent them from turning

inside out. Pressure generated by the powerful contraction of the ventricles closes the AV valves, keeping blood from flowing back into the atria. **Semilunar valves** are located at the two exits of the heart: where the aorta leaves the left ventricle and the pulmonary artery leaves the right ventricle. These valves are forced open by pressure generated by contraction of the ventricles. When the ventricles relax, blood starts to flow back toward the heart, closing the semilunar valves, which prevents blood from flowing back into the ventricles. The elastic walls of the arteries expand when they receive the blood expelled from the ventricles. By feeling your **pulse**—the rhythmic stretching of arteries caused by the pressure of blood driven by the powerful contractions of the ventricles—you can measure your heart rate.

The heart sounds heard with a stethoscope are caused by the closing of the valves. (Even without a stethoscope, you can hear these sounds by pressing your ear tightly against the chest of a friend—a close friend.) The sound pattern is “lub-dup, lub-dup, lub-dup.” The first heart sound (“lub”) is created by the recoil of blood against the closed AV valves. The second sound (“dup”) is the recoil of blood against the semilunar valves.

A defect in one or more valves causes a condition known as a **heart murmur**, which may be detectable as a hissing sound when a stream of blood squirts backward through a valve. Some people are born with heart murmurs; in others, the valves may be damaged by infection (from rheumatic fever, for instance). Most heart murmurs do not reduce the efficiency of blood flow enough to warrant surgery.

Maintaining the Heart's Rhythmic Beat

The timely delivery¹ of oxygen to the body's organs is critical. For example, brain cells die within a few minutes if their oxygen supply is interrupted. Thus, maintaining heart function is crucial for survival. Several mechanisms have evolved that ensure the continuity and control of heartbeat.

Some cardiac muscle cells are self-excitatory, meaning they contract without any signal from the nervous system, even if removed from the heart and placed in tissue culture. Each of these cells has its own intrinsic contraction rhythm. How are their contractions coordinated in the intact heart? A region of the heart called the **sinoatrial (SA) node**, or **pacemaker**, sets the rate and timing at which all cardiac muscle cells contract. Composed of specialized muscle tissue, the SA node is located in the wall of the right atrium, near the point where the superior vena cava enters the heart. Because the pacemaker of the human heart (and of other vertebrates) is made up of specialized muscle tissues and located within the heart itself, the vertebrate heart is referred to as a **myogenic heart**. In contrast, the pacemakers of most arthropod hearts originate in motor nerves arising from the outside, an arrangement called a **neurogenic heart**.

The SA node generates electrical impulses much like those produced by nerve cells. Because cardiac muscle cells are electrically coupled (by the intercalated disks between adjacent cells), impulses from the SA node spread rapidly through the walls of the atria, causing both atria to contract in unison (Figure 42.8). The impulses also pass to another region of specialized cardiac muscle tissue, a relay point called the **atrioventricular (AV) node**, located in the wall between the right atrium and right ventricle. Here the impulses are delayed for about 0.1 second before spreading to the walls of the ventricles. This delay ensures that the atria empty completely before the ventricles contract. Specialized muscle fibers called bundle branches and Purkinje fibers then conduct the signals to the apex of the heart and throughout the ventricular walls.

The impulses that travel through cardiac muscle during the heart cycle produce electrical currents that are conducted through body fluids to the skin, where the currents can be detected by electrodes and recorded as an **electrocardiogram (ECG or EKG)**.

The SA node sets the tempo for the entire heart, but is influenced by a variety of physiological cues. Two sets of nerves affect heart rate: one set speeds up the pacemaker, and the other set slows it down. Heart rate is a compromise regulated by the opposing actions of these two sets of nerves. The pacemaker is also influenced by hormones secreted into the blood by glands. For example, epinephrine, the "fight-or-flight" hormone secreted by the adrenal glands, increases heart rate (see Chapter 45). Body temperature is another factor that affects the pacemaker. An increase of only 1°C raises the heart rate by about 10 beats per minute. This is the reason your pulse increases substantially when you have a fever. Heart rate

also increases with exercise, an adaptation that enables the circulatory system to provide the additional O₂ needed by muscles hard at work.

Concept Check 42.2

- Some babies are born with a small hole between their left and right ventricles. Explain how, if not surgically corrected, this hole would affect the O₂ content of the blood entering the systemic circuit from the heart.
- Why is it important that the AV node of the heart slow or delay the electrical impulse moving from the SA node and the atrial walls to the ventricles?

For suggested answers, see Appendix A.

Concept 42.3

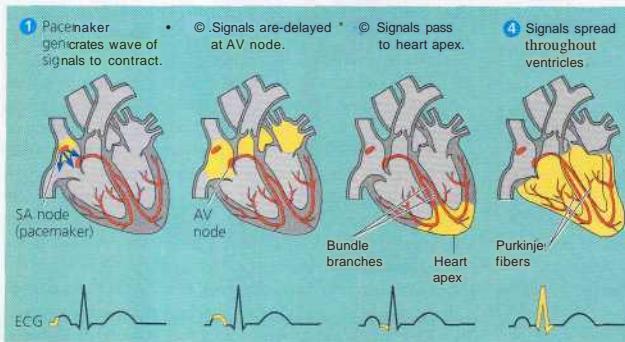

Physical principles govern blood circulation

Blood delivers nutrients and removes wastes throughout an animal's body. These functions are made possible by the circulatory system, a branching network of vessels similar in some ways to the plumbing system that delivers fresh water to a city and removes the city's wastes. The same physical principles that govern the operation of such **plumbing** systems also influence the functioning of animal circulatory systems.

Blood Vessel Structure and Function

The "infrastructure"⁵ of the circulatory system consists of its network of blood vessels. All blood vessels are built of similar tissues. The walls of both arteries and veins, for instance, have three similar layers (Figure 42.9). On the outside, a layer of connective tissue with elastic fibers allows the vessel to stretch and recoil. A middle layer contains smooth muscle and more elastic fibers. Lining the lumen of all blood vessels, including capillaries, is an **endothelium**, a single layer of flattened cells that provides a smooth surface that minimizes resistance to the flow of blood.

Structural differences correlate with the different functions of arteries, veins, and capillaries. Capillaries lack the two

A Figure 42.8 The control of heart rhythm. The gold portions of the graphs at the bottom indicate the components of an electrocardiogram (ECG) corresponding to the sequence of electrical events in the heart. In step 4, the black portion of the ECG to the right of the gold "spike" represents electrical activity after the ventricles contract; during this phase, the ventricles become electrically re-primed and thus able to conduct the next round of contraction signals.

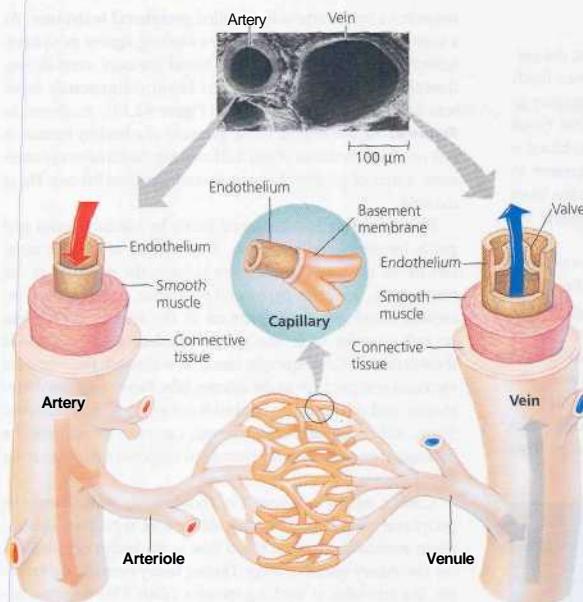

Figure 42.9 The structure of blood vessels. This micrograph (SEM) shows an artery next to a thinner-walled vein.

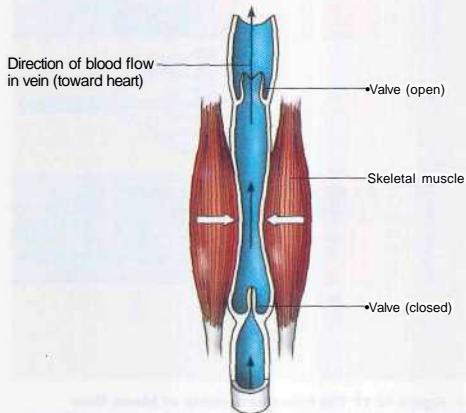

outer layers, and their very thin walls consist only of endothelium and its basement membrane. This facilitates the exchange of substances between the blood and the interstitial fluid that bathes the cells. Arteries have thicker middle and outer layers than veins. Blood flows through the vessels of the circulatory system at uneven speeds and pressures. The thicker walls of arteries provide strength to accommodate blood pumped rapidly and at high pressure by the heart, and their elasticity helps maintain blood pressure even when the heart relaxes between contractions. The thinner-walled veins convey blood back to the heart at low velocity and pressure. Blood flows through the veins mainly as a result of muscle action; whenever you move, your skeletal muscles squeeze your veins and push blood through them. Within large veins, flaps of tissue act as one-way valves that allow blood to flow only toward the heart (Figure 42.10).

Blood Flow Velocity

Blood travels over a thousand times faster in the aorta (about 30 cm/sec on average) than in capillaries (about 0.026 cm/sec). This velocity change follows from the law of continuity, which describes fluid movement through pipes. If a pipe's diameter changes over its length, a fluid flows through narrower

segments of the pipe faster than it flows through wider segments. Since the volume of flow per second must be constant through the entire pipe, the fluid must flow faster as the cross-sectional area of the pipe narrows (think of the velocity of water squirted by a hose with and without a nozzle).

Based on the law of continuity, you might think that blood should travel faster through capillaries than through arteries, because the diameter of capillaries is very small. However, it is the total cross-sectional area of capillaries that determines flow rate. Each artery conveys blood to such an enormous number of capillaries that the total cross-sectional area is much greater in capillary beds than in any other part of the circulatory system. For this reason, the blood slows substantially as it enters the arterioles from arteries, and slows further still in the capillary beds. Capillaries are the only vessels with walls thin enough to permit the transfer of substances between the blood and interstitial fluid, and the slower flow of blood through these tiny vessels enhances this exchange. As blood leaves the capillaries and enters the venules and veins, it speeds up again as a result of the reduction in total cross-sectional area (Figure 42.11, on the next page).

A Figure 42.10 Blood flow in veins. Contracting skeletal muscles squeeze the veins. Flaps of tissue within the veins act as one-way valves that keep blood moving only toward the heart. If we sit or stand too long, the lack of muscular activity causes our feet to swell with stranded blood unable to return to the heart.

Blood Pressure

Fluids exert a force called hydrostatic pressure against the surfaces they contact, and it is that pressure that drives fluids through pipes. Fluids flow from areas of higher pressure to areas of lower pressure. The hydrostatic pressure that blood exerts against the wall of a vessel and that propels the blood is called blood pressure. Blood pressure is much greater in arteries than in veins and is highest in arteries when the heart contracts during ventricular systole (**systolic pressure**; see Figure 42.11).

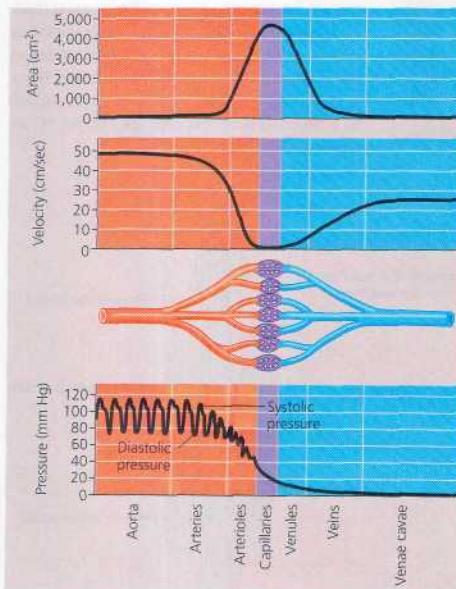

When you take your pulse by placing your fingers on your wrist, you can feel an artery bulge with each heartbeat. The surge of pressure is partly due to the narrow openings of arterioles impeding the exit of blood from the arteries. Thus, when the heart contracts, blood enters the arteries faster than it can leave, and the vessels stretch from the pressure. The elastic walls of the arteries snap back during diastole, but the heart contracts again before enough blood has flowed into the arterioles to completely relieve pressure in the arteries. This

impediment by the arterioles is called **peripheral resistance**. As a consequence of the elastic arteries working against peripheral resistance, there is a substantial blood pressure even during diastole (**diastolic pressure**), and blood continuously flows into arterioles and capillaries (see Figure 42.11). As shown in Figure 42.12, the arterial blood pressure of a healthy human at rest oscillates between about 120 mm Hg (millimeters of mercury; a unit of pressure) at systole and less than 80 mm Hg at diastole.

Blood pressure is determined partly by cardiac output and partly by peripheral resistance. Contraction of smooth muscles in the walls of the arterioles reduces the diameter of the tiny vessels, increases peripheral resistance, and therefore increases blood pressure upstream in the arteries. When the smooth muscles relax, the arterioles dilate, which increases their diameter. Consequently, blood flow through the arterioles increases and pressure in the arteries falls. Nerve impulses, hormones, and other signals control these arteriole wall muscles. Stress, either physical or emotional, can raise blood pressure by triggering nervous and hormonal responses that constrict blood vessels.

Cardiac output is adjusted in coordination with changes in peripheral resistance. This coordination of regulatory mechanisms maintains adequate blood flow as the body's demands on the circulatory system change. During heavy exercise, for example, the arterioles in working muscles dilate. This response admits a greater flow of oxygen-rich blood to the muscles and also decreases peripheral resistance. By itself, this would cause a drop in blood pressure (and therefore blood flow) in the body as a whole. However, cardiac output increases, maintaining blood pressure and supporting the **necessary** increase in blood flow.

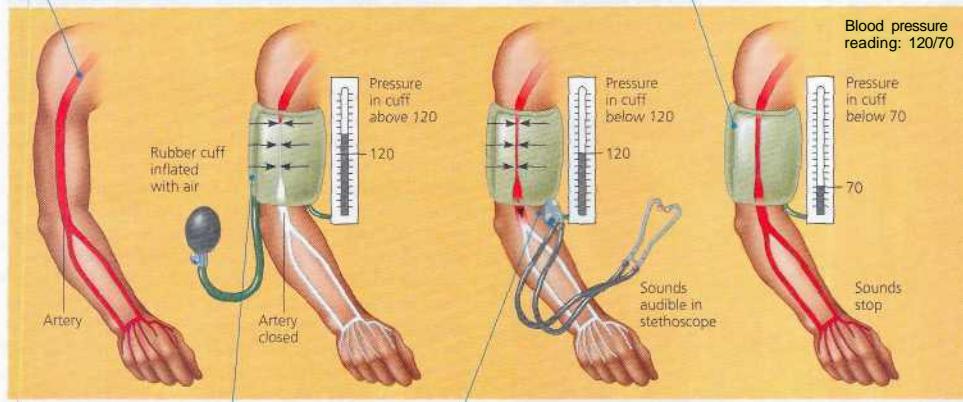

In large land animals, another factor that affects blood pressure is gravity. Besides the force needed to overcome peripheral resistance, additional pressure is necessary to push blood above the level of the heart. In a standing human, blood must rise about 0.35 m to get from the heart to the brain. This demands an extra 27 mm Hg of pressure, which requires the heart to expend more energy in its contraction cycle. This pumping challenge is significantly greater for animals with long necks. A standing giraffe, for example, needs to pump blood as much as 2.5 m above the heart. That requires about 190 mm Hg of additional blood pressure in the left ventricle, and a giraffe's normal systolic pressure near the heart is over 250 mm Hg. (Systolic pressure that high would be extremely dangerous in a human.) Check valves and sinuses, along with feedback mechanisms that reduce cardiac output, prevent this high pressure from damaging the giraffe's brain when it lowers its head to drink—a body position that causes blood to flow downhill almost 2 m from the heart, adding an extra 150 mm Hg of blood pressure in the arteries leading to the brain. Physiologists speculate about blood pressure and cardiovascular adaptations in dinosaurs—some of which had necks almost

A Figure 42.11 The interrelationship of blood flow velocity, cross-sectional area of blood vessels, and blood pressure. Blood flow velocity decreases markedly in the arterioles and is slowest in the capillaries, owing to an increase in total cross-sectional area. Blood pressure, the main force driving blood from the heart to the capillaries, is highest in the arteries.

O A typical blood pressure reading for a 20-year-old is 120/70. The units for these numbers are mm of mercury (Hg); a blood pressure of 120 is a force that can support a column of mercury 120 mm high.

O The cuff is loosened further until the blood flows freely through the artery and the sounds below the cuff disappear. The pressure at this point is the diastolic pressure remaining in the artery when the heart is relaxed.

f& A sphygmomanometer, an inflatable cuff attached to a pressure gauge, measures blood pressure in an artery. The cuff is wrapped around the upper arm and inflated until the pressure closes the artery, so that no blood flows past the cuff. When this occurs, the pressure exerted by the cuff exceeds the pressure in the artery.

C A stethoscope is used to listen for sounds of blood flow below the cuff. If the artery is closed, there is no pulse below the cuff. The cuff is gradually deflated until blood begins to flow into the forearm, and sounds from blood pulsing into the artery below the cuff can be heard with the stethoscope. This occurs when the blood pressure is greater than the pressure exerted by the cuff. The pressure at this point is the systolic pressure.

ii **Figure 42.12 Measurement of blood pressure.** Blood pressure is recorded as two numbers separated by a slash. The first number is the systolic pressure; the second is the diastolic pressure.

10 m long, which would have required a systolic pressure of nearly 760 mm Hg to pump blood to the brain when the head was fully raised. But evidence indicates that dinosaurs probably did not have hearts powerful enough to generate such pressures. Based on this analysis and on studies of neck-bone structure, some biologists have concluded that the long-necked dinosaurs fed close to the ground rather than raising their head to feed on high foliage.

By the time blood reaches the veins, its pressure is not affected much by the action of the heart. This is because the blood encounters so much resistance as it passes through the millions of tiny arterioles and capillaries that the pressure generated by the pumping heart has been dissipated and can no longer propel the blood through the veins. How does blood return to the heart, especially when it must travel from the lower extremities against gravity? Rhythmic contractions of smooth muscles in the walls of venules and veins account for some movement of the blood. More importantly, the activity of skeletal muscles during exercise squeezes blood through the veins (see Figure 42.10). Also, when we inhale, the change in pressure within the thoracic (chest) cavity causes the venae cavae and other large veins near the heart to expand and fill with blood.

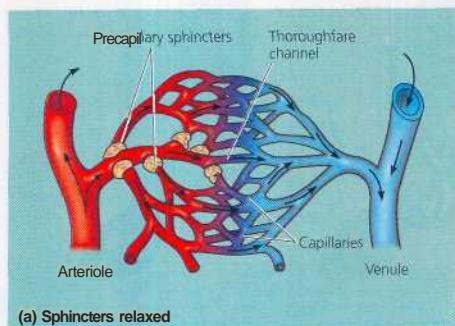

Capillary Function

At any given time, only about 5–10% of the body's capillaries have blood flowing through them. However, each tissue has many capillaries, so every part of the body is supplied with blood at all times. Capillaries in the brain, heart, kidneys, and liver are usually filled to capacity, but in many other sites, the blood supply varies over time as blood is diverted from one destination to another. After a meal, for instance, blood supply to the digestive tract increases. During strenuous exercise, blood is diverted from the digestive tract and supplied more generously to skeletal muscles and skin. This is one reason that exercising heavily immediately after eating a big meal may cause indigestion.

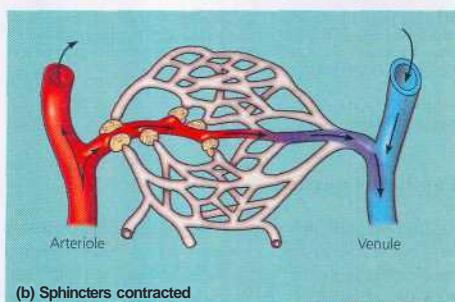

Two mechanisms regulate the distribution of blood in capillary beds. Both depend on smooth muscles controlled by nerve signals and hormones. In one mechanism, contraction of the smooth muscle layer in the wall of an arteriole constricts the vessel, reducing its diameter and decreasing blood flow through it to a capillary bed. When the muscle layer relaxes, the arteriole dilates, allowing blood to enter the capillaries. In the other mechanism, rings of smooth muscle—called precapillary sphincters because they are located at the

entrance to capillary beds—control the flow of blood between arterioles and venules (**Figure 42.13**).

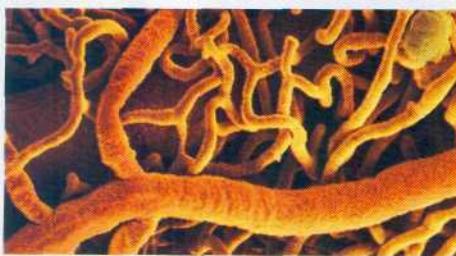

As you have read, the critical exchange of substances between the blood and the interstitial fluid that bathes the cells takes place across the thin endothelial walls of the capillaries. Some substances may be carried across an endothelial cell in vesicles that form by endocytosis on one side of the cell and

(a) Sphincters relaxed

(b) Sphincters contracted

(c) Capillaries and larger vessels (SEM)

20 μm

K Figure 42.13 Blood flow in capillary beds. Precapillary sphincters regulate the passage of blood into capillary beds. Some blood flows directly from arterioles to venules through capillaries called thoroughfare channels, which are always open.

then release their contents by exocytosis on the opposite side. Others simply diffuse between the blood and the interstitial fluid. Small molecules, such as O_2 and CO_2 , diffuse down concentration gradients across the endothelial cells. Diffusion can also occur through the clefts between adjoining cells. However, transport through these clefts occurs mainly by bulk flow due to fluid pressure. Blood pressure within the capillary pushes fluid (consisting of water and small solutes such as sugars, salts, O_2 , and urea) through the capillary clefts. The outward movement of this fluid causes a net loss of fluid from the upstream end of the capillary near an arteriole. Blood cells suspended in blood and most proteins dissolved in the blood are too large to pass readily through the endothelium and remain in the capillaries. The blood proteins remaining in the capillaries, especially albumin, create approximately constant osmotic pressure from the arteriole to the venous end of a capillary bed. In contrast, blood pressure drops sharply. This difference between blood pressure and osmotic pressure drives fluids out of capillaries at the arteriole end and into capillaries at the venous end (**Figure 42.14**). About 85% of the fluid that leaves the blood at the arterial end of a capillary bed reenters from the interstitial fluid at the venous end, and the remaining 15% is eventually returned to the blood by the vessels of the lymphatic system.

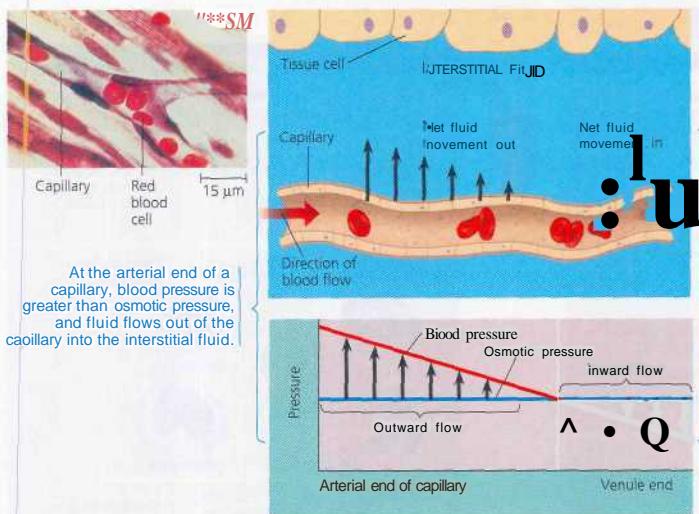

Fluid Return by the Lymphatic System

So much blood passes through the capillaries that the cumulative loss of fluid adds up to about 4 L per day. There is also some leakage of blood proteins, even though the capillary wall is not very permeable to large molecules. The lost fluid and proteins return to the blood via the lymphatic system. Fluid enters this system by diffusing into tiny lymph capillaries intermingled among capillaries of the cardiovascular system. Once inside the lymphatic system, the fluid is called lymph; its composition is about the same as that of interstitial fluid. The lymphatic system drains into the circulatory system near the junction of the venae cavae with the right atrium (see **Figure 43.5**).

Lymph vessels, like veins, have valves that prevent the backflow of fluid toward the capillaries. Rhythmic contractions of the vessel walls help draw fluid into lymphatic capillaries. Also like veins, lymph vessels depend mainly on the movement of skeletal muscles to squeeze fluid toward the heart.

Along a lymph vessel are organs called lymph nodes. By filtering the lymph and attacking viruses and bacteria, lymph nodes play an important role in the body's defense. Inside each lymph node is a honeycomb of connective tissue with spaces filled by white blood cells specialized for defense. When the body is fighting an infection, these cells multiply rapidly, and the lymph nodes become swollen and tender (which is why your doctor checks your neck for swollen lymph nodes when you feel sick).

The lymphatic system helps defend against infection and maintains the volume and protein concentration of the blood.

▲ Figure 42.14 Fluid exchange between capillaries and the interstitial fluid. The micrograph at top left shows red blood cells traveling through a capillary (LM).

Recall from Chapter 41 that the lymphatic system also transports fats from the digestive tract to the circulatory system.

Concept Check 42.3

- What is the primary cause of the low velocity of blood flow through capillaries?
- How does increasing blood pressure by increasing cardiac output combined with diverting most blood flow to the skeletal muscles prepare the body to confront or flee danger?
- Explain how edema—the accumulation of fluid in body tissues—can result from a decrease in plasma protein due to severe protein deficiency in the diet.

For suggested answers, see Appendix A.

Concept 42.4

Blood is a connective tissue with cells suspended in plasma

We now shift our focus from the tubes and pumps of circulatory systems to the fluids being circulated. As explained earlier,

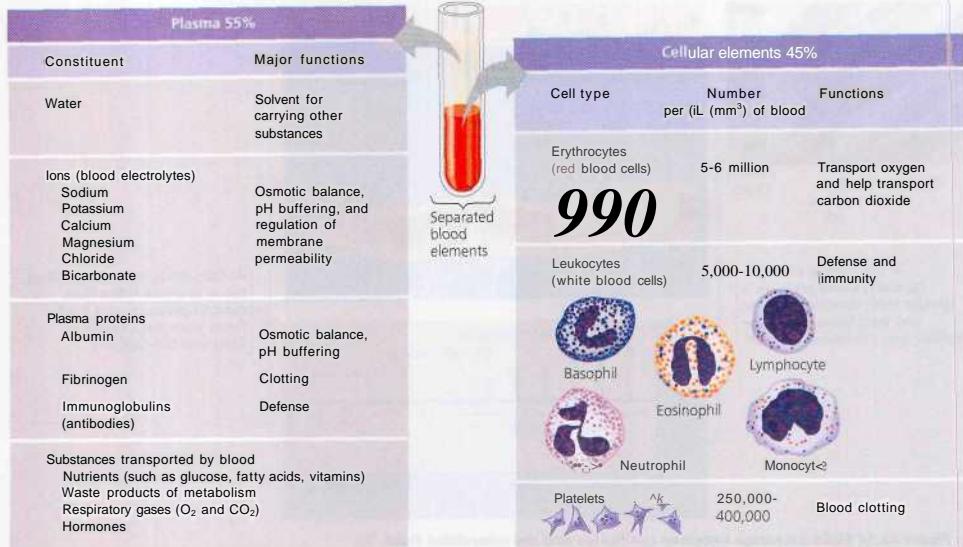

in invertebrates with open circulation, blood (hemolymph) is not different from interstitial fluid. However, blood in the closed circulatory systems of vertebrates is a specialized connective tissue.

Blood Composition and Function

Blood consists of several kinds of cells suspended in a liquid matrix called plasma. After a blood sample is collected, the cells can be separated from plasma by spinning the whole blood in a centrifuge (an anticoagulant must be added to prevent the blood from clotting). The cellular elements (cells and cell fragments), which occupy about 45% of the volume of blood, settle to the bottom of the centrifuge tube, forming a dense red pellet. Above this cellular pellet is the transparent, straw-colored plasma.

Plasma

Blood plasma is about 90% water. Among its many solutes are inorganic salts in the form of dissolved ions, sometimes referred to as blood electrolytes (Figure 42.15, on the next page). The combined concentration of these ions is important in maintaining the osmotic balance of the blood. Some ions also help to buffer the blood, which in humans normally has a pH of 7.4. And the normal functioning of muscles and nerves depends on the concentration of key ions in the interstitial

A Figure 42.15 The composition of mammalian blood.

fluid, which reflects their concentration in plasma. The kidney maintains plasma electrolytes at precise concentrations, an example of homeostasis we will explore in detail in Chapter 44.

Another important class of solutes is the plasma proteins, which have many functions. Collectively, they act as buffers against pH changes, help maintain the osmotic balance between blood and interstitial fluid, and contribute to the blood's viscosity (thickness). The various types of plasma proteins also have specific functions. Some are escorts for lipids, which are insoluble in water and can travel in blood only when bound to proteins. Another class of proteins, the immunoglobulins, or antibodies, help combat viruses and other foreign agents that invade the body (see Chapter 43). And the plasma proteins called fibrinogens are clotting factors that help plug leaks when blood vessels are injured. Blood plasma from which these clotting factors have been removed is called serum.

Plasma also contains a wide variety of substances in transit from one part of the body to another, including nutrients, metabolic wastes, respiratory gases, and hormones. Blood plasma and interstitial fluid are similar in composition, except that plasma has a much higher protein concentration (capillary walls, remember, are not very permeable to proteins).

Cellular Elements

Suspended in blood plasma are two classes of cells (see Figure 42.15): **red blood cells**, which transport oxygen, and **white blood cells**, which function in defense. A third cellular element, **platelets**, are fragments of cells that are involved in the clotting process.

Erythrocytes. Red blood cells, or **erythrocytes**, are by far the most numerous blood cells. Each microliter (pL; or mm³) of human blood contains 5 to 6 million red cells, and there are about 25 trillion of these cells in the body's 5 L of blood.

Erythrocytes are an excellent example of the close relationship between structure and function. Their main function of O₂ transport depends on rapid diffusion of O₂ across their plasma membranes. Human erythrocytes are small disks (about 7-8.5 µm in diameter) that are biconcave—thinner in the center than at the edges. Their small size and biconcave shape provide a large collective surface area for the total population of erythrocytes, and the greater the total area of erythrocyte membrane in a given volume of blood, the more rapidly O₂ can diffuse. Mammalian erythrocytes lack nuclei, an unusual characteristic that leaves more space in these tiny cells for **hemoglobin**, the iron-containing protein that transports oxygen (see Figure 5.20). Erythrocytes also lack mitochondria and generate their ATP exclusively by anaerobic

metabolism. Oxygen transport by erythrocytes would be less efficient if their own metabolism were aerobic and consumed some of the oxygen they carry.

Despite its small size, an erythrocyte contains about 250 million molecules of hemoglobin. Since each hemoglobin binds up to four molecules of O₂, one erythrocyte can transport about 3 billion O₂ molecules. Researchers have found that hemoglobin also binds the gaseous molecule nitric oxide (NO) as well as O₂. As erythrocytes pass through the capillary beds of lungs, gills, or other respiratory organs, O₂ diffuses into the erythrocytes where hemoglobin binds O₂ and NO. In the systemic capillaries, hemoglobin unloads O₂, which then diffuses into body cells. The NO relaxes the capillary walls, allowing them to expand, which probably helps deliver O₂ to the cells.

Leukocytes. The blood contains five major types of white blood cells, or leukocytes: monocytes, neutrophils, basophils, eosinophils, and lymphocytes (see Figure 42.15). Their collective function is to fight infections. For example, monocytes and neutrophils are phagocytes, which engulf and digest bacteria and debris from the body's own dead cells. As we will see in Chapter 43, lymphocytes develop into specialized B cells and T cells, which produce the immune response against foreign substances. White blood cells spend most of their time outside the circulatory system, patrolling through interstitial fluid and the lymphatic system, where most of the battles against pathogens are waged. Normally, a microliter of human blood has about 5,000 to 10,000 leukocytes, but their numbers increase temporarily whenever the body is fighting an infection.

Platelets. The third cellular element of blood, platelets, are fragments of cells about 2–3 µm in diameter. They have no nuclei and originate as pinched-off cytoplasmic fragments of large cells in the bone marrow. Platelets then enter the blood and function in the important process of blood clotting.

Stem Cells and the Replacement of Cellular Elements

The cellular elements of blood (erythrocytes, leukocytes, and platelets) wear out and are replaced constantly throughout a person's life. Erythrocytes, for example, usually circulate for only three to four months and then are destroyed by phagocytic cells in the liver and spleen. Enzymes digest the old cell's macromolecules, and biosynthetic processes construct new macromolecules using many of the monomers, such as amino acids, harvested from the old blood cells, as well as new materials and energy from food. Many of the iron atoms derived from the hemoglobin in old erythrocytes are incorporated into new hemoglobin molecules.

Erythrocytes, leukocytes, and platelets all develop from a common source, a single population of cells called pluripotent stem cells in the red marrow of bones, particularly the ribs, vertebrae, breastbone, and pelvis (Figure 42.16). "Pluripo-

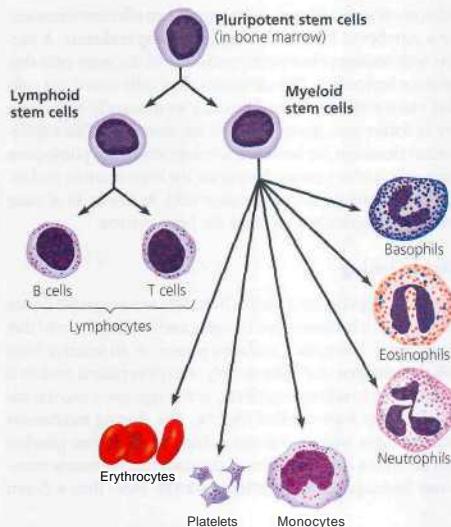

Figure 42.16 Differentiation of blood cells. Some of the pluripotent stem cells differentiate into lymphoid stem cells, which then develop into B cells and T cells, two types of lymphocytes that function in the immune response (see Chapter 43). All other blood cells differentiate from myeloid stem cells.

tent" means that these cells have the potential to differentiate into any type of blood cell or into cells that produce platelets. Pluripotent stem cells arise in the early embryo, and the population renews itself while replenishing the blood with cellular elements. (See Chapter 21 for more on stem cells.)

A negative-feedback mechanism, sensitive to the amount of O₂ reaching the body's tissues via the blood, controls erythrocyte production. If the tissues do not receive enough O₂, the kidney synthesizes and secretes a hormone called erythropoietin (EPO), which stimulates production of erythrocytes. If blood is delivering more O₂ than the tissues can use, the level of EPO falls and erythrocyte production slows.

Physicians use synthetic erythropoietin to treat people with health problems such as anemia, a condition of lower-than-normal hemoglobin levels. However, some athletes abuse EPO by injecting themselves with the drug to increase their erythrocyte levels. This practice, known as blood doping, is banned by the International Olympic Committee and other sports federations. In 2002, several athletes competing in the winter Olympics in Salt Lake City tested positive for EPO-like chemicals and as a result were stripped of some of their medals.

Recently researchers succeeded in isolating pluripotent stem cells and growing these cells in laboratory cultures. Purified

pluripotent stem cells may soon provide an effective treatment for a number of human diseases, including leukemia. A person with leukemia has a cancerous line of the stem cells that produce leukocytes. The cancerous stem cells crowd out cells that make erythrocytes and produce an unusually high number of leukocytes, many of which are abnormal. One experimental treatment for leukemia involves removing pluripotent stem cells from a patient, destroying the bone marrow, and restocking it with noncancerous stem cells. As few as 30 of these cells can completely repopulate the bone marrow.

Blood Clotting

Most people get cuts and scrapes from time to time, yet we do not bleed to death because blood contains a self-sealing material that plugs leaks. The sealant is always present in an inactive form called fibrinogen. A clot forms only when this plasma protein is converted to its active form, fibrin, which aggregates into threads that form the framework of the clot. The clotting mechanism usually begins with the release of clotting factors from platelets and involves a complex chain of reactions that ultimately transforms fibrinogen to fibrin (**Figure 42.17**). More than a dozen

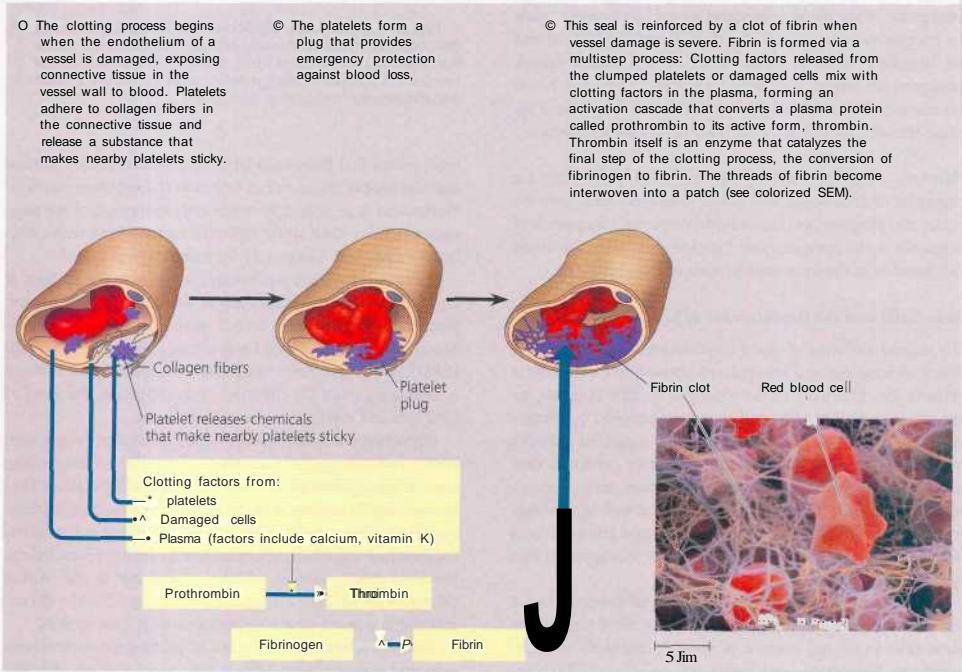

clotting factors have been discovered, and the mechanism is still not fully understood. A genetic mutation that affects any step of the clotting process causes hemophilia, a disease characterized by excessive bleeding from even minor cuts and bruises.

Anticlotting factors in the blood normally prevent spontaneous clotting in the absence of injury. Sometimes, however, platelets clump and fibrin coagulates within a blood vessel, blocking the flow of blood. Such a clot is called a thrombus. These potentially dangerous clots are more likely to form in individuals with cardiovascular disease.

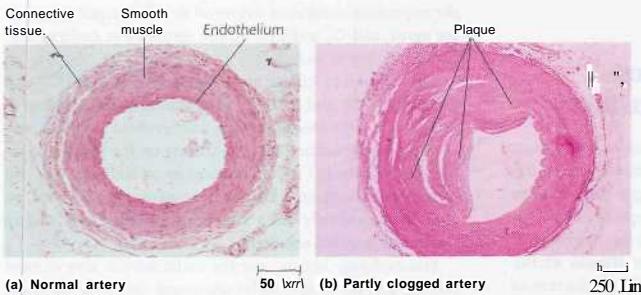

Cardiovascular Disease

More than half the deaths in the United States are caused by cardiovascular diseases, disorders of the heart and blood vessels. The tendency to develop cardiovascular disease is inherited to some extent, but lifestyle plays a large role, too. Nongenetic factors that increase the risk of cardiovascular problems include smoking, lack of exercise, a diet rich in animal fat, and high concentrations of cholesterol in the blood.

Cholesterol travels in the blood plasma mainly in the form of particles consisting of thousands of cholesterol molecules.

• **Figure 42.17** Blood clotting.

A | Figure 42.18 Atherosclerosis. These light micrographs contrast a cross section of (a) a normal (healthy) artery with (b) an artery partially blocked by an atherosclerotic plaque. Plaques consist mostly of fibrous connective tissue and smooth muscle cells infiltrated with lipids.

and other lipids bound to a protein. One type of particle—low-density lipoproteins (LDLs), often called the "bad cholesterol"—is associated with the deposition of cholesterol in arterial plaques, growths that develop on the inner walls of arteries. Another type—high-density lipoproteins (HDLs), or "good cholesterol"—appears to reduce the deposition of cholesterol. Exercise increases HDL concentration, whereas smoking has the opposite effect on the LDL/HDL ratio.

Healthy arteries have smooth inner linings that promote unimpeded blood flow. The deposition of cholesterol thickens and roughens this smooth lining. A plaque forms at the site and becomes infiltrated with fibrous connective tissue and even more cholesterol. Such plaques narrow the bore of the artery, leading to a chronic cardiovascular disease known as atherosclerosis (**Figure 42.18**). The rough lining of an atherosclerotic artery seems to encourage the adhesion of platelets, triggering the clotting process and interfering with circulation.

Hypertension (high blood pressure) promotes atherosclerosis and increases the risk of heart attack and stroke. Atherosclerosis tends to raise blood pressure by narrowing the vessels and reducing their elasticity. According to one hypothesis, chronic high blood pressure damages the endothelium that lines arteries, promoting plaque formation. Fortunately, hypertension is simple to diagnose and can usually be controlled by diet, exercise, medication, or a combination of these. A diastolic pressure above 90 may be cause for concern, and living with extreme hypertension—say, 200/120—is courting disaster.

As atherosclerosis progresses, arteries become narrower, and the threat of heart attack or stroke increases. There may be warning signs. For example, if a coronary artery is only partially blocked, the person may feel occasional chest pain, a condition known as angina pectoris. The pain is most likely to appear when the heart is laboring hard as a result of physical or emotional stress, and it signals that part of the heart is not receiving enough O₂. However, many people with atherosclerosis are completely unaware of their condition until catastrophe strikes.

The final blow is usually a heart attack or a stroke. A heart attack is the death of cardiac muscle tissue resulting from prolonged blockage of one or more coronary arteries, the vessels that supply oxygen-rich blood to the heart. Because they are small in diameter to begin with, the coronary arteries are particularly vulnerable. Such blockage can destroy cardiac muscle quickly, since the constantly beating heart muscle cannot survive long without oxygen. A stroke is the death of nervous tissue in the brain, usually resulting from rupture or blockage of arteries in the head.

Heart attacks and strokes frequently result from a thrombus, or blood clot, that clogs an artery. A key process leading to

the clogging of an artery by a thrombus is an inflammatory response triggered by the accumulation of LDLs in the artery's inner lining. Such an inflammation, which is analogous to the body's response to a cut infected by bacteria (see Figure 43.6), can cause plaques to rupture, releasing fragments that form a thrombus. The thrombus may originate in a coronary artery or an artery in the brain, or it may develop elsewhere in the circulatory system and reach the heart or brain via the bloodstream. The transported clot, called an embolus, is swept along until it lodges in an artery too small for the clot to pass. An embolus is more likely to become trapped in a vessel that has been narrowed by plaques. The embolus blocks blood flow, and cardiac or brain tissue downstream from the obstruction may die from O₂ deprivation. If damage in the heart interrupts the conduction of electrical impulses through cardiac muscle, heart rate may change drastically or the heart may stop beating altogether. Still, the victim may survive if a heartbeat is restored by cardiopulmonary resuscitation (CPR) or some other emergency procedure within a few minutes of the attack. The effects of a stroke and the individual's chance of survival depend on the extent and location of the damaged brain tissue.

Concept Check 42.4

- About how many red blood cells does the bone marrow of a human produce per day, assuming a total red blood cell count of 25 trillion (2.5×10^{12}) and an average longevity of 4 months for the cells?
- Explain why a physician might order a white-cell count for a patient with symptoms of an infection.
- How can a few dozen transplanted bone marrow stem cells replace the wide variety of cells that occur in bone marrow?

For suggested answers, see Appendix A.

42.5

Concept

Gas exchange occurs across specialized respiratory surfaces

In the remainder of this chapter, we will focus on the process of gas exchange. Although this process is often called respiration, it should not be confused with the energy transformations of cellular respiration. Gas exchange is the uptake of molecular oxygen (O_2) from the environment and the discharge of carbon dioxide (CO_2) to the environment (Figure 42.19). These exchanges are necessary to support the production of ATP in cellular respiration and usually involve both the respiratory system and the circulatory system of an animal.

The source of O_2 , called the respiratory medium, is air for terrestrial animals and water for most aquatic animals. The atmosphere is Earth's main reservoir of O_2 and is about 21% OT (by volume). Oceans, lakes, and other bodies of water contain O_2 in dissolved form. The amount of O_2 dissolved in a given volume of water varies considerably, but is always much less than in an equivalent volume of air.

The part of an animal's body where gases are exchanged with the surrounding environment is called the respiratory surface. Animals do not move O_2 and CO_2 across membranes by active transport, so movement of these gases between the respiratory surface and the environment occurs entirely by diffusion. The rate of diffusion is proportional to the surface area across which diffusion occurs and inversely proportional to the square of the distance through which molecules must move. As a result, respiratory surfaces tend to be thin and have a large surface area, structural adaptations that maximize the rate of gas exchange. Additionally, all living cells must be bathed in water to maintain their plasma membranes. Thus,

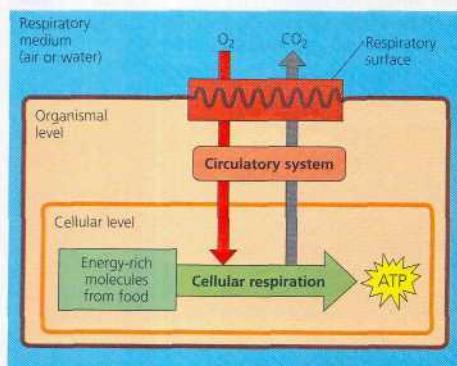

the respiratory surfaces of terrestrial as well as aquatic animals are moist, and O_2 and CO_2 diffuse across these surfaces after first dissolving in water.

The respiratory surface must supply O_2 and expel CO_2 for the entire body, and a variety of solutions to the problem of providing a large enough surface have evolved. The structure of a respiratory surface depends mainly on the size of the organism and whether it lives in water or on land, but it is also influenced by metabolic demands for gas exchange. Thus, an endotherm generally has a larger area of respiratory surface than a similar-sized ectotherm.

Gas exchange occurs over the entire surface area of most protists and other unicellular organisms. Similarly, for some relatively simple animals, such as sponges, cnidarians, and flatworms, the plasma membrane of every cell in the body is close enough to the external environment for gases to diffuse in and out. In many animals, however, the bulk of the body does not have direct access to the respiratory medium. The respiratory surface in these animals is a thin, moist epithelium separating the respiratory medium from the blood (or capillaries), which transport gases to and from the rest of the body (see Figure 42.19).

Some animals use their entire outer skin as a respiratory organ. An earthworm, for example, has moist skin and exchanges gases by diffusion across its general body surface. Just below the earthworm's skin is a dense net of capillaries. Because the respiratory surface must remain moist, earthworms and many other skin-breathers, including some amphibians, must live in water or damp places.

Animals whose only respiratory organ is moist skin are usually small and are either long and thin or flat, with a high ratio of surface area to volume. For most other animals, the general body surface lacks sufficient area to exchange gases for the whole body. The solution is a respiratory organ that is extensively folded or branched, thereby enlarging the available surface area for gas exchange. Gills, tracheae, and lungs are the three most common respiratory organs.

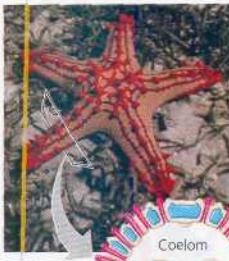

A. Figure 42.19 The role of gas exchange in bioenergetics.

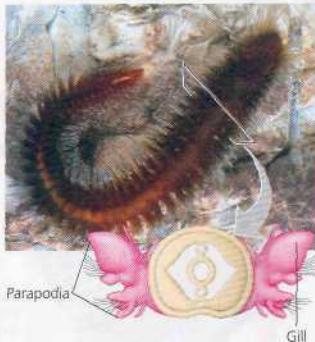

Gills in Aquatic Animals

Gills are outfoldings of the body surface that are suspended in the water. In some invertebrates, such as sea stars, the gills have a simple shape and are distributed over much of the body (Figure 42.20a). Many segmented worms have flaplike gills that extend from each segment of their body (Figure 42.20b) or long, feathery gills clustered at the head or tail. The gills of scallops (Figure 42.20c), crayfish (Figure 42.20d), and many other animals are restricted to a local body region. The total surface area of the gills is often much greater than that of the rest of the body.

As a respiratory medium, water has both advantages and disadvantages. There is no problem keeping the plasma membranes of the respiratory surface cells moist, since the

(a) **Sea star.** The gills of a sea star are simple tubular projections of the skin. The hollow core of each gill is an extension of the coelom (body cavity). Gas exchange occurs by diffusion across the gill surfaces, and fluid in the coelom circulates in and out of the gills, aiding gas transport. The surfaces of a sea star's tube feet also function in gas exchange.

(b) **Marine worm.** Many polychaetes (marine worms of the phylum Annelida) have a pair of flattened appendages called parapodia on each body segment. The parapodia serve as gills and also function in crawling and swimming.

(c) **Scallop.** The gills of a scallop are long, flattened plates that project from the main body mass inside the hard shell. Cilia on the gills circulate water around the gill surfaces.

(d) **Crayfish.** Crayfish and other crustaceans have long, feathery gills covered by the exoskeleton. Specialized body appendages drive water over the gill surfaces.

Figure 42.20 Diversity in the structure of gills, external body surfaces functioning in gas exchange.

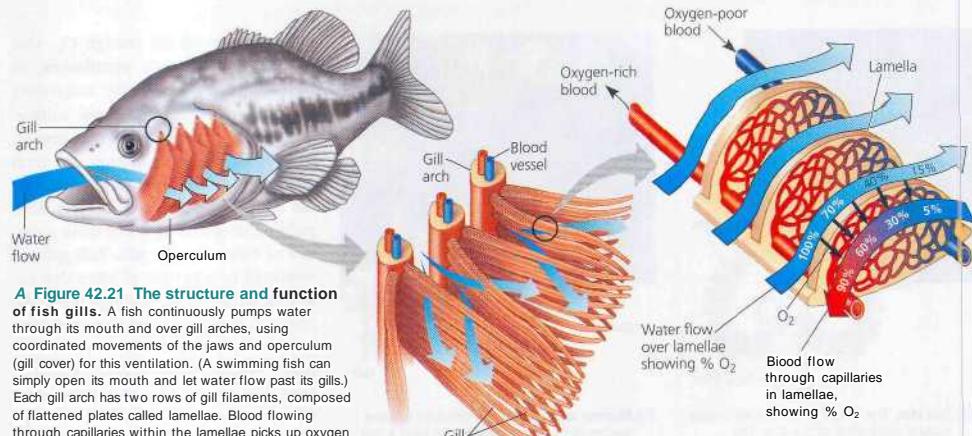

gills are surrounded by the aqueous environment. However, O_2 concentrations in water are low; and the warmer and saltier the water, the less dissolved O_2 it can hold (water in many marine and freshwater habitats contains only 4–8 mL of dissolved O_2 per liter). Thus, gills must be **very** effective for

the animal to obtain enough O_2 . One process that helps is ventilation, or increasing the flow^T of the respiratory medium over the respiratory surface. Without ventilation, a region of low O_2 and high CO_2 concentration can form around the gill as it exchanges gases with the water. Crayfish and lobsters have paddle-like appendages that drive a current of water over the gills. Fish gills are ventilated by a current of water that enters the mouth, passes through slits in the pharynx, flows over the gills, and then exits the body (**Figure 42.21**, on the next page). Because water is dense and contains little O_2 per unit of volume, most fishes must expend considerable energy in ventilating their gills.

The arrangement of capillaries in a fish gill enhances gas exchange and reduces the energy cost of ventilation. Blood flows in the direction opposite to the movement of water past the gills. This makes it possible to transfer O_2 to the blood by a very efficient process called **countercurrent exchange**. As blood moves through a gill capillary, it becomes more and more loaded with O_2 , but it simultaneously encounters water with ever higher O_2 concentrations because the water is just beginning its passage over the gills. This means that along the entire length of the capillary, **there** is a diffusion gradient favoring the transfer of O_2 from water to blood. The countercurrent exchange mechanism is so efficient that the gills can remove more than 80% of the O_2 dissolved in the water passing over the respiratory surface. The basic mechanism of countercurrent exchange is also important in temperature regulation, as we saw in Chapter 40, and in the functioning of the mammalian kidney, as we will see in Chapter 44.

Gills are generally unsuitable for an animal living on land. An expansive surface of wet membrane exposed to air

would lose too much water by evaporation, and the gills would collapse as their fine filaments, no longer supported by water, would cling together. Most terrestrial animals house their respiratory surfaces within the body, opening to the atmosphere through narrow tubes.

A Figure 42.21 The structure and function of fish gills.

A fish continuously pumps water through its mouth and over gill arches, using coordinated movements of the jaws and operculum (gill cover) for this ventilation. (A swimming fish can simply open its mouth and let water flow past its gills.) Each gill arch has two rows of gill filaments, composed of flattened plates called lamellae. Blood flowing through capillaries within the lamellae picks up oxygen from the water. Notice that the countercurrent flow of water and blood maintains a concentration gradient down which O_2 diffuses from the water into the blood over the entire length of a capillary.

Tracheal Systems in Insects

As a respiratory medium, air has many advantages over water, including a much higher concentration of oxygen (about 210 mL O_2 per liter of air). Also, since O_2 and CO_2 diffuse much faster in air than in water, respiratory surfaces exposed to air do not have to be ventilated as vigorously as gills. As the respiratory surface removes O_2 from the air and expels CO_2 , diffusion rapidly brings more O_2 to the respiratory surface and carries the CO_2 away. When a terrestrial animal does ventilate, less energy is needed because air is far lighter and easier to pump than water and because much less volume needs to be breathed to obtain an equal amount of O_2 . But along with these advantages comes a problem: The respiratory surface, which must be large and moist, continuously loses water to the air by evaporation. The problem is greatly reduced by a respiratory surface folded into the body. While the most familiar such respiratory structure among terrestrial animals is the lung, the most common is the tracheal system of insects.

The tracheal system of insects, made up of air tubes that branch throughout the body, is one variation on the theme of a folded internal respiratory surface. The largest tubes, called tracheae, open to the outside. The finest branches extend to the surface of nearly every cell, where gas is exchanged by diffusion across the moist epithelium that lines the terminal ends of the tracheal system (Figure 42.22a). With virtually all body cells within a very short distance of the respiratory medium, the open circulatory system of insects is not involved in transporting O_2 and CO_2 .

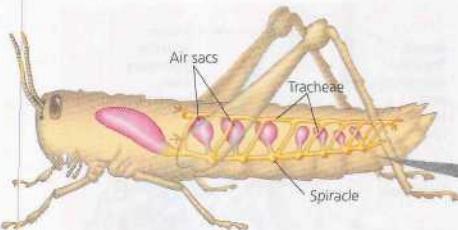

For a small insect, diffusion through the trachea brings in enough O_2 and removes enough CO_2 to support cellular res-

piration. Larger insects with higher energy demands ventilate their tracheal systems with rhythmic body movements that compress and expand the air tubes like bellows. An insect in flight has a very high metabolic rate, consuming 10 to 200 times more O_2 than it does at rest. In many flying insects, alternating contraction and relaxation of the flight muscle cells compress and expand the body, rapidly pumping air through the tracheal system. The flight muscle cells are packed with mitochondria that support the high metabolic rate, and the tracheal tubes supply each of these ATP-generating organelles with ample O_2 (Figure 42.22b). Thus, adaptations of tracheal systems are directly related to bioenergetics.

Lungs

Unlike tracheal systems that branch throughout the insect body, lungs are restricted to one location. Because the respiratory surface of a lung is not in direct contact with all other parts of the body, the gap must be bridged by the circulatory system, which transports gases between the lungs and the rest of the body. Lungs have a dense net of capillaries just under the epithelium that forms the respiratory surface. Lungs have evolved in spiders, terrestrial snails, and vertebrates.

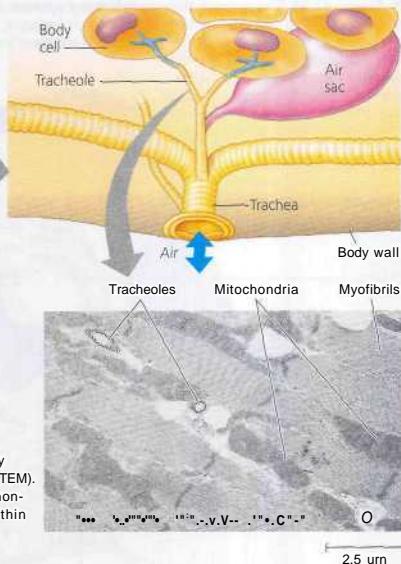

Among the vertebrates, amphibians have relatively small lungs that do not provide a very large surface (many lack lungs altogether), relying heavily on diffusion across other body surfaces for gas exchange. The skin of a frog, for example, supplements gas exchange in the lungs. In contrast, most reptiles* (including all birds) and all mammals rely entirely on lungs for gas exchange. Turtles are an exception; they supplement lung breathing with gas exchange across moist epithelial surfaces in

(a) The respiratory system of an insect consists of branched internal tubes that deliver air directly to body cells. Rings of chitin reinforce the largest tubes, called tracheae, keeping them from collapsing. Enlarged portions of tracheae form air sacs near organs that require a large supply of oxygen. Air enters the tracheae through openings called spiracles on the insect's body surface and passes into smaller tubes called tracheoles. The tracheoles are closed and contain fluid (blue-gray). When the animal is active and is using more O₂, most of the fluid is withdrawn into the body. This increases the surface area of air in contact with cells.

(b) This micrograph shows cross sections of tracheoles in a tiny piece of insect flight muscle (TEM). Each of the numerous mitochondria in the muscle cells lies within about 5 μm of a tracheole.

▲ Figure 42.22 Tracheal systems.

their mouth and anus. Lungs and air breathing have evolved in a few aquatic vertebrates (lungfishes) as adaptations to living in oxygen-poor water or to spending part of their time exposed to air (for instance, when the water level of a pond recedes).

In general, the size and complexity of lungs are correlated with an animal's metabolic rate (and hence its rate of gas exchange). For example, the lungs of endotherms have a greater area of exchange surface than those of similar-sized ectotherms.

Mammalian Respiratory Systems: A Closer Look

Located in the thoracic (chest) cavity, the lungs of mammals have a spongy texture and are honeycombed with a moist epithelium that functions as the respiratory surface. A system of branching ducts conveys air to the lungs (Figure 42.23, on the next page). Air enters through the nostrils and is then filtered by hairs, warmed, humidified, and sampled for odors as it flows through a maze of spaces in the nasal cavity. The nasal cavity leads to the pharynx, an intersection where the paths for air and food cross. When food is swallowed, the larynx (the upper part of the respiratory tract) moves upward and tips the epiglottis over the glottis (the opening of the windpipe). This allows food to go down the esophagus to the stomach (see Figure 41.16). The rest of the time, the glottis is open, enabling breathing.

The larynx wall is reinforced with cartilage, and in most mammals, the larynx is adapted as a voice box. Exhaled air rushes by a pair of vocal cords in the larynx. Sounds are

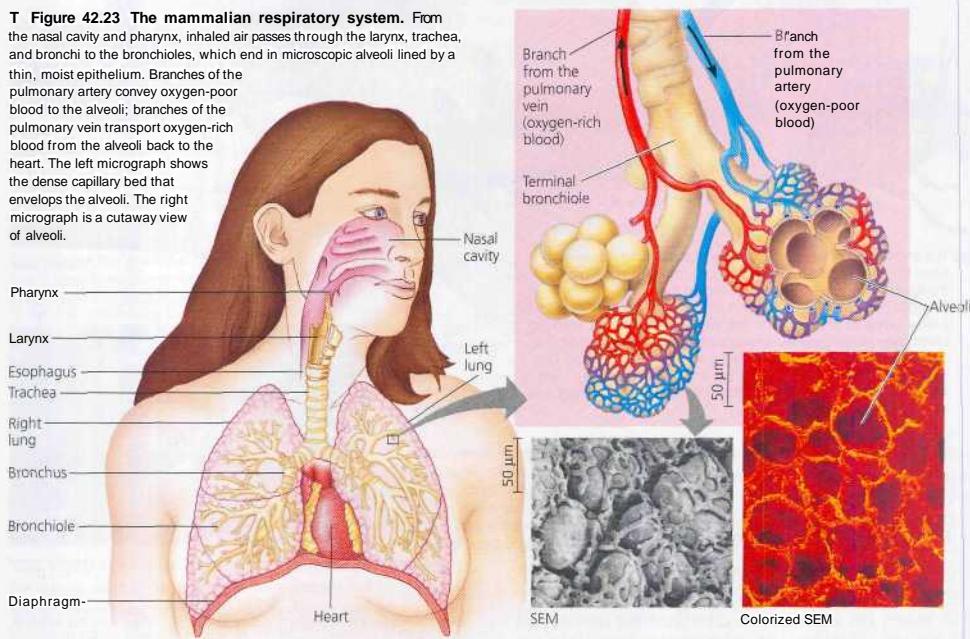

produced when voluntary muscles in the voice box are tensed, stretching the cords so they vibrate. High-pitched sounds result from tightly stretched cords vibrating rapidly; low-pitched sounds come from less tense cords vibrating slowly.

From the larynx, air passes into the trachea, or windpipe. C-shaped rings of cartilage maintain the trachea's shape. The trachea forks into two **bronchi** (singular, bronchus), one leading to each lung. Within the lung, the bronchus branches repeatedly into finer and finer tubes called bronchioles. The entire system of air ducts has the appearance of an inverted tree, the trunk being the trachea. The epithelium lining the major branches of this respiratory tree is covered by cilia and a thin film of mucus. The mucus traps dust, pollen, and other particulate contaminants, and the beating cilia move the mucus upward to the pharynx, where it can be swallowed into the esophagus. This process helps cleanse the respiratory system.

At their tips, the tiniest bronchioles dead-end as a cluster of air sacs called alveoli (singular, alveolus; see Figure 42.23). Gas exchange occurs across the thin epithelia of the lung's millions of alveoli, which have a total surface area of about 100 m² in humans, sufficient to carry out gas exchange for the entire body. Oxygen in the air entering the alveoli dissolves in the moist film and rapidly diffuses across the epithelium into a web of capillaries that surrounds each alveolus. Carbon dioxide diffuses in the opposite direction, from the capillaries across the epithelium of the alveolus and into the air space.

Oxygen-poor blood

T Figure 42.23 The mammalian respiratory system. From the nasal cavity and pharynx, inhaled air passes through the larynx, trachea, and bronchi to the bronchioles, which end in microscopic alveoli lined by a thin, moist epithelium. Branches of the pulmonary artery convey oxygen-poor blood to the alveoli; branches of the pulmonary vein transport oxygen-rich blood from the alveoli back to the heart. The left micrograph shows the dense capillary bed that envelopes the alveoli. The right micrograph is a cutaway view of alveoli.

Concept Check 42.5

1. Why is the position of lung tissues *within* the body an advantage for terrestrial animals?
2. Explain how countercurrent exchange maximizes the ability of fish gills to extract dissolved O₂ from water.

For suggested answers, see Appendix A.

Concept 42.6

Breathing ventilates the lungs

Like fishes, terrestrial vertebrates rely on ventilation to maintain high O₂ and low CO₂ concentration at the gas exchange surface. The process that ventilates lungs is breathing, the alternate inhalation and exhalation of air.

How an Amphibian Breathes

An amphibian such as a frog ventilates its lungs by positive pressure breathing. During a breathing cycle, muscles lower the floor of the oral cavity, drawing in air through the nostrils. Then, with the nostrils and mouth closed, the floor of

the oral cavity rises, forcing air down the trachea. Elastic recoil of the lungs and compression by the muscular body wall force air back out of the lungs during exhalation.

How a Mammal Breathes

Unlike amphibians, mammals ventilate their lungs by negative pressure breathing, which works like a suction pump, pulling air instead of pushing it into the lungs (Figure 42.24). Muscle action changes the volume of the rib cage and the chest cavity, and the lungs match these volume changes. The inner layer of the lung's double-walled sac adheres to the outside of the lungs, and the outer layer adheres to the wall of the chest cavity. A thin space filled with fluid separates the two layers. Because of surface tension, the two layers are like two plates of glass stuck together by a film of water. The layers can slide smoothly past each other, but they cannot be pulled apart easily. Surface tension couples movement of the lungs to movement of the rib cage.

Lung volume increases as a result of contraction of the rib muscles and the diaphragm, a sheet of skeletal muscle that forms the bottom wall of the chest cavity. Contraction of the rib muscles expands the rib cage by pulling the ribs upward and the breastbone outward. At the same time, the chest cavity expands as the diaphragm contracts and descends like a piston.

All these changes increase the lung volume, and as a result, air pressure within the alveoli becomes lower than atmospheric pressure. Because gas flows from a region of higher pressure to a region of lower pressure, air rushes through the nostrils and down the breathing tubes to the alveoli. During exhalation, the rib muscles and diaphragm relax, lung volume is reduced, and the increased air pressure within the alveoli forces air up the breathing tubes and out through the nostrils (see Figure 42.24).

The rib muscles and diaphragm change lung volume during shallow breathing, when a mammal is at rest. During vigorous exercise, other muscles of the neck, back, and chest further increase ventilation volume by raising the rib cage even more. In some species, the rhythmic movements during running cause visceral organs, including the stomach and liver, to slide forward and backward in the body cavity with each stride. This "visceral pump" further increases ventilation volume.

The volume of air a mammal inhales and exhales with each breath is called **tidal volume**. It averages about 500 mL in resting humans. The maximum tidal volume during forced breathing is the **vital capacity**, which is about 3.4 L and 4.8 L for college-age females and males, respectively. The lungs hold more air than the vital capacity, but since it is impossible to completely collapse the alveoli, a **residual volume** of air remains in the lungs even after you forcefully exhale as much as you can. As lungs lose their resilience owing to aging or disease (such as emphysema), residual volume increases at the expense of vital capacity.

Since the lungs do not completely empty and refill with each breath cycle, newly inhaled air mixes with oxygen-depleted residual air, and the maximum O₂ concentration in alveoli is considerably less than in the atmosphere. Though this limits the effectiveness of gas exchange, the CO₂ in residual air is critical for regulating the pH of blood and breathing rate in mammals.

How a Bird Breathes

Ventilation is much more complex in birds than in mammals. Besides lungs, birds have eight or nine air sacs that penetrate the abdomen, neck, and wings. The

air sacs do not function directly in gas exchange, but act as bellows that keep air flowing through the lungs (Figure 42.25).

The entire system—lungs and air sacs—is ventilated when the bird breathes. Air

flows through the system in a circuit that passes through the lungs in one direction only, regardless of whether the animal is inhaling or exhaling. Instead of alveoli, which are dead ends, the sites of gas exchange in bird lungs are tiny channels called **parabronchi**, through which air flows in one direction.

This system completely renews the air in the lungs with every exhalation, so maximum lung O₂ concentrations are higher in birds than in mammals. Partly because of this advantage, birds perform much better than mammals at high altitude. For example, humans have great difficulty obtaining enough O₂ when climbing the Earth's highest peaks, such as Mount Everest in the Himalayas (8,848 m). But several

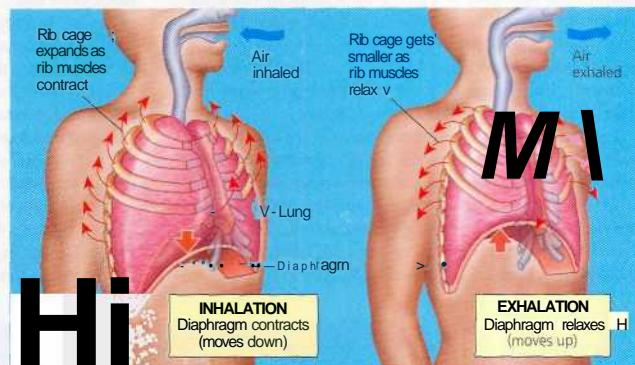

Figure 42.24 Negative pressure breathing. A mammal breathes by changing the air pressure within its lungs relative to the pressure of the outside atmosphere.

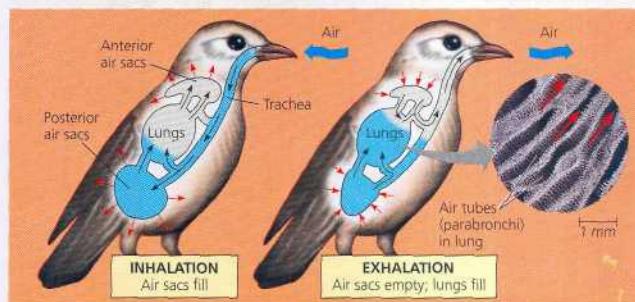

Figure 42.25 The avian respiratory system. Contraction and relaxation of the air sacs ventilates the lungs, forcing air in one direction through tiny parallel tubes in the lungs called parabronchi (inset, SEM). Gas exchange occurs across the walls of the parabronchi. During inhalation, both sets of air sacs expand. The posterior sacs fill with fresh air (blue) from the outside, while the anterior sacs fill with stale air (9% CO_2) from the lungs. During exhalation, both sets of air sacs deflate, forcing air from the posterior sacs into the lungs, and air from the anterior sacs out of the system via the trachea. Two cycles of inhalation and exhalation are required for the air to pass all the way through the system and out of the bird.

species of birds (notably the bar-headed goose) easily fly over the same mountains during migration.

Control of Breathing in Humans

Humans can voluntarily hold their breath or breathe faster and deeper, but most of the time automatic mechanisms regulate breathing. This ensures that the work of the respiratory system is coordinated with that of the cardiovascular system and with metabolic demands for gas exchange.

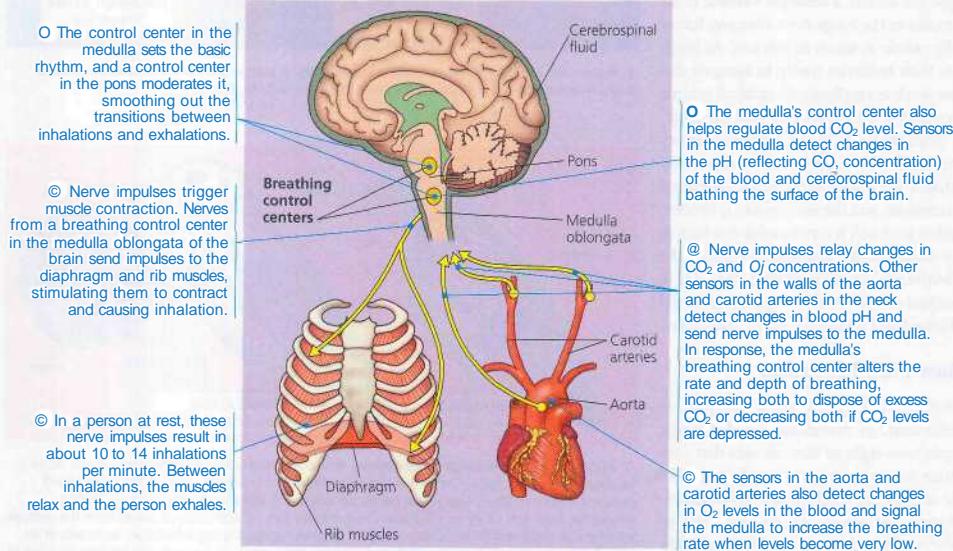

The main "breathing control centers are located in two regions of the brain, the medulla oblongata and the pons (Figure 42.26). Aided by the control center in the pons, the medulla's center sets the basic breathing rhythm. Secondary control over breathing is exerted by sensors in the aorta and carotid arteries that monitor O₂ and CO₂ concentrations in the blood as well as blood pH. During deep breathing, a negative-feedback mechanism prevents the lungs from over-expanding; stretch sensors in the lung tissue send nerve impulses that inhibit the medulla's control center.

The medulla control center regulates breathing activity in response to changes in pH of the tissue fluid (cerebrospinal fluid) bathing the brain. The pH of the cerebrospinal fluid is determined mainly by CO₂ concentrations in the blood. Carbon dioxide diffuses from the blood to the cerebrospinal fluid, where it reacts with water and forms carbonic acid, which lowers the pH. When the medulla control center registers a slight drop in

pH (increase in CO₂) of the cerebrospinal fluid, it increases the depth and rate of breathing, and the excess CO₂ is eliminated in exhaled air. This occurs during exercise, for example.

Oxygen concentrations in the blood usually have little effect on the breathing control centers. However, when the O₂ level is severely depressed (at high altitudes, for instance), O₂ sensors in the aorta and carotid arteries in the neck send alarm signals to the breathing control centers, which respond by increasing the breathing rate. Normally, a rise in CO₂ concentration is a good indication of a fall in O₂ concentration, because CO₂ is produced by the same process that consumes O₂—cellular respiration. However, it is possible to trick the breathing center by hyperventilating. Excessively deep, rapid breathing purges the blood of so much CO₂ that the breathing center temporarily ceases to send impulses to the rib muscles and diaphragm. Breathing stops until CO₂ levels increase (or O₂ levels decrease) enough to switch the breathing center back on.

The breathing center responds to a variety of nervous and chemical signals and adjusts breathing rate and depth to meet changing demands. However, breathing control is only effective if it is coordinated with control of the cardiovascular system so that there is a good match between lung ventilation and the amount of blood flowing through alveolar capillaries. During exercise, for instance, increased cardiac output is matched to the increased breathing rate, which enhances O₂ uptake and CO₂ removal as blood flows through the lungs.

A Figure 42.26 Automatic control of breathing.

Concept Check 42.6

- How does an increase in the CO₂ concentration in the blood affect the pH of cerebrospinal fluid?
- A slight decrease in blood pH causes the heart's pacemaker to speed up. What is the function of this control mechanism?
- How does breathing differ in mammals and birds?

For suggested answers, see Appendix A.

Concept 42.7

Respiratory pigments bind and transport gases

The high metabolic demands of many organisms require that the blood transport large quantities of O₂ and CO₂. It appears that similar solutions that address the transport requirements set by high metabolic demands have evolved independently in different groups of animals. First, we'll see the role that O₂ and CO₂ gradients play, using the mammalian respiratory system as an example. Then we'll examine blood molecules called respiratory pigments that aid in the process of gas exchange.

The Role of Partial Pressure Gradients

Gases diffuse down pressure gradients in the lungs and other organs. Diffusion of a gas, whether present in air or dissolved in water, depends on differences in a quantity called partial pressure. At sea level, the atmosphere exerts a total pressure of 760 mm Hg. This is a downward force equal to that exerted by a column of mercury 760 mm high. Since the atmosphere is 21% O₂ (by volume), the partial pressure of O₂ (abbreviated P_{O₂}) is 0.21 × 760, or about 160 mmHg. This is the portion of atmospheric pressure contributed by O₂; hence the term *partial pressure*. The partial pressure of CO₂ (P_{CO₂}) at sea level is only 0.23 mm Hg. When water is exposed to air, the amount of a gas that dissolves in the water is proportional to its partial pressure in the air and its solubility in water. An equilibrium is eventually reached when gas molecules enter and leave the solution at the same rate. At this point, the gas is said to have the same partial pressure in solution as it does in the air. Thus, in a glass of water exposed to air at sea-level air pressure, the P_{O₂} is 160 mm Hg and the P_{CO₂} is 0.23 mm Hg.

A gas always diffuses from a region of higher partial pressure to a region of lower partial pressure. Blood arriving at the lungs via the pulmonary arteries has a lower P_{O₂} and a higher P_{CO₂} than the air in the alveoli (Figure 42.27). Notice that the air in the alveoli has a lower P_{O₂} and a higher P_{CO₂} than air at sea level, since it is not completely replaced with fresh air during breathing. As blood enters the alveolar capillaries, CO₂

diffuses from the blood to the air in the alveoli. Meanwhile, O₂ in the air dissolves in the fluid that coats the epithelium and diffuses into the blood. By the time the blood leaves the lungs in the pulmonary veins, its P_{O₂} has been raised and its P_{CO₂} lowered. After returning to the heart, this blood is pumped through the systemic circuit. In the tissue capillaries, gradients of partial pressure favor the diffusion of O₂ out of the blood and CO₂ into the blood. This is because cellular respiration removes O₂ from and adds CO₂ to the interstitial fluid (again, by diffusion, from mitochondria in nearby cells). After the blood unloads O₂ and loads CO₂, it is returned to the heart and pumped to the lungs again, where it exchanges gases with air in the alveoli.

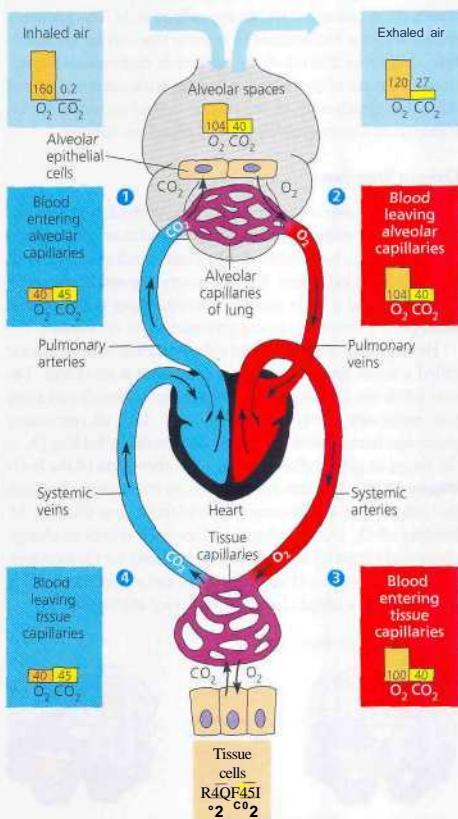

Figure 42.27 Loading and unloading of respiratory gases. The colored bars indicate the partial pressures (in mm Hg) of O₂ (P_{O₂}) and CO₂ (P_{CO₂}) in different locations.

Respiratory Pigments

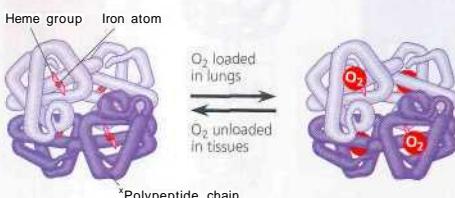

The low solubility of O_2 in water (and thus in blood) is a problem for animals that rely on the circulatory system to deliver O_2 . Suppose all our O_2 were delivered in solution in 1 L of blood. During intense exercise, a person can consume almost 2 L of O_2 per minute, and all of it must be carried in the blood from the lungs to the active tissues. But at normal body temperature and air pressure, only 4.5 mL of O_2 can dissolve into a liter of blood in the lungs. If 80% of the dissolved O_2 were delivered to the tissues (an unrealistically high percentage), the heart would need to pump 500 L of blood per minute.

In fact, most animals transport most of their O_2 bound to certain proteins called respiratory pigments instead of in dissolved form. Respiratory pigments circulate with the blood, often contained within specialized cells. The pigments greatly increase the amount of oxygen that can be carried in blood (to about 200 mL of O_2 per liter in mammalian blood). In our example of an exercising human with a delivery rate of 80%, that greatly reduces the cardiac output necessary for O_2 transport to a manageable 12.5 L of blood per minute.

Oxygen Transport

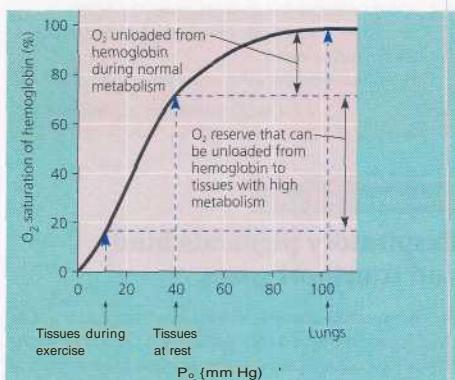

A diversity of respiratory pigments have evolved in various animal taxa. One example, hemocyanin, found in arthropods and many molluscs, has copper as its oxygen-binding component, coloring the blood bluish. The respiratory pigment of almost all vertebrates and a wide variety of invertebrates is the protein hemoglobin, contained in the erythrocytes of vertebrates.

Hemoglobin consists of four subunits, each with a cofactor called a heme group that has an iron atom at its center. The iron binds the O_2 ; thus, each hemoglobin molecule can carry four molecules of O_2 (see Figure 5.20). Like all respiratory pigments, hemoglobin must bind O_2 reversibly, loading O_2 in the lungs or gills and unloading it in other parts of the body (Figure 42.28). This process depends on cooperation between the subunits of the hemoglobin molecule (see Chapter 8). Binding of O_2 to one subunit induces the others to change shape slightly, with the result that their affinity for O_2 increases. And when one subunit unloads its O_2 , the other three quickly unload too as a shape change lowers their affinity for O_2 .

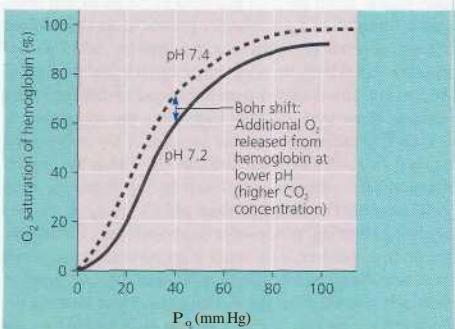

A Figure 42.28 Hemoglobin loading and unloading O_2 .

Cooperative O_2 binding and release is evident in the dissociation curve for hemoglobin (Figure 42.29). Over the

(a) PQ and Hemoglobin Dissociation at $37^\circ C$ and $pH 7.4$.

The curve shows the relative amounts of O_2 bound to hemoglobin exposed to solutions varying in their PQ . At a PQ of 104 mm Hg, typical in the lungs, hemoglobin is about 98% saturated with O_2 . At a PQ of 40 mm Hg, common in the vicinity of tissues, hemoglobin is only about 70% saturated. Hemoglobin can release its O_2 to metabolically very active tissues, such as muscle tissue during exercise.

(b) pH and Hemoglobin Dissociation. Hydrogen ions affect the conformation of hemoglobin—a drop in pH shifts the O₂-dissociation curve toward the right. At a given PQ , say 40 mm Hg, hemoglobin gives up more O_2 at pH 7.2 than at pH 7.4, the normal pH of human blood. The pH decreases (becomes more acidic) in very active tissues because the CO_2 produced by respiration reacts with water, forming carbonic acid. Hemoglobin then releases more O_2 , which supports the increased cellular respiration in the active tissues.

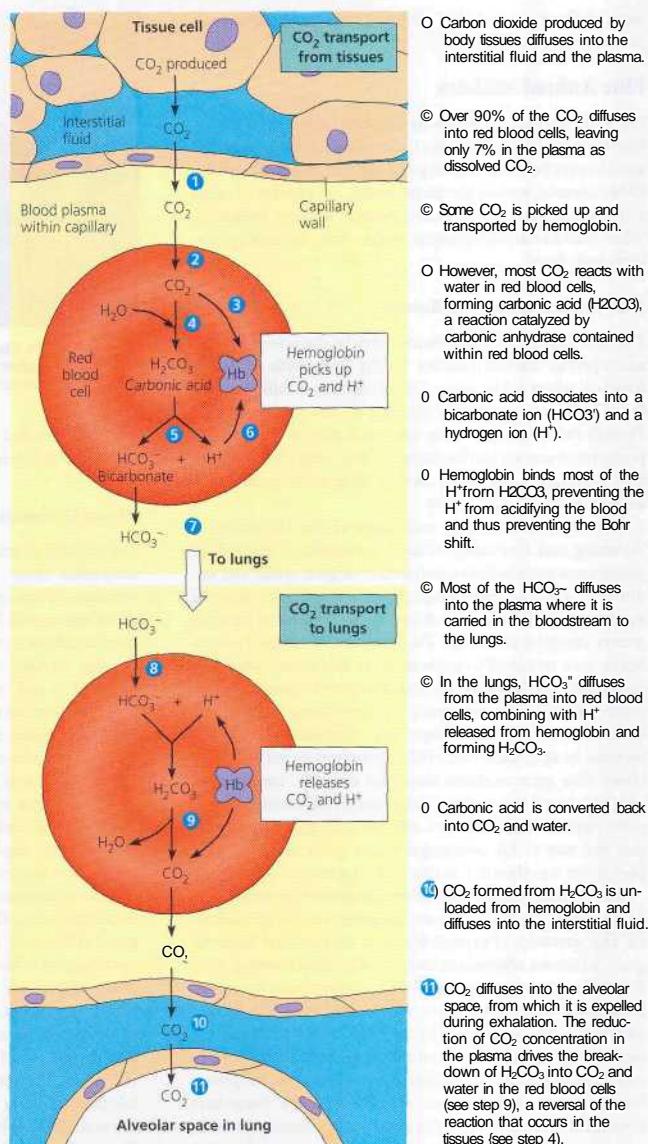

A Figure 42.29 Dissociation curves for hemoglobin.

range of O_2 partial pressures (P_{O_2}) where the dissociation curve has a steep slope. A slight change in P_{O_2} causes hemoglobin to load or unload a substantial amount of O_2 . Notice that the steep part of the curve corresponds to the range of O_2 partial pressures found in body tissues. When cells in a particular location begin working harder—during exercise, for instance— P_{O_2} dips in their vicinity as the O_2 is consumed in cellular respiration. Because of the effect of subunit cooperativity, a slight drop in P_{O_2} is enough to cause a relatively large increase in the amount of O_2 the blood unloads.

As with all proteins, hemoglobin's conformation is sensitive to a variety of factors. For example, a drop in pH lowers the affinity of hemoglobin for O_2 , an effect called the **Bohr shift** (see Figure 42.29b). Because CO_2 reacts with water, forming carbonic acid (H_2CO_3), an active tissue lowers the pH of its surroundings and induces hemoglobin to release more O_2 , which can then be used for cellular respiration.

Carbon Dioxide Transport

In addition to its role in oxygen transport, hemoglobin also helps transport CO_2 and assists in buffering—that is, preventing harmful changes in blood pH. Only about 7% of the CO_2 released by respiring cells is transported in solution in blood plasma. Another 23% binds to the multiple amino groups of hemoglobin, and about 70% is transported in the blood in the form of bicarbonate ions (HCO_3^-). Carbon dioxide from respiring cells diffuses into the blood plasma and then into the erythrocytes (Figure 42.30). The CO_2 first reacts with water (assisted by the enzyme carbonic anhydrase) and forms H_2CO_3 , which then dissociates into a hydrogen ion (H^+) and HCO_3^- . Most of the H^+ attaches to hemoglobin and other proteins, minimizing the change in blood pH. The HCO_3^- diffuses into the plasma. As blood flows through the lungs, the process is rapidly reversed as diffusion of CO_2 out of the

A Figure 42.30 Carbon dioxide transport in the blood.

O Carbon dioxide produced by body tissues diffuses into the interstitial fluid and the plasma.

© Over 90% of the CO₂ diffuses into red blood cells, leaving only 7% in the plasma as dissolved CO₂.

© Some CO₂ is picked up and transported by hemoglobin.

O However, most CO₂ reacts with water in red blood cells, forming carbonic acid (H₂CO₃), a reaction catalyzed by carbonic anhydrase contained within red blood cells.

O Carbonic acid dissociates into a bicarbonate ion (HCO₃⁻) and a hydrogen ion (H⁺).

O Hemoglobin binds most of the H⁺ from H₂CO₃, preventing the H⁺ from acidifying the blood and thus preventing the Bohr shift.

© Most of the HCO₃⁻ diffuses into the plasma where it is carried in the bloodstream to the lungs.

© In the lungs, HCO₃⁻ diffuses from the plasma into red blood cells, combining with H⁺ released from hemoglobin and forming H₂CO₃.

O Carbonic acid is converted back into CO₂ and water.

© CO₂ formed from H₂CO₃ is unloaded from hemoglobin and diffuses into the interstitial fluid.

© CO₂ diffuses into the alveolar space, from which it is expelled during exhalation. The reduction of CO₂ concentration in the plasma drives the breakdown of H₂CO₃ into CO₂ and water in the red blood cells (see step 9), a reversal of the reaction that occurs in the tissues (see step 4).

blood shifts the chemical equilibrium in favor of the conversion of HCO_3^- to CO_2 .

Elite Animal Athletes

For some animals, such as long-distance runners and migratory birds and mammals, the O_2 demands of daily activities would overwhelm the capacity of a typical respiratory system. Other animals, such as diving mammals, are capable of being active underwater for extended periods without breathing. What evolutionary adaptations enable these animals to perform such feats?

The Ultimate Endurance Runner

The elite animal marathon runner may be the pronghorn, an antelope-like mammal native to the grasslands of North America, where it has roamed for more than 4 million years. Pronghorns are capable of running as fast as 100 km/hr. Though their top speed does not reach that of the cheetah, pronghorns can sustain high speeds over long distances and have been timed sprinting 11 km in 10 minutes, maintaining an average speed of 65 km/hr.

Stan Lindstedt and his colleagues at the University of Wyoming and University of Bern were curious about how pronghorns sustain their combination of great speed and endurance: through enhancements of normal physiological mechanisms that supply increased O_2 to muscles or through greater energetic efficiency? The researchers exercised pronghorns on a treadmill to estimate their maximum rate of O_2 consumption (**Figure 42.31**) and discovered something surprising: Pronghorns consume O_2 at three times the rate predicted for an animal of their size. Normally, as animals increase in size, their rate of O_2 consumption per gram declines. One gram of shrew tissue, for example, consumes as much O_2 in a day as a gram of elephant tissue consumes in an entire month. But Lindstedt and his colleagues discovered that the rate of O_2 consumption per gram of tissue by a pronghorn was the same as that of a 10-g mouse!

To establish a more appropriate perspective on pronghorn performance, the research team compared various physiological characteristics of pronghorns with similar-sized domestic goats, which are adapted to climbing rather than running. They found that the maximum rate of O_2 consumption by pronghorns is five times that of goats. Why? Pronghorns have a larger surface area for O_2 diffusion in the lungs, nearly five times the cardiac output, much higher muscle mass, and a higher volume and density of mitochondria than goats. In addition, the pronghorns maintain higher muscle temperatures. The researchers concluded that the pronghorns' extreme O_2 consumption rate, which underlies their ability to run at high speeds over long distances, results from enhancements of the normal physiological mechanisms present in other mammals. We can see in these enhancements the results of natural selection, perhaps exerted by

A Figure 42.31 Measuring rate of O_2 consumption in a running pronghorn. Stan Lindstedt collects respiratory data from pronghorn running on a treadmill at 40 km/hr.

the predators that have chased pronghorns across the open plains of North America for millions of years.

Diving Mammals

The majority of animals can exchange gases continuously, but sometimes there is no access to the normal respiratory medium—for example, when an air-breather swims underwater. Whereas most humans, even well-trained divers, can hold their breath for 2 or 3 minutes and swim to depths of 20 m or so, the Weddell seal of Antarctica routinely plunges to 200–500 m and remains there for about 20 minutes (sometimes for more than an hour). Some species of seals, sea turtles and whales make even more impressive dives. Elephant seal can reach depths of 1,500 m—almost a mile—and stay submerged for as much as 2 hours! One elephant seal carrying a recording device spent 40 days at sea diving almost continuously, with no surface period longer than 6 minutes. In contrast, humans need to carry extra air—in the form of scuba tanks—to remain submerged for comparable periods.

One adaptation of the Weddell seal (and other diving mammals) is an ability to store large amounts of O_2 . Compared to humans, the seal can store about twice as much O_2 per kilogram of body mass, mostly in the blood and muscles. About 36% of our total O_2 is in our lungs, and 51% is in our blood. In contrast, the Weddell seal holds only about 5% of its oxygen in its relatively small lungs (and may exhale before diving, which reduces buoyancy), stockpiling 70% in the blood. The seal has about twice the volume of blood per kilogram of body mass as a human. Another adaptation is the seal's huge spleen, which can store about 24 L of blood. The spleen probably contracts after a dive begins, fortifying the blood with erythrocytes loaded with O_2 . Diving mammals also have a high concentration of an oxygen-storing protein called myoglobin in their muscles. The Weddell seal

cal store about 25% of its O₂ in muscle, compared to only 12% in humans.

Diving mammals not only begin an underwater trip with a relatively large O₂ stockpile, but also have adaptations that conserve O₂. They swim with little muscular effort and often use buoyancy changes to glide passively upward or downward. Their heart rate and O₂ consumption rate decrease during a dive, and regulatory mechanisms affecting peripheral resistance route most blood to the brain, spinal cord, eyes, adrenal glands, and placenta (in pregnant seals). Blood supply to the muscles is restricted and is shut off altogether during the longest dives. During dives of more than about 20 minutes, a Weddell seal's muscles deplete the O₂ stored in myoglobin and then derive their ATP from fermentation instead of respiration (see Chapter 9).

The unusual abilities of the Weddell seal and other air-breathing divers to power their bodies during long dives showcase two related themes in our study of organisms—the response to environmental challenges over the short term by

physiological adjustments and over the long term as a result of natural selection.

Concept Check 42.7

- What determines whether O₂ and CO₂ diffuse into or out of the capillaries in the tissues and near the alveolar spaces? Explain.
- How does the Bohr shift help deliver O₂ to very active tissues?
- Carbon dioxide within red blood cells in the tissue capillaries combines with water, forming carbonic acid. What causes the reverse of this reaction in red blood cells in capillaries near the alveolar spaces?
- Describe three adaptations that enable Weddell seals to stay underwater much longer than humans can.

For suggested answers, see Appendix A.

SUMMARY OR KEY CONCEPTS

Concept 42.1

Circulatory systems reflect phylogeny

► Transport systems functionally connect the organs of exchange with the body cells. Most complex animals have internal transport systems that circulate fluid, providing a lifeline between the aqueous environment of living cells and the organs, such as lungs, that exchange chemicals with the outside environment (pp. 867–868).

► **Invertebrate Circulation** (pp. 868–869) Most invertebrates have a gastrovascular cavity or a circulatory system for internal transport.

► **Survey of Vertebrate Circulation** (pp. 869–871)

Adaptations of the cardiovascular system reflect vertebrate phylogeny. Blood flows in a closed cardiovascular system consisting of blood vessels and a two- to four-chambered heart. Arteries convey blood to capillaries, the sites of chemical exchange between blood and interstitial fluid. Veins return blood from capillaries to the heart.

Concept 42.2

Double circulation in mammals depends on the anatomy and pumping cycle of the heart

► **Mammalian Circulation: The Pathway** (p. 872) Heart valves dictate a one-way flow of blood through the heart, beginning with the right ventricle pumping blood to the lungs, where it loads O₂ and unloads CO₂. Oxygen-rich blood from the lungs enters the heart at the left atrium and is pumped to the body

tissues by the left ventricle. Blood returns to the heart through the right atrium.

Activity Mammalian Cardiovascular System Structure

► **The Mammalian Heart: A Closer Look** (pp. 872–873) The heart rate (pulse) is the number of times the heart beats each minute. The cardiac cycle, one complete sequence of the heart's pumping and filling, consists of periods of contraction, called systole, and periods of relaxation, called diastole. The cardiac output is the volume of blood pumped into the systemic circulation per minute.

► **Maintaining the Heart's Rhythmic Beat** (pp. 873–874)

Impulses originating at the sinoatrial (SA) node (pacemaker) of the right atrium pass to the atrioventricular (AV) node. After a delay, they are conducted along the bundle branches and Purkinje fibers. The pacemaker is influenced by nerves, hormones, body temperature, and exercise.

Concept 42.3

Physical principles govern blood circulation

• **Blood Vessel Structure and Function** (pp. 874–875) Structural differences of arteries, veins, and capillaries correlate with their different functions.

• **Blood Flow Velocity** (pp. 875–876) Physical laws governing the movement of fluids through pipes influence blood flow and blood pressure. The velocity of blood flow varies in the circulatory system, being slowest in the capillary beds as a result of the high resistance and large total cross-sectional area of the arterioles and capillaries.

• **Blood Pressure** (pp. 876–877) Blood pressure, the hydrostatic force that blood exerts against the wall of a vessel, is determined by the cardiac output and peripheral resistance due to variable constriction of the arterioles.

- **Capillary Function** (pp. 877-879) Transfer of substances between the blood and the interstitial fluid occurs across the thin walls of capillaries.
- **Fluid Return by the Lymphatic System** (pp. 878-879) The lymphatic system returns fluid to the blood and aids in body defense. Fluid reenters the circulation directly at the venous end of the capillary and indirectly through the lymphatic system.
Activity Path of Blood Flow in Mammals
Biology Labs On-Line CardioLab
Activity Mammalian Cardiovascular System Function

Concept 42.4

Blood is a connective tissue with cells suspended in plasma

- **Blood Composition and Function** (pp. 879-882) Whole blood consists of cellular elements (cells and fragments of cells called platelets) suspended in a liquid matrix called plasma. Plasma proteins influence blood pH, osmotic pressure, and viscosity and function in lipid transport, immunity (antibodies), and blood clotting (fibrinogens). Red blood cells, or erythrocytes, transport oxygen. Five types of white blood cells, or leukocytes, function in defense by phagocytosing bacteria and debris or by producing antibodies. Platelets function in blood clotting, a cascade of complex reactions that converts plasma fibrinogen to fibrin.
- **Cardiovascular Disease** (pp. 882-883) Cardiovascular diseases are the leading cause of death in most developed nations, including the United States.
Investigation How Is Cardiovascular Fitness Measured?

Concept 42.5

Gas exchange occurs across specialized respiratory surfaces

- Gas exchange supplies oxygen for cellular respiration and disposes of carbon dioxide. Animals require large, moist respiratory surfaces for the adequate diffusion of respiratory gases (O_2 and CO_2) between their cells and the respiratory medium, either air or water (p. 884).
- **Gills in Aquatic Animals** (pp. 884-886) Gills, the respiratory adaptations of most aquatic animals, are outfoldings of the body surface specialized for gas exchange. The effectiveness of gas exchange in some gills, including those of fishes, is increased by ventilation and countercurrent flow of blood and water.
- **Tracheal Systems in Insects** (pp. 886-887) The tracheae of insects are tiny branching tubes that penetrate the body, bringing O_2 directly to cells.
- **Lungs** (pp. 886-888) Spiders, land snails, and most terrestrial vertebrates have internal lungs. In mammals, air inhaled through the nostrils passes through the pharynx into the trachea, bronchi, bronchioles, and dead-end alveoli, where gas exchange occurs.
Activity The Human Respiratory System

Concept 42.6

Breathing ventilates the lungs

- **How an Amphibian Breathes** (p. 888) An amphibian ventilates its lungs by positive pressure breathing, which forces air down the trachea.
- **How a Mammal Breathes** (pp. 888-889) Mammals ventilate their lungs by negative pressure breathing, which pulls air into the lungs. Lung volume increases as the rib muscles and diaphragm contract.

- **How a Bird Breathes** (pp. 889-890) Besides lungs, birds have eight or nine air sacs that act as bellows, keeping air flowing through the lungs. Air passes through the lungs in one direction only. Every exhalation completely renews the air in the lungs.
- **Control of Breathing in Humans** (p. 890) Control centers in the medulla oblongata of the brain regulate the rate and depth of breathing. Sensors detect the pH of cerebrospinal fluid (reflecting CO_2 concentration in the blood), and the medulla adjusts breathing rate and depth to match metabolic demands. Secondary control over breathing is exerted by sensors in the aorta and carotid arteries that monitor blood levels of O_2 and CO_2 and blood pH.

Concept 42.7

Respiratory pigments bind and transport gases

- **The Role of Partial Pressure Gradients** (p. 891) Gases diffuse down pressure gradients in the lungs and other organs. Oxygen and CO_2 diffuse from where their partial pressures are higher to where they are lower.
- **Respiratory Pigments** (pp. 892-894) Respiratory pigments transport gases and help buffer the blood. Respiratory pigments greatly increase the amount of O_2 that blood can carry. Many arthropods and molluscs have copper-containing hemocyanin; vertebrates and a wide variety of invertebrates have hemoglobin.
Activity Transport of Respiratory Gases
Biology Labs On-Line HemoglobinLab
- **Elite Animal Athletes** (pp. 894-895) The pronghorn's extreme O_2 consumption rate underlies its ability to run at high speeds over long distances. Deep-diving air-breathers stockpile O_2 and deplete it slowly

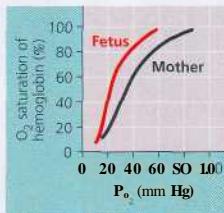

TESTING YOUR KNOWLEDGE

Evolution Connection

One of the many mutant opponents that the movie monster Godzilla contends with is Mothra, a giant mothlike creature with a wingspan of several dozen feet. Science fiction creatures like these can be critiqued on the grounds of biomechanical and physiological principles. Focusing on respiration and the principles of gas exchange you learned about in this chapter, what physiological problems would Mothra face? The largest insects that have ever lived are Paleozoic dragonflies with half-meter wingspans. Why do you think truly giant insects are improbable?

Scientific Inquiry

The hemoglobin of a human fetus differs from adult hemoglobin. Compare the dissociation curves of the two hemoglobins in the graph below. Propose a hypothesis for the junction of this difference between these two versions of hemoglobin.

The Immune System

A Figure 43.1 A macrophage (blue) ingesting a yeast cell (green).

Key Concepts

- 43.1 Innate immunity provides broad defenses against infection
- 43.2 In acquired immunity, lymphocytes provide specific defenses against infection
- 43.3 Humoral and cell-mediated immunity defend against different types of threats
- 43.4 The immune system's ability to distinguish self from nonself limits tissue transplantation
- 43.5 Exaggerated, self-directed, or diminished immune responses can cause disease

Overview

Reconnaissance, Recognition, and Response

Animal must defend itself against the many potentially dangerous viruses, bacteria, and other pathogens it encounters in the air, in food, and in water. It must also contend with abnormal body cells that may develop into cancer. Two major kinds of defense have evolved that counter these threats. The first, called innate immunity, is present before any exposure to pathogens and is effective from the time of birth. Innate defenses are largely nonspecific, quickly recognizing and responding to a broad range of microbes regardless of their precise identity. Innate immunity consists of external barriers formed by the skin and mucous membranes, plus a set of internal cellular and chemical defenses that combat infectious agents that breach the external barriers. Key players in these internal defenses are macrophages and other phagocytic cells, which ingest

and then destroy pathogens. For example, **Figure 43.1** (colorized SEM) shows a macrophage engulfing a yeast cell.

The second major kind of defense is acquired immunity also called *adaptive immunity*. It develops only after exposure to inducing agents such as microbes, abnormal body cells, toxins, or other foreign substances. Acquired defenses are highly specific—that is, they can distinguish one inducing agent from another, even those that differ only slightly. This recognition is achieved by white blood cells called lymphocytes, which produce two general types of immune responses. In the humoral response, cells derived from B lymphocytes secrete defensive proteins called antibodies that bind to microbes and mark them for elimination. In the cell-mediated response, cytotoxic lymphocytes directly destroy infected body cells, cancer cells, or foreign tissue.

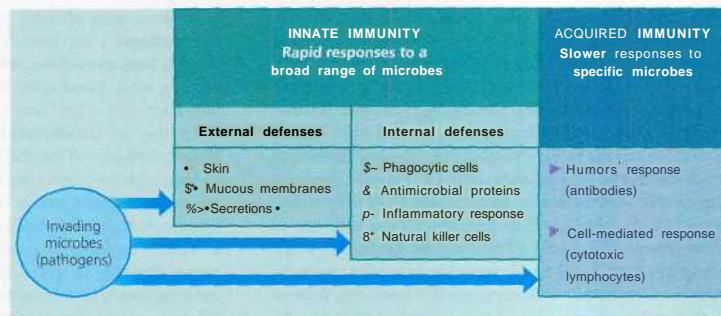

Figure 43.2 summarizes innate and acquired immunity. In this chapter, you will learn how the various cellular and chemical components of these two kinds of defense together protect vertebrates from various threats. Later in the chapter, we will also look briefly at immunity in invertebrates, which are protected solely by innate, nonspecific mechanisms.

Concept 43.1

Innate immunity provides broad defenses against infection

An invading microbe must penetrate the external barriers formed by an animal's skin and mucous membranes, which cover the surface and line the openings of the body. A pathogen that successfully breaks through these external defenses soon encounters several innate cellular and chemical mechanisms that impede its attack on the body.

Figure 43.2 Overview of vertebrate defenses against bacteria, viruses, and other pathogens. Defenses in vertebrates can be divided into innate and acquired immunity. If an invading pathogen breaches the body's external innate defenses, various internal innate defenses quickly come into play. The defenses provided by acquired immunity against specific pathogens develop more slowly. Some components of innate immunity also function in acquired immunity.

External Defenses

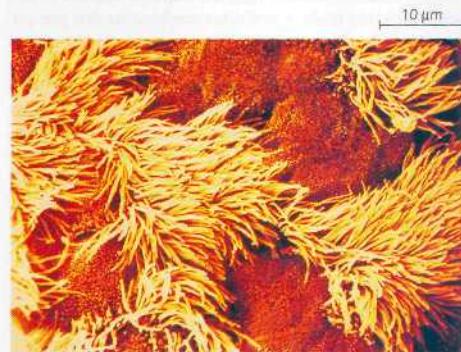

Intact skin is a barrier that cannot normally be penetrated by viruses or bacteria, but even tiny abrasions may allow their passage. Likewise, the mucous membranes lining the digestive, respiratory, and genitourinary tracts bar the entry of potentially harmful microbes. Certain cells of these mucous membranes also produce mucus, a viscous fluid that traps microbes and other particles. In the trachea, for example, ciliated epithelial cells sweep mucus and any entrapped microbes upward, preventing the microbes from entering the lungs (Figure 43.3). Microbial colonization of the body is also inhibited by the washing action of the mucous secretions, saliva, and tears that constantly bathe the surfaces of various exposed epithelia.

Beyond their physical role in inhibiting microbe entry, secretions of the skin and mucous membranes provide an environment that is often hostile to microbes. In humans, secretions from sebaceous (oil) glands and sweat glands give the skin a pH ranging from 3 to 5, which is acidic enough to prevent colonization by many microbes. (Bacteria that normally inhabit the skin are adapted to its acidic, relatively dry environment.) Similarly, microbes in food or water and those in swallowed mucus must contend with the acidic environment of the stomach, which destroys most pathogens before they can enter the intestines. But some pathogens, such as the hepatitis A virus, can survive gastric acidity and successfully enter the body via the digestive tract.

Secretions from the skin and mucous membranes also contain antimicrobial proteins. One such protein is lysozyme, an enzyme that digests the cell walls of many bacteria. Present in saliva, tears, and mucous secretions, lysozyme can destroy susceptible bacteria as they enter the upper respiratory tract or the openings around the eyes.

Internal Cellular and Chemical Defenses

Microbes that penetrate the body's external defenses, such as those that enter through a break in the skin, must contend

A Figure 43.3 External innate defense by mucous membranes. The lining of the trachea contains mucus-producing cells (orange) and cells with cilia (yellow). Synchronized beating of the cilia expels mucus and trapped microbes upward into the pharynx (colorized SEM).

with the body's internal mechanisms of innate defense. These defenses depend mainly on phagocytosis, the ingestion of invading microorganisms by certain types of white blood cells generically referred to as *phagocytes*. These cells produce certain antimicrobial proteins and help initiate inflammation, which can limit the spread of microbes in the body. Non-phagocytic white blood cells called natural killer cells also play a key role in innate defenses. The various nonspecific mechanisms help limit the spread of microbes before the body can mount acquired, specific immune responses.

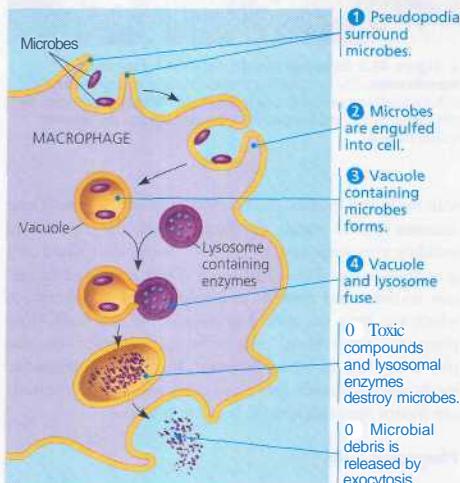

Phagocytic Cells

Phagocytes attach to their prey via surface receptors that bind to structures found on many microorganisms but not on normal body cells. Among the structures bound by these receptors are certain polysaccharides on the surface of bacteria.

After attaching to one or more microbes, a phagocyte engulfs the microbes, forming a vacuole that fuses with a lysosome (Figure 43.4). Microbes are destroyed by lysosomes in two ways. First, nitric oxide and other toxic forms of oxygen contained in the lysosomes may poison the engulfed microbes. Second, lysozyme and other enzymes degrade microbial components.

Some microorganisms have adaptations that enable them to evade destruction by phagocytic cells. For example, the outer capsule that surrounds some bacterial cells hides their surface polysaccharides and prevents phagocytes from attaching to them. Other bacteria, such as *Mycobacterium tuberculosis*, which causes tuberculosis, are readily bound and engulfed by phagocytes but are resistant to destruction within lysosomes. Because such microbes can grow and reproduce within their host's cells, they are effectively hidden from the acquired defenses of the body. Evolution of these and other mechanisms that prevent destruction by the immune system has increased the pathogenic threat of many microbes.

Four types of white blood cells (leukocytes) are phagocytic. They differ in their abundance, average life span, and phagocytic ability. By far the most abundant are neutrophils, which constitute about 60–70% of all white blood cells. Neutrophils are attracted to and then enter infected tissue, engulfing and destroying the microbes there. However, neutrophils tend to self-destruct in the process of phagocytosis, and their average life span is only a few days.

A Figure 43.4 Phagocytosis. This schematic depicts events following attachment of one kind of phagocyte, a macrophage, to microbes via its surface receptors (not shown). The process is similar in other types of phagocytic cells.

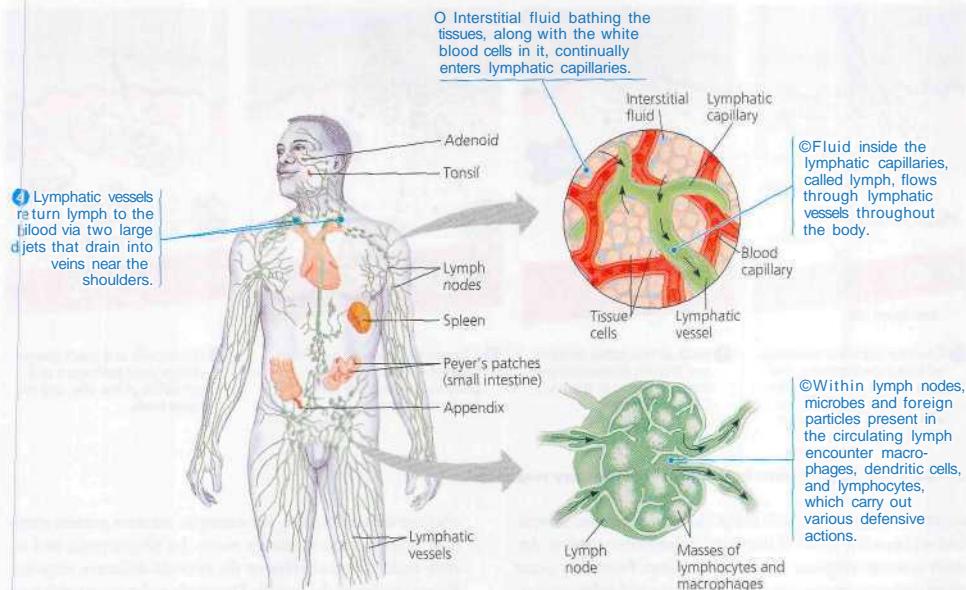

An even more effective phagocytic defense comes from macrophages ("big eaters"). These large, long-lived cells develop from monocytes, which constitute about 5% of circulating white blood cells. New monocytes circulate in the blood for only a few hours and then migrate into tissues where they are transformed into macrophages. Carrying out phagocytosis sets off internal signaling pathways that activate the macrophages, increasing their defensive abilities in various ways (described later in this chapter). Some macrophages migrate throughout the body, while others reside permanently in various organs and tissues. Macrophages that are permanent residents in the spleen, lymph nodes, and other tissues of the lymphatic system are particularly well positioned to combat infectious agents. Microbes that enter the blood become trapped in the netlike architecture of the spleen, whereas microbes in interstitial fluid flow into lymph and are trapped in lymph nodes. In either location microbes soon encounter resident macrophages. Figure 43.5 shows the components of the lymphatic system and summarizes its role in the body's defenses.

The other two types of phagocytes are less abundant and play a more limited role in innate defense than neutrophils and macrophages. Eosinophils have low phagocytic activity but are critical to defense against multicellular parasitic invaders, such as the blood fluke *Schistosoma mansoni*. Rather than engulfing such a parasite, eosinophils position themselves against the parasites body and then discharge destructive enzymes that damage the invader. The fourth type of phagocyte, dendritic cells, can ingest microbes like macrophages do. However, as you will learn later in the chapter, their primary role is to stimulate the development of acquired immunity.

Antimicrobial Proteins

Numerous proteins function in innate defense by attacking microbes directly or by impeding their reproduction. You have already learned about the antimicrobial action of lysozyme. Other antimicrobial proteins include about 30 serum proteins that make up the complement system. In the absence of infection, these proteins are inactive. Substances on the surface of many microbes, however, can trigger a cascade of steps that activate the complement system, leading to lysis (bursting) of invading cells. Certain complement proteins also help trigger inflammation or play a role in acquired defense.

Two types of interferon (α and β) provide innate defense against viral infections. These proteins are secreted by virus-infected body cells and induce neighboring uninfected cells to produce other substances that inhibit viral reproduction. In this way, interferons limit the cell-to-cell spread of viruses in the body, helping control viral infections such as colds and influenza. This innate defense mechanism is not virus-specific; interferons produced in response to one virus may also confer short-term resistance to unrelated viruses. Certain lymphocytes secrete a third type of interferon (γ) that helps activate

A Figure 43.5 The human lymphatic system. The lymphatic system consists of lymphatic vessels, through which lymph travels, and various structures that trap “foreign” molecules and particles. These structures include the adenoids, tonsils, lymph nodes, spleen, Peyer’s patches, and appendix. The flow of lymph is traced in steps 1–4.

macrophages, enhancing their phagocytic ability. Interferons can now be mass-produced by recombinant DNA technology and are being tested for the treatment of viral infections and cancer.

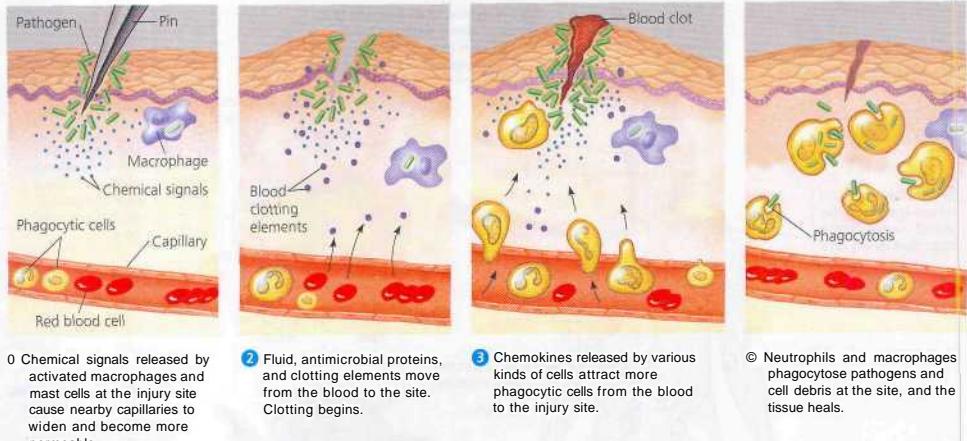

Yet another group of antimicrobial proteins, fittingly named *defensins*, are secreted by activated macrophages. These small proteins damage broad groups of pathogens by various mechanisms without harming body cells.

Inflammatory Response

Damage to tissue by physical injury or the entry of pathogens leads to release of numerous chemical signals that trigger a localized **inflammatory response**. One of the most active chemicals is **histamine**, which is stored in **mast cells** found in connective tissues. When injured, mast cells release their histamine, triggering dilation and increased permeability of nearby capillaries. Activated macrophages and other cells discharge additional signals, such as prostaglandins, that further promote blood flow to the injured site. The resulting increased local blood supply causes the redness and heat typical of inflammation (from the Latin *inflammare*, to set on fire). The blood-engorged capillaries leak fluid into neighboring tissues, causing swelling, another sign of local inflammation.

Although heat and swelling are uncomfortable sensations, the enhanced blood flow and vessel permeability that cause them are critical to innate defense. These vascular changes help deliver antimicrobial proteins and clotting elements to the injured area. Several activated complement proteins, for example, promote the release of histamine or attract phagocytes to the site. Blood clotting begins the repair process and helps block the spread of microbes to other parts of the body. In addition, increased local blood flow and vessel permeability allow more neutrophils and monocyte-macrophages to move from the blood into injured tissues. Small proteins called **chemokines** direct the migration of these phagocytes and signal them to increase production of microbe-killing compounds. Chemokines are secreted by many cell types, including blood vessel endothelial cells, near a site of injury or infection. **Figure 43G**, on the next page, summarizes the major events in local inflammation resulting from an infected pinprick.

A minor injury causes local inflammation, but the body may also mount a systemic (widespread) response to severe tissue damage or infection. Injured cells often put out a call for reinforcements, secreting chemicals that stimulate the release of additional neutrophils from the bone marrow. In a severe infection, such as meningitis or appendicitis, the

A Figure 43.6 Major events in the local inflammatory response.

number of white blood cells in the blood may increase several-fold within a few hours of the initial inflammatory events. Another systemic response to infection is fever. Fever may occur when certain toxins produced by pathogens and substances released by activated macrophages set the body's thermostat at a higher temperature. A very high fever is dangerous, but moderate fever may facilitate phagocytosis and, by speeding up body reactions, hasten the repair of tissues.

Certain bacterial infections can induce an overwhelming systemic inflammatory response, leading to a condition known as *septic shock*. Characterized by very high fever and low blood pressure, septic shock is a common cause of death in hospital critical care units. Clearly, local inflammation is essential for healing, but systemic inflammation can be devastating.

Natural Killer Cells

We wrap up our discussion of vertebrate innate defenses with natural killer (NK) cells. NK cells patrol the body and attack virus-infected body cells and cancer cells. Surface receptors on an NK cell recognize general features on the surface of its targets. Once it is attached to a virus-infected cell or cancer cell, the NK cell releases chemicals that lead to the death of the stricken cell by apoptosis, or programmed cell death (see Figure 21.18). Although the defense provided by NK cells is not 100% effective, viral infections and cancer would occur much more often without these innate sentinels of the body.

Invertebrate Immune Mechanisms

Before we move on to examine acquired immunity in vertebrates, we should note that invertebrates also have highly

effective innate defenses. For example, sea stars possess amoeboid cells that ingest foreign matter by phagocytosis and secrete molecules that enhance the animal's defensive response. Recent studies of the fruit fly *Drosophila melanogaster* also have revealed striking parallels between insect defenses and vertebrate innate defenses. The exoskeleton of insects, like the skin and mucous membranes of vertebrates, provides an external barrier that can prevent entry of intruders. If an insect's exoskeleton is damaged, pathogens that enter the insect's body must face several internal innate defenses.

The insect equivalent to blood, the hemolymph, contains circulating cells called *hemocytes*. Some hemocytes ingest bacteria and other foreign substances by phagocytosis, while other hemocytes form a cellular capsule around large parasites. The presence of pathogens signals still other hemocytes to make and secrete various antimicrobial peptides that bind to their pathogen targets, leading to death of the pathogens. The internal signaling pathways that trigger hemocytes to produce antimicrobial peptides are comparable to those that activate vertebrate macrophages. In addition, certain hemocytes contain the enzyme phenoloxidase. Once activated, this enzyme converts phenols to reactive compounds that link together into large aggregates. These are deposited around parasites and wounded tissue, helping to prevent the spread of parasites beyond the affected area. Activation of phenoloxidase in insects occurs by a cascade of steps similar to those that activate vertebrate complement proteins.

Recent research indicates that invertebrates lack cells analogous to lymphocytes, the white blood cells responsible for acquired, specific immunity in vertebrates (see Figure 43.2). But even though they depend on innate, nonspecific mechanisms,

certain invertebrate defenses do exhibit some features characteristic of acquired immunity. For instance, acquired immunity usually is directed against nonself cells, not normal body (self) cells. The ability to distinguish self from nonself is seen in the most ancient invertebrate lineage, the sponges. If cells from two sponges of the same species are mixed, the cells from each sponge sort themselves and reaggregate, excluding cells from the other individual.

Another hallmark of acquired immunity is immunological memory—the ability to respond more quickly to a particular invader or foreign tissue the second time it is encountered. Earthworms exhibit something like this: Phagocytic cells in a worm attack a second graft from the same donor worm much more rapidly than the first graft. Most invertebrates, however, exhibit no such immunological memory.

Following this glimpse at invertebrate host defenses, we begin in the next section to examine the highly developed mechanisms of acquired immunity found in vertebrates.

Concept Check 43.1

1. Innate defenses are nonspecific. How, then, do macrophages recognize an infectious agent, such as a bacterium?
2. What causes the common signs of inflammation—redness, swelling, and heat—and how do these changes help protect the body against infection?
3. State two ways in which the innate defenses of insects (invertebrates) and vertebrates are similar.

For suggested answers, see Appendix A.

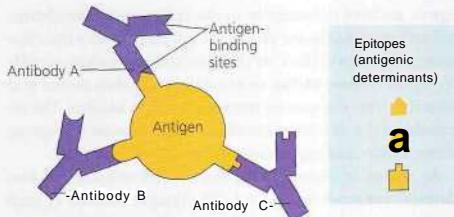

Figure 43.7 Epitopes (antigenic determinants). Only small, specific regions on antigens, called epitopes, are bound by the antigen receptors on lymphocytes and by secreted antibodies. In this example, three different secreted antibody molecules react with different epitopes on the same large antigen molecule.

polysaccharides. Some antigens, such as toxins secreted by bacteria, are dissolved in extracellular fluid, but many protrude from the surface of pathogens or transplanted cells. A lymphocyte actually recognizes and binds to just a small, accessible portion of an antigen, called an **epitope** or **antigenic determinant**. A single antigen usually has several different epitopes, each capable of inducing a response from lymphocytes that recognize that epitope. Antibodies, which are secreted by certain lymphocytes in response to antigens, likewise bind to specific epitopes (**Figure 43.7**).

In this section, we first describe how **lymphocytes** recognize antigens, or more specifically the epitopes on antigens. We then trace how the vertebrate body becomes populated with a large set of lymphocytes that collectively can recognize and mount a pinpoint attack against any one of a multitude of antigens. Later in the chapter we will examine the various defensive actions of the different types of lymphocytes.

Antigen Recognition by Lymphocytes

The vertebrate body is populated by two main types of lymphocytes: **B lymphocytes (B cells)** and **T lymphocytes (T cells)**. Both types of lymphocytes circulate through the blood and lymph and are concentrated in the spleen, lymph nodes, and other lymphoid tissues (see Figure 43.5). B cells and T cells recognize antigens by means of antigen-specific receptors embedded in their plasma membranes. A single B or T cell bears about 100,000 of these **antigen receptors**, and all the receptors on a single cell are identical—that is, they all recognize the same epitope. In other words, each lymphocyte displays **specificity** for a particular epitope on an antigen and defends against that antigen or a small set of closely related antigens.

B Cell Receptors for Antigens

Each **B cell receptor** for an antigen is a Y-shaped molecule consisting of four polypeptide chains: two identical **heavy chains** and two identical **light chains** linked by disulfide bridges. A region in the tail portion of the molecule, the transmembrane

Concept 43.2

In acquired immunity, lymphocytes provide specific defenses against infection

While invading pathogens are under assault by a vertebrate's innate defenses, the intruders inevitably come into contact with lymphocytes, the key cells of acquired immunity—the body's second major kind of defense (see Figure 43.2). Direct contact with microbes and signals from active innate defenses cause lymphocytes to join the fight. For example, as macrophages and dendritic cells phagocytose microbes, the phagocytes begin to secrete **cytokines**, proteins that help activate lymphocytes and other cells of the immune system. This is just one example of how innate and acquired defenses interact.

Any foreign molecule that is specifically recognized by lymphocytes and elicits a response from them is called an **antigen**. Most antigens are large molecules, either proteins or

region, anchors the receptor in the cell's plasma membrane, and a short region at the end of the tail extends into the cytoplasm. At the tips of the Y are the light- and heavy-chain *variable* (V) regions (**Figure 43.8a**), so named because their amino acid sequences vary extensively from one B cell to another. The remainder of the molecule is made up of the *constant* (C) regions, whose amino acid sequences vary little from cell to cell.

As shown in Figure 43.8a, each B cell receptor has two identical antigen-binding sites. The unique contour of each binding site is formed from part of a heavy-chain V region and part of a light-chain V region. The interaction between an antigen-binding site and its corresponding antigen is stabilized by multiple noncovalent bonds between chemical groups on the respective molecules. The antigens bound by B cell receptors in this way include molecules that are on the surface of, or are released from, all types of infectious agents. In other words, a B cell recognizes an intact antigen in its native state.

Secreted antibodies, or immunoglobulins, are structurally similar to B cell receptors, but they lack the transmembrane regions that anchor receptors in the plasma membrane. Because of this structural similarity, B cell receptors are often called *membrane antibodies* or *membrane immunoglobulins*.

T Cell Receptors for Antigens and the Role of the MHC

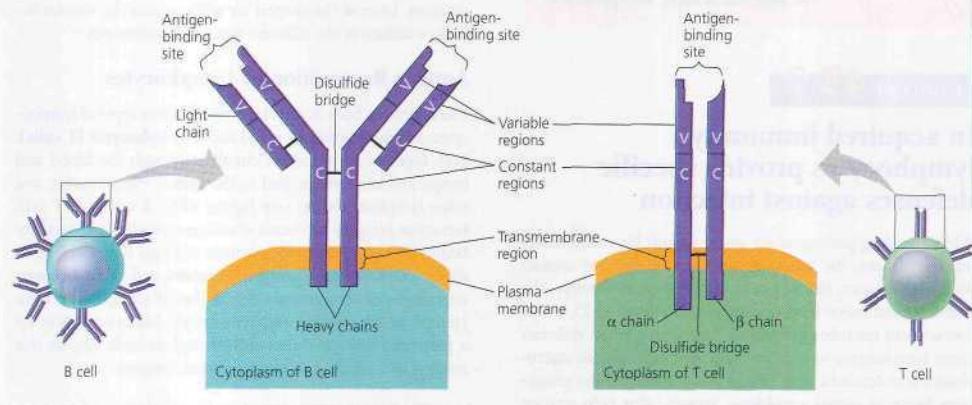

Each T cell receptor for an antigen consists of two different polypeptide chains, an *α chain* and a *β chain*, linked by a disulfide bridge (**Figure 43.8b**). Near the base of the molecule is a transmembrane region that anchors the molecule in the

cell's plasma membrane. At the outer tip of the molecule, the α and β chain variable (V) regions form a single antigen-binding site. The remainder of the molecule is made up of the constant (C) regions.

T cell receptors recognize and bind with antigens just as specifically as B cell receptors. However, while the receptors on B cells recognize intact antigens, the receptors on T cells recognize small fragments of antigens that are bound to normal cell-surface proteins called MHC molecules. MHC molecules are so named because they are encoded by a family of genes called the major histocompatibility complex (MHC). As a newly synthesized MHC molecule is transported toward the plasma membrane, it binds with a fragment of protein (peptide) antigen *within* the cell and brings it to the cell surface, a process called antigen presentation. A nearby T cell can detect the antigen fragment thus displayed on the cell's surface (**Figure 43.9**).

There are two ways in which foreign antigens can end up inside cells of the body. Depending on their source, these peptide antigens are handled by a different class of MHC molecule and recognized by a particular subgroup of T cells:

- Class I MHC molecules, found on almost all nucleated cells of the body, bind peptides derived from foreign antigens that have been synthesized within the cell. Any body cell that becomes infected or cancerous can display such peptide antigens by virtue of its class I MHC molecules. Class I MHC molecules displaying bound peptide antigens are recognized by a subgroup of T cells called *cytotoxic T cells* (see Figure 43.9a).

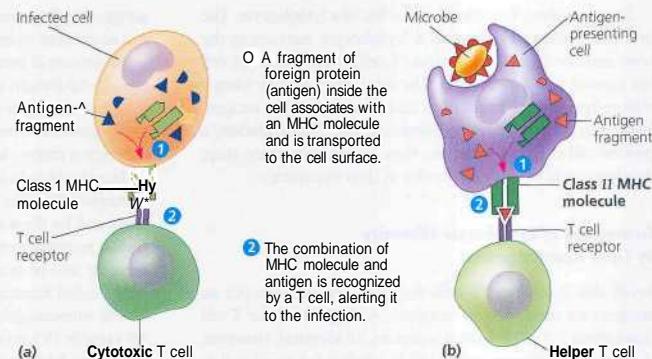

(a) A B cell receptor consists of two identical heavy chains and two identical light chains linked by several disulfide bridges.

(b) A T cell receptor consists of one α chain and one β chain linked by a disulfide bridge.

A Figure 43.8 Antigen receptors on lymphocytes. All the antigen receptors on a particular B cell or T cell bind the same antigen. The variable (V) regions vary extensively from cell to cell, accounting for the different binding specificities of individual lymphocytes; the constant (C) regions vary little or not at all.

> Figure 43.9 The interaction of T cells with MHC molecules. Class I and class II MHC molecules display peptide fragments of antigens to (a) cytotoxic T cells and (b) helper T cells, respectively. In each case, the T cell receptor binds with an MHC molecule-peptide antigen complex. Class I MHC molecules are made by most nucleated cells, whereas class II MHC molecules are made primarily by antigen-presenting cells (macrophages, dendritic cells, and B cells).

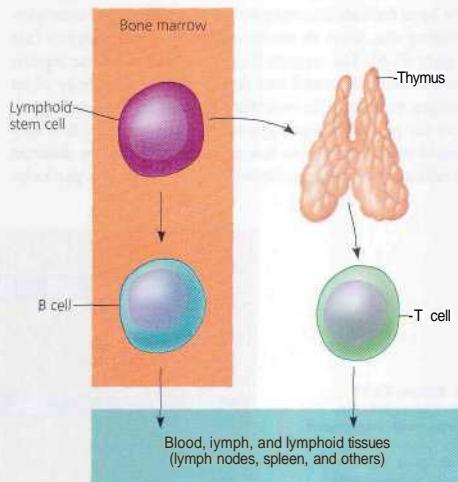

- **Class II MHC molecules** are made by just a few cell types, mainly dendritic cells, macrophages, and B cells, in these cells, class II MHC molecules bind peptides derived from foreign materials that have been internalized and fragmented through phagocytosis or endocytosis. Dendritic cells, macrophages, and B cells are known as **antigen-presenting cells** because of their key role in displaying such internalized antigens to another subgroup of T cells called helper T cells (see Figure 43.9b).

Each vertebrate species possesses numerous different alleles for each class I and class II MHC gene; MHC proteins are the most polymorphic known. Because of the large number of different MHC alleles in the human population, most of us are heterozygous for every one of our MHC genes and produce a broad array of MHC molecules. Collectively these molecules are capable of binding to and presenting a large number of peptide antigens. Moreover, any two people, except identical twins, are very unlikely to have exactly the same set of MHC molecules. Thus the MHC provides a biochemical fingerprint, unique to virtually every individual, that marks body cells as "self." In fact, the discovery of the MHC occurred in the process of studying the phenomena of skin graft rejection and acceptance.

Lymphocyte Development

Now that you have read how lymphocytes recognize antigens, let's examine how these cells develop and populate the vertebrate body. Like all blood cells, lymphocytes originate from pluripotent stem cells in the bone marrow (see Chapter 42). Newly formed lymphocytes are all alike, but they later develop into either T cells or B cells, depending on where they continue their maturation (Figure 43.10). Lymphocytes that migrate from the bone marrow to the **thymus**, a gland in the thoracic cavity above the heart, develop into T cells ("T" for thymus).

A Figure 43.10 Overview of lymphocyte development. Lymphocytes arise from stem cells in the bone marrow and differentiate without any contact with antigens. B cells develop entirely in the bone marrow, whereas T cells complete their development in the thymus. Mature lymphocytes, each specific for a particular epitope, circulate in the blood and lymph to various lymphoid tissues, where they encounter antigens.

Lymphocytes that remain in the bone marrow and complete their maturation there become B cells. (The "B" actually stands for the bursa of Fabricius, an organ unique to birds where avian B cells mature and the site where B cells were first discovered. But you can think of "B" as standing for bone marrow, since that is where B cells mature in other vertebrates.)

There are three key events in the life of a lymphocyte. The first two events take place as a lymphocyte matures in the bone marrow (B cell) or thymus (T cell), well before the cell has contact with any antigen. The third event occurs when a mature lymphocyte encounters and binds a specific antigen, leading to its activation, proliferation, and differentiation, a process called clonal selection. Here we describe these three developmental events in the order of their occurrence.

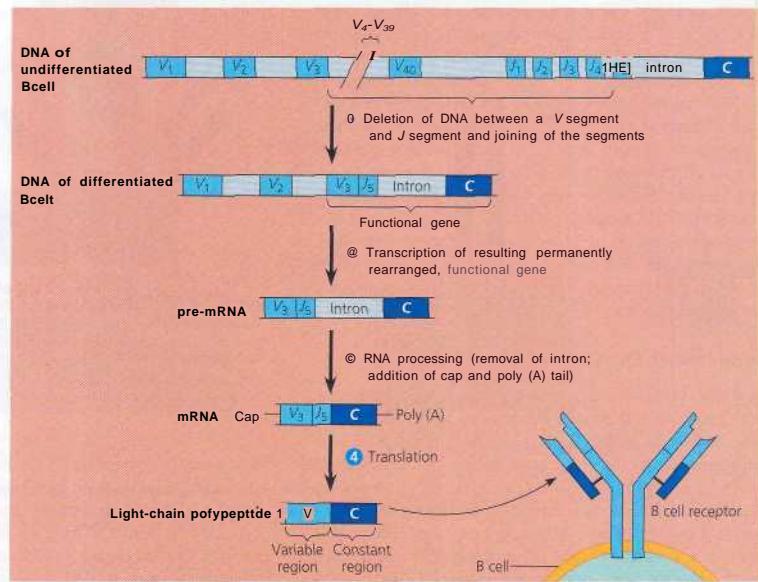

Generation of Lymphocyte Diversity by Gene Rearrangement

Recall that B cells and T cells recognize specific epitopes on antigens via their antigen receptors. A single B cell or T cell bears about 100,000 of these receptors, all identical. However, if we were to compare one B cell to another (or one T cell to another), the chances that both would have the same B cell receptor (or T cell receptor) are very slim. The variable regions at the tip of each antigen receptor chain, which form the antigen-binding site, account for the diversity of lymphocytes (see Figure 43-8). The sequence of amino acids in these regions varies from cell to cell and determines the specificity of an antigen receptor. The variability of these regions, and therefore the possible antigen specificities, is enormous. It is estimated that each person has as many as 1 million different B cells and 10 million different T cells, each with a particular

antigen-binding specificity. Thus, our repertoire of lymphocytes can respond to an enormous number of different antigens.

At the core of lymphocyte diversity are the unique genes that encode the antigen receptor chains. These genes consist of numerous coding *gene segments* that undergo random, permanent rearrangement, forming functional genes that can be expressed as receptor chains. In this discussion we will focus on the gene coding for the light chain of the B cell receptor (membrane immunoglobulin), but keep in mind that the genes for the heavy chain and for the α and β chains of the T cell receptor undergo similar rearrangements. The light and heavy chains of the B cell receptor and of secreted antibody are encoded by the same genes, called immunoglobulin (Ig) genes.

The immunoglobulin light-chain gene contains a series of 40 variable (*V*) gene segments separated by a long stretch of DNA from 5 joining (*J*) gene segments (Figure 43.11). Beyond the *J* gene segments is an intron, followed by a single exon designated *C* because it codes for the constant region of the light chain (see Figure 17.10 to review introns and exons). In this state, the light-chain gene is not functional. However, early in B cell development, a set of enzymes collectively called recombinase links one *V* gene segment to one *J* gene segment, eliminating the long stretch of DNA between them and forming a single exon that is part *V* and part *J*. Recombinase acts randomly; that is, it can link any one of the 40 *V*ⁿ gene segments to any one of the 5 *J* gene segments. So,

• **Figure 43.11**
Immunoglobulin gene rearrangement.

The random joining of *V* and *J* gene segments (*V₃* and *J₅* in this example) results in a functional gene that encodes the light-chain polypeptide of a B cell receptor. In a cell that produces secreted antibody, the same pre-mRNA is formed, but alternative processing yields an mRNA that lacks coding sequences for the transmembrane region that anchors receptors in the membrane. Gene rearrangement plays a major role in generating a diverse repertoire of lymphocytes and secreted antibodies.

for the light-chain gene, there are 200 possible gene products (40 V X 5 J). In any one cell, however, only one of the 200 possible light chains is made.

Once V-J rearrangement has occurred, the gene can be transcribed. The resulting pre-mRNA is processed, forming mRNA that is translated into a light chain containing a variable region and a constant region. The light chains produced in this way combine randomly with the heavy chains that are similarly produced, forming the B cell's antigen receptors (see Figure 43.11).

Testing and Removal of Self-Reactive Lymphocytes

Because the rearrangements of antigen receptor genes are random, a developing lymphocyte may end up with antigen receptors that are specific for some of the body's own molecules. As B cells and T cells are maturing in the bone marrow and thymus, respectively, their antigen receptors are tested for potential self-reactivity. For example, the receptors of maturing T cells are tested against class I and class II MHC molecules, which are both expressed at high levels in the thymus.

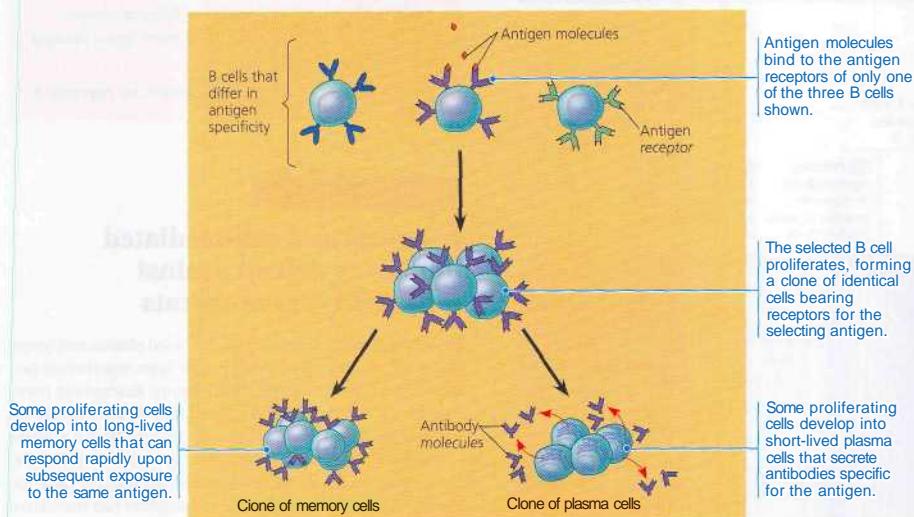

For the most part, lymphocytes bearing receptors specific for molecules already present in the body are either destroyed by apoptosis or rendered nonfunctional, leaving only lymphocytes that react to foreign (nonself) molecules. This capacity to distinguish self from nonself continues to develop even

as the cells migrate to lymphoid organs. Thus, the body normally has no mature lymphocytes that react against self components: The immune system exhibits the critical feature of *self-tolerance*. Failure of self-tolerance can lead to autoimmune diseases such as multiple sclerosis, as you will read later.

Clonal Selection of Lymphocytes

A soluble antigen or an antigen present on the surface of a microbe, infected body cell or cancer cell encounters a large repertoire of B cells and T cells in the body. However, a given antigen interacts only with the relatively few lymphocytes bearing receptors specific for epitopes on that antigen. The selection of a B cell or T cell by an antigen activates the lymphocyte, stimulating it to divide many times and to differentiate, forming two clones of daughter cells. One clone consists of a large number of short-lived effector cells that combat the same antigen. The nature and function of the effector cells depend on whether the lymphocyte selected is a helper T cell, a cytotoxic T cell, or a B cell. The other clone consists of memory cells, long-lived cells bearing receptors specific for the same inducing antigen.

This antigen-driven cloning of lymphocytes is called clonal selection (Figure 43.12). The concept of clonal selection is so fundamental to understanding acquired immunity that it is worth restating: Each antigen, by binding to specific receptors,

A Figure 43.12 Clonal selection of B cells. A B cell is selected by an antigen to proliferate and differentiate into memory B cells and antibody-secreting plasma cells. All the B cells whose receptors have a different specificity (indicated by different shapes and colors) do not respond to this antigen. T lymphocytes undergo a similar process, generating memory T cells and effector T cells.

selectively activates a tiny fraction of cells from the body's diverse pool of lymphocytes; this relatively small number of selected cells gives rise to clones of thousands of cells, all specific for and dedicated to eliminating that antigen.

The selective proliferation and differentiation of lymphocytes that occurs the first time the body is exposed to a particular antigen represents the primary immune response. In the primary response, the maximum effector response does not occur until about 10 to 17 days after the initial exposure to the antigen. During this time, selected B cells generate antibody-secreting effector B cells, called plasma cells, and selected T cells are activated to their effector forms, which have distinct functions (discussed in the next section). While these effector cells are developing, a stricken individual may become ill. Eventually, symptoms of illness diminish and disappear as antibodies and effector T cells clear the antigen from the body. If an individual is exposed again to the same antigen, the response is faster (typically only 2 to 7 days), of greater magnitude, and more prolonged. This is the secondary immune response. Measures of antibody concentrations in the blood serum over time show clearly the difference between primary and secondary immune responses (**Figure 43.13**). In addition to being more numerous, antibodies produced in the secondary response tend to have greater affinity for the antigen than those secreted in the primary response.

The immune system's capacity to generate secondary immune responses, called *immunological memory*, depends on the

clones of long-lived T and B memory cells generated following initial exposure to an antigen. These memory cells are poised to proliferate and differentiate rapidly when they later contact the same antigen. The long-term protection developed after exposure to a pathogen was recognized 2,400 years ago by Thucydides of Athens, who described how those sick and dying of plague were cared for by others who had recovered, "for no one was ever attacked a second time."

Concept Check 43.2

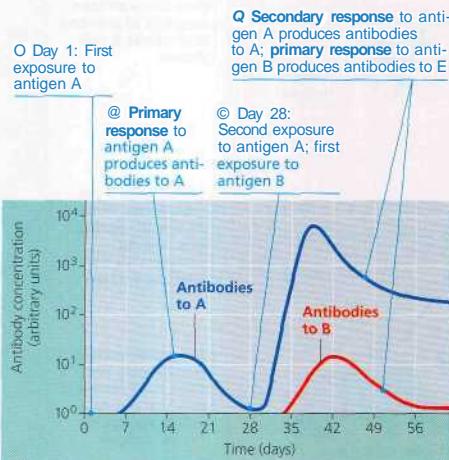

- Draw a B cell receptor, and label the following: light chains, heavy chains, disulfide bridges, variable (V) regions, constant (C) regions, antigen-binding sites, transmembrane region, and cytoplasmic tails. How does the structure of a secreted antibody differ?
- What is the major difference in the types of antigens bound by B cell receptors and T cell receptors?
- Consider the process of clonal selection of B cells shown in Figure 43.12. How does this process demonstrate both the specificity and memory of acquired immunity?
- A light-chain immunoglobulin gene consists of 40 V gene segments and 5 J gene segments, and a heavy-chain gene consists of 51 V gene segments, 6 J gene segments, and another set of gene segments D, of which there are 27. How many different antigen-binding specificities can be generated, given random V-J and V-D-J rearrangements?

For suggested answers, see Appendix A.

Concept 43.3

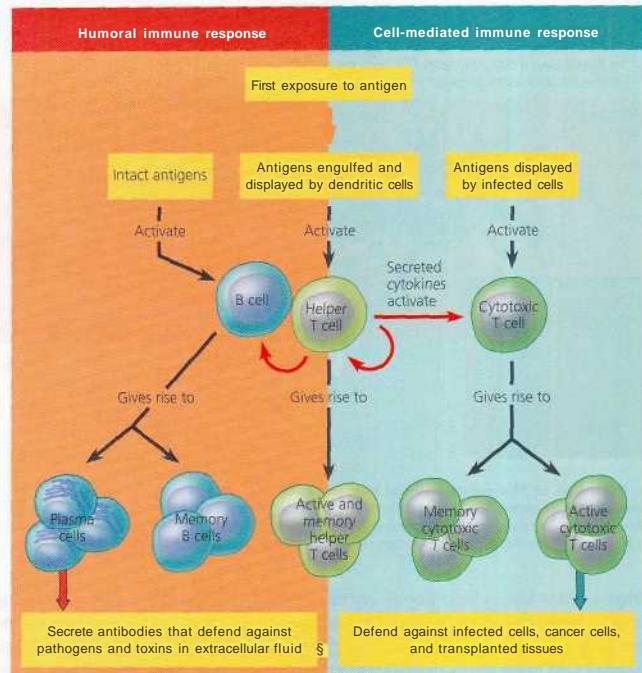

Humoral and cell-mediated immunity defend against different types of threats

Early evidence that substances in the blood plasma and lymph play a role in acquired immunity came from experiments performed near the end of the 19th century. Researchers transferred such fluids (long ago called humors) from an animal that had recovered from an infection by a particular microbe to another animal that had not been exposed to that microbe. Later, when the second animal was infected with the same microbe, it did not become ill. The investigators had transferred what we now know were secreted antibodies from one animal to the other. They also found that immunity to some infections could be passed along only if certain cells, later identified as cytotoxic T cells, were transferred.

A Figure 43.13 The specificity of immunological memory. Long-lived memory cells generated in the primary response to antigen A give rise to a heightened secondary response to the same antigen, but do not affect the primary response to a different antigen (B).

Figure 43.14 An overview of the acquired immune response. Stimulation of helper T cells by an antigen generally requires direct contact between a dendritic cell and helper T cell in a primary response (shown here) or between a macrophage and memory T cell in a secondary response (not shown). Once activated, a helper T cell stimulates the humoral response directly by contacting B cells and indirectly by secreting cytokines. An activated helper T cell stimulates the cell-mediated response indirectly via cytokines.

These and many other studies led to the current understanding that acquired immunity includes two branches. The **humoral immune response** involves the activation and clonal selection of B cells, resulting in production of secreted antibodies that circulate in the blood and lymph. The **cell-mediated immune response** involves the activation and clonal selection of cytotoxic T cells, which directly destroy certain target cells.

Figure 43.14 outlines the roles of the major participants in acquired immune responses. Central to this network of cellular interactions is the **helper T cell**, which responds to peptide antigens displayed on antigen-presenting cells and in turn stimulates the activation of nearby B cells and cytotoxic T cells. Now let's fill in the details of this road map and examine how each branch of the acquired immune response defends against particular types of assault.

Helper T Cells: A Response to Nearly All Antigens

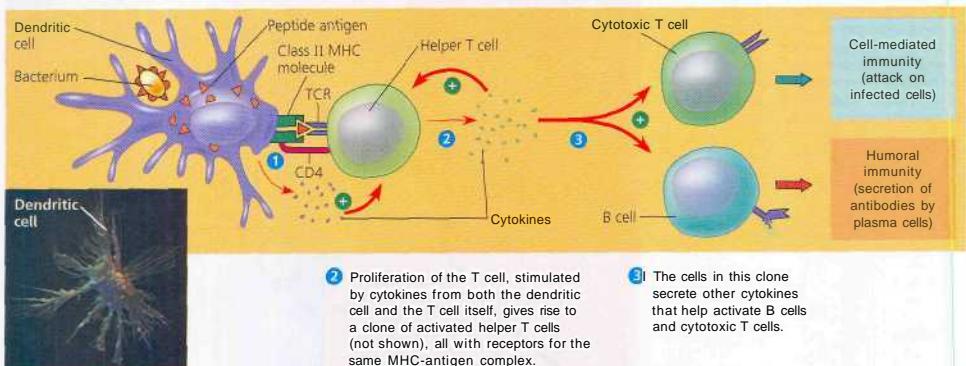

When a helper T cell encounters and recognizes a class II MHC molecule—**antigen** complex on an antigen-presenting cell, the helper T cell proliferates and differen-

tiates into a clone of activated helper T cells and memory helper T cells. A surface protein called **CD4**, present on most helper T cells, binds the class II MHC molecule. This interaction helps keep the helper T cell and the antigen-presenting cell joined while activation of the helper T cell proceeds.

Activated helper T cells secrete several different cytokines that stimulate other lymphocytes, thereby promoting cell-mediated and humoral responses. The helper T cell itself is also subject to regulation by cytokines. For instance, as a dendritic cell presents an antigen to a helper T cell, the dendritic cell is stimulated to secrete cytokines that, along with an antigen, stimulate the helper T cell to produce its own set of cytokines.

As you've read, the class II MHC molecules recognized by helper T cells are found mainly on dendritic cells, macrophages, and B cells. Dendritic cells are particularly **effective** in presenting antigens to *naive* helper T cells, so called because they have not previously detected an antigen. In other words, dendritic cells are important in triggering a primary immune response. Dendritic cells are located in the epidermis and in many other tissues, where they efficiently capture antigens. They then migrate from the site of infection to various lymphoid tissues, where they present antigens, via class II MHC molecules, to helper T cells.

O After a dendritic cell engulfs and degrades a bacterium, it displays bacterial antigen fragments (peptides) complexed with a class II MHC molecule on the cell surface. A specific helper T cell binds to the displayed complex via its TCR with the aid of CD4. This interaction promotes secretion of cytokines by the dendritic cell.

▲ Figure 43.15 The central role of helper T cells in humoral and cell-mediated immune responses.

The SEM of a dendritic cell reveals its long branching extensions, reminiscent of the dendrites of a nerve cell. Dendritic cells are the primary antigen-presenting cells during the primary response to an antigen. TCR = T cell receptor. A + indicates stimulation.

(Figure 43.15). Macrophages play the key role in initiating a secondary immune response by presenting antigens to memory helper T cells, while B cells primarily present antigens to helper T cells in the course of the humoral response.

Cytotoxic T Cells: A Response to Infected Cells and Cancer Cells

Cytotoxic T cells, the effectors of cell-mediated immunity, eliminate body cells infected by viruses or other intracellular pathogens as well as cancer cells and transplanted cells. Fragments of nonself proteins synthesized in such target cells associate with class I MHC molecules and are displayed on the cell surface, where they can be recognized by cytotoxic T cells. A surface protein called CD8, present on most cytotoxic T cells, greatly enhances the interaction between a target cell and a cytotoxic T cell. Binding of CD8 to the side of a class I MHC molecule helps keep the two cells in contact during activation of the cytotoxic T cell. Thus, the role of class I MHC molecules and CD8 is similar to that of class II MHC molecules and CD4, except that different cell types are involved.

When a cytotoxic T cell is selected by binding to class I MHC molecule-antigen complexes on an infected body cell, the cytotoxic T cell is activated and differentiates into an active killer. Cytokines secreted from nearby helper T cells promote this activation. The activated cytotoxic T cell then secretes proteins that act on the bound infected cell, leading to its destruction (**Figure 43.16**). The death of the infected cell not only

deprives the pathogen of a place to reproduce but also exposes it to circulating antibodies, which mark it for disposal. After destroying an infected cell, the cytotoxic T cell may move on and kill other cells infected with the same pathogen.

In the same way cytotoxic T cells defend against malignant tumors. Because tumor cells carry distinctive molecules (tumor antigens) not found on normal body cells, they are identified as foreign by the immune system. Class I MHC molecules on a tumor cell display fragments of tumor antigens to cytotoxic T cells. Interestingly, certain cancers and viruses (such as the Epstein-Barr virus) actively reduce the number of class I MHC molecules on affected cells, helping them escape detection by cytotoxic T cells. But the body has a backup defense: Recall that natural killer (NK) cells, part of the body's nonspecific innate defenses, can induce apoptosis in virus-infected and cancer cells.

B Cells: A Response to Extracellular Pathogens

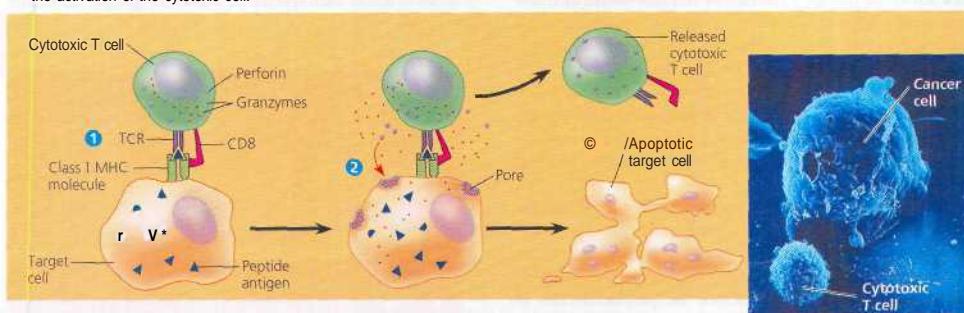

Antigens that elicit a humoral immune response are typically proteins and polysaccharides present on the surface of bacteria or incompatible transplanted tissue or transfused blood cells. In addition, for some people, proteins of foreign substances such as pollen or bee venom act as antigens that induce an allergic, or hypersensitive, humoral response.

Figure 43.17 depicts the events in the humoral response to a typical protein antigen. The activation of B cells is aided by cytokines secreted from helper T cells activated by the same

O A specific cytotoxic T cell binds to a class I MHC-antigen complex on a target cell via its TCR with the aid of CD8. This interaction, along with cytokines from helper T cells, leads to the activation of the cytotoxic cell.

O The activated T cell releases perforin molecules, which form pores in the target cell membrane, and proteolytic enzymes (granzymes), which enter the target cell by endocytosis.

O The granzymes initiate apoptosis within the target cells, leading to fragmentation of the nucleus, release of small apoptotic bodies, and eventual cell death. The released cytotoxic T cell can attack other target cells.

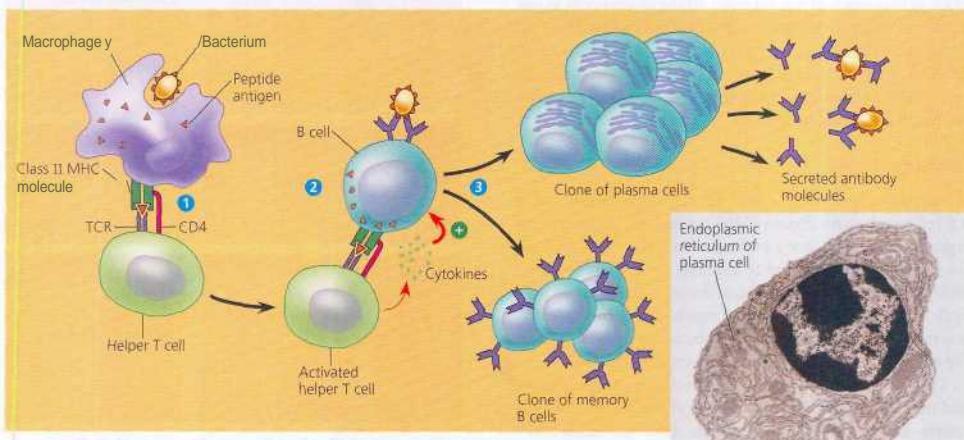

• **Figure 43.16 The killing action of cytotoxic T cells.** After interacting with a target cell, such as an infected body cell or cancer cell, an activated cytotoxic T cell releases perforins and proteolytic enzymes (granzymes) that promote death of the target cell. The colorized SEM shows a cancer cell with a perforin-induced pore in the early stages of apoptosis. TCR = T cell receptor.

① After a macrophage engulfs and degrades a bacterium, it displays a peptide antigen complexed with a class II MHC molecule. A helper T cell that recognizes the displayed complex is activated with the aid of cytokines secreted from the macrophage, forming a clone of activated helper T cells (not shown).

② A B cell that has taken up and degraded the same bacterium displays class II MHC-peptide antigen complexes. An activated helper T cell bearing receptors specific for the displayed antigen binds to the B cell. This interaction, with the aid of cytokines from the T cell, activates the B cell.

③ The activated B cell proliferates and differentiates into memory B cells and antibody-secreting plasma cells. The secreted antibodies are specific for the same bacterial antigen that initiated the response.

A **Figure 43.17 Humoral immune response.** Most protein antigens require activated helper T cells to trigger a humoral response. Either a macrophage (shown here) or a dendritic cell can activate helper T cells. The TEM of a plasma cell reveals abundant endoplasmic reticulum, a common feature of cells dedicated to making proteins for secretion. TCR = T cell receptor.

A ① indicates stimulation,

antigen. Stimulated by both an antigen and cytokines, the B cell proliferates and differentiates into a clone of antibody-secreting plasma cells and a clone of memory B cells. When an antigen first binds to receptors on the surface of a B cell, the cell takes in a few of the foreign molecules by receptor-mediated endocytosis. In a process similar to antigen presentation by macrophages and dendritic cells, the B cell then presents antigen fragments to a helper T cell. This achieves the direct cell-cell contact critical to B cell activation (see step 2 in Figure 43.17). Note, however, that a macrophage or dendritic cell can present peptide fragments from a wide variety of antigens, whereas a B cell internalizes and presents only the antigen to which it specifically binds.

Antigens that induce antibody production only with assistance from helper T cells, as shown in Figure 43.17, are known as *T-dependent antigens*. Some antigens, however, can evoke a B cell response without involvement of helper T cells. Such *T-independent antigens* include the polysaccharides of many bacterial capsules and the proteins that make up bacterial flagella. Apparently the repeated subunits of these molecules bind simultaneously to several antigen receptors on a single B cell, providing enough stimulus to activate the cell without the help of cytokines. The response to T-independent antigens is very important in defending against many bacteria. However, this response is generally weaker than the response to T-dependent antigens and generates no memory B cells.

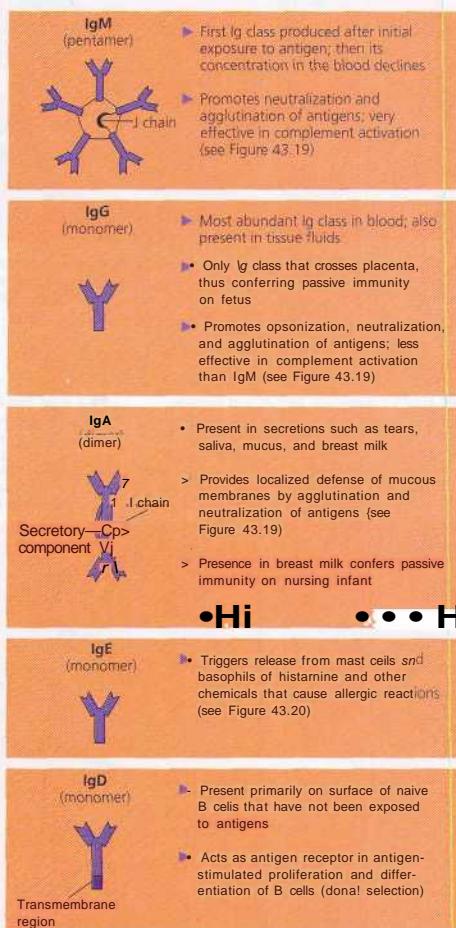

Most antigens recognized by B cells contain multiple epitopes. For this reason, exposure to a single antigen normally stimulates a variety of different B cells, each giving rise to a clone of thousands of plasma cells. All the plasma cells in one clone secrete antibodies specific for the epitope that provoked their production. Each plasma cell secretes an estimated 2,000 antibody molecules per second over the cell's 4- to 5-day life span. Next we look more closely at antibodies and how they mediate the disposal of antigens.

Antibody Classes

A secreted antibody has the same general Y-shaped structure as a B cell receptor (see Figure 43.8a) but lacks a transmembrane region that would anchor it to the plasma membrane. Although the antigen-binding sites on an antibody are responsible for its ability to identify a specific antigen, the tail of the Y-shaped molecule, formed by the constant (C) regions of the heavy chains, is responsible for the antibody's distribution in the body and for the mechanisms by which it mediates antigen disposal.

There are five major types of heavy-chain constant regions, and these determine five major classes of antibodies. The class names are based on the alternate term for antibody—immunoglobulin (Ig). The structures and functions of these antibody classes are summarized in **Figure 43.18**. Note that two classes exist primarily as polymers of the basic antibody molecule: IgM as a pentamer and IgA as a dimer. The other three classes—IgG, IgE, and IgD—exist exclusively as monomers.

The power of antibody specificity and antigen-antibody binding has been harnessed in laboratory research, clinical diagnosis, and the treatment of diseases. Some of these antibody tools are *polyclonal*: They are the products of many different clones of B cells, each specific for a different epitope. Antibodies

A Figure 43.18 The five classes of immunoglobulins.

All classes consist of similar Y-shaped molecules in which the tail region determines the distribution and functions characteristic of each class. IgM and IgA antibodies contain a J chain (unrelated to the J gene segment) that helps hold the monomeric subunits together. As an IgA antibody is secreted across a mucous membrane, it acquires a secretory component that protects it from cleavage by enzymes.

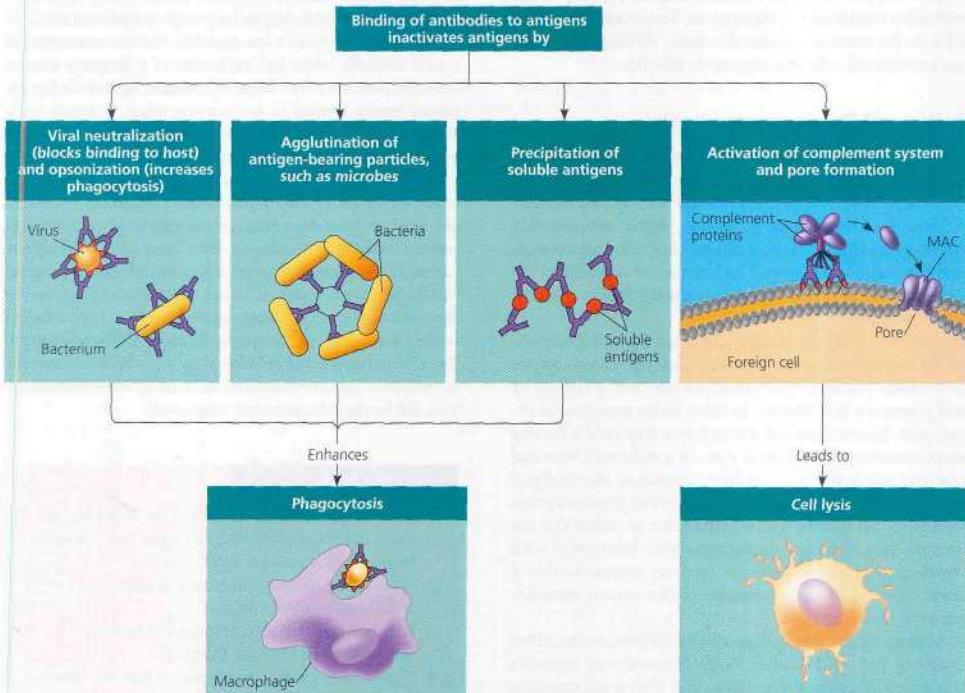

produced in the body following exposure to a microbial antigen are polyclonal. In contrast, other antibody tools are *monoclonal*. They are prepared from a single clone of B cells grown in culture. All the monoclonal antibodies produced by such a culture are identical and specific for the same epitope on an antigen. In both basic research and medical applications, monoclonal antibodies are particularly useful for tagging specific molecules. For example, certain types of cancer are treated with tumor-specific monoclonal antibodies bound to toxin molecules. The toxin-linked antibodies carry out a precise search-and-destroy mission, selectively attaching to and killing tumor cells.

Antibody-Mediated Disposal of Antigens

The binding of antibodies to antigens is also the basis of several antigen disposal mechanisms (Figure 43.19). In the simplest of

these, viral neutralisation, antibodies bind to certain proteins on the surface of a virus, thereby blocking the virus's ability to infect a host cell. Similarly, antibodies may bind to a pathogenic bacterium, coating much of the bacterial surface. In a process called *opsonization*, the bound antibodies enhance macrophage attachment to the microbes, and thus increase phagocytosis.

Antibody-mediated agglutination (clumping) of bacteria or viruses forms aggregates that can be readily phagocytosed by macrophages. Agglutination is possible because each antibody molecule has at least two antigen-binding sites that can bind to identical epitopes on separate bacterial cells or virus particles, linking them together. Because of their pentameric structure, IgM antibodies can link together five or more viruses or bacteria (as shown in Figure 43.19). In the similar process of *precipitation*, antibodies cross-link soluble antigen molecules dissolved in body fluids, forming immobile aggregates that are disposed of by phagocytes.

* **Figure 43.19 Antibody-mediated mechanisms of antigen disposal.** The binding of antibodies to antigens marks microbes, foreign particles, and soluble antigens for inactivation or destruction. Following activation of the complement system, the membrane attack complex (MAC) forms pores in foreign cells. The pores allow ions and water to rush into the cell, leading to its swelling and eventual lysis.

As you read earlier in the chapter, substances on many microbes activate the complement system as part of the body's innate defenses. The complement system also participates in the antibody-mediated disposal of microbes and transplanted body cells. In this case, binding of antigen-antibody complexes on a microbe or foreign cell to one of the complement proteins triggers a cascade in which each component activates the next. Ultimately, activated complement proteins generate a membrane attack complex (MAC) that forms a pore in the membrane. Ions and water rush into the cell, causing it to swell and lyse (see Figure 43.19, right). Whether activated as part of innate or acquired defenses, the complement cascade results in lysis of microbes and produces activated complement proteins that also promote inflammation or stimulate phagocytosis.

As shown in Figure 43.19, antibodies promote phagocytosis in several ways. Recall that phagocytosis enables macrophages and dendritic cells to present antigens to and stimulate helper T cells, which in turn stimulate the very B cells whose antibodies contribute to phagocytosis. This positive feedback between the innate and acquired immune systems contributes to a coordinated, effective response to infection.

Active and Passive Immunization

Immunity conferred by natural exposure to an infectious agent is called active immunity because it depends on the action of a person's own lymphocytes and the resulting memory cells specific for the invading pathogen. Active immunity also can develop following immunization, often called vaccination (from the Latin *vaccina*, cow). The first vaccine consisted of the virus causing cowpox, a mild disease usually seen in cows but also occasionally in humans.

In the late 1700s, the English physician Edward Jenner observed that milkmaids who previously had contracted cowpox were resistant to subsequent smallpox infection, a disfiguring and potentially fatal disease. In 1796, in his now-famous experiment, Jenner scratched a farm boy with a needle bearing virus-containing fluid from a sore on a milkmaid who had cowpox. When the boy was later exposed to the smallpox virus, he did not become sick. Cowpox virus protects against smallpox virus because the two viruses are so similar that the immune system cannot distinguish them. Vaccination with the cowpox virus sensitizes the immune system, so that it reacts vigorously if later exposed to cowpox virus or, more importantly, smallpox virus.

Modern vaccines include inactivated bacterial toxins, killed microbes, parts of microbes, viable but weakened microbes that generally do not cause illness, and even genes encoding microbial proteins. All these agents induce an immediate immune response and long-lasting immunological memory (thanks to memory cells). A vaccinated person who encounters the actual pathogen from which the vaccine was

derived will have the same quick secondary response as a person previously infected with the pathogen.

A worldwide vaccination campaign led to eradication of smallpox in the late 1970s. Routine active immunization of infants and children has dramatically reduced the incidence of other infectious diseases, such as polio, measles, and whooping cough, in developed countries. Unfortunately, not all infectious agents are easily managed by vaccination. For example, the emergence of new strains of pathogens with slightly altered surface antigens complicates development of vaccines against some microbes, such as the parasite that causes malaria.

Immunity can also be conferred by transferring antibodies from an individual who is immune to a particular infectious agent to someone who is not. This is called passive immunity because it does not result from the action of the recipient's own B and T cells. Instead, the transferred antibodies are poised to immediately help destroy any microbes for which they are specific. Passive immunity provides immediate protection, but it persists only as long as the transferred antibodies last (a few weeks to a few months). Passive immunization occurs naturally when IgG antibodies of a pregnant woman cross the placenta to her fetus. In addition, IgA antibodies are passed from mother to her nursing infant in breast milk. These help protect the infant from infection while the baby's own immune system is maturing.

In artificial passive immunization, antibodies from an immune animal are injected into a nonimmune animal. For example, a person bitten by a rabid animal may be given antibodies isolated from other people who have been vaccinated against rabies. This measure is important because rabies may progress rapidly, and the response to active immunization may be too slow to save the victim. Most people who have been exposed to the rabies virus are both passively and actively immunized. The injected antibodies help keep the virus in check until the victim's own immune response, induced by active immunization and by the infection itself, takes over.

Concept Check 43.3

- Describe the main role of each of the following cell types, once it is activated by antigens and cytokines: helper T cell, cytotoxic T cell, and B cell.
- What cells and functions would be deficient in a child born without a thymus?
- Discuss how antibodies help protect us from infection or the effects of infection.
- Explain why passive immunization provides short-term protection from an infection, whereas active immunization provides long-term protection.

For suggested answers, see Appendix A.

Concept 43.4

The immune system's ability to distinguish self from nonself limits tissue transplantation

In addition to distinguishing between the body's own cells and invading pathogens, the immune system can wage war against cells from other individuals. For example, skin transplanted from one person to a genetically nonidentical person will look healthy for a week or so, but will then be destroyed (rejected) by the recipient's immune response. (Interestingly, however, a pregnant woman does not reject her fetus as nonself tissue. Apparently, the structure of the placenta—described in Chapter 46—is the key to this tolerance.) Keep in mind that the body's hostile reaction to an incompatible blood transfusion or transplant of other tissues or whole organs is not a disorder of the immune system, but the normal reaction of a healthy immune system exposed to foreign antigens.

Blood Groups and Transfusions

In Chapter 14, we discussed the genetics of ABO blood groups in humans. Recall that type A red blood cells have A antigen molecules on their surface. The A antigen may be recognized as foreign if placed in the body of another person. Similarly, the B antigen is found on type B red blood cells; both A and B antigens are found on type AB red blood cells; and neither antigen is found on type O red blood cells (see Table 14.2).

Individuals with type A blood do not, of course, produce antibodies against the A antigen, because they are self-tolerant. However, these individuals do have circulating antibodies against the B antigen, even if they have never been exposed to type B blood! You may find it odd that antibodies to foreign blood group antigens exist in the body even in the absence of exposure to foreign blood cells. The explanation

is that these antibodies arise in response to normal bacterial inhabitants of the body that have epitopes very similar to blood group antigens.

For example, a person with type A blood makes antibodies against B-like bacterial epitopes, which the immune system considers foreign, but does not make antibodies against A-like bacterial epitopes, which the immune system recognizes as self. The preexisting anti-B antibodies in a person with type A blood will cause an immediate and devastating transfusion reaction if that person receives a transfusion of type B blood. This reaction involves lysis of the transfused red blood cells, which can lead to chills, fever, shock, and kidney malfunction. By the same token, anti-A antibodies in the donated type B blood can act against the recipient's type A red blood cells. This latter reaction can be minimized by transfusing packed cells instead of whole blood, so that donor antibodies in the fluid portion are not transferred.

Table 43.1 lists the recipient and donor (packed cell) combinations that are safe and those that result in transfusion reactions. Note that the row shaded in blue indicates that a person with type AB blood can safely receive blood of any type (and thus is called a "universal recipient"). The column shaded in green indicates that a person with type O blood can safely donate blood to any recipient (and thus is called a "universal donor").

Blood group antigens and related bacterial epitopes are polysaccharides. Such polysaccharide antigens induce immune responses in which no memory cells are generated. As a result, anti-blood group antibodies are always IgM (generated from primary responses) rather than IgG (generated from secondary responses). This is fortunate in pregnancy because IgM does not cross the placenta, so no harm comes to a fetus with a blood type that is not compatible with its mother's. However, another red blood cell antigen, the **Rh factor**, can cause trouble for a fetus. As a protein antigen, the Rh factor induces immune responses in which memory cells are generated. Later exposure of these memory cells to the Rh factor leads to production of anti-Rh antibodies that are IgG.

Table 43.1 Blood Groups That Can and Cannot Be Safely Combined in Transfusion*

| Recipient's Blood Group | Antibodies in Recipient's Blood | Presence (+) or Absence (-) of Transfusion Reaction: Donated Blood Group (Packed Cells) | | | |
|-------------------------|---------------------------------|---|---|----|---|
| | | A | B | AB | O |
| A | Anti-B | - | + | + | - |
| B | Anti-A | + | - | + | - |
| AB | No anti-A or anti-B | - | - | - | - |
| 0 | Anti-A and anti-B | + | + | + | - |

* Individuals with type AB blood are universal recipients (blue row); those with type O blood are universal donors (green column).

A potentially dangerous situation can arise when a mother who is Rh-negative (lacks the Rh factor) carries a fetus that is Rh-positive, having inherited the factor from its father. If small amounts of fetal blood cross the placenta, which may happen late in pregnancy or during delivery, the mother mounts a humoral response against the Rh factor. The danger occurs in subsequent pregnancies with an Rh-positive fetus, when the mother's Rh-specific memory B cells are exposed to the Rh factor from the fetus. These B cells produce anti-Rh IgG antibodies, which can cross the placenta and destroy the red blood cells of the fetus. To prevent this, the mother is injected with anti-Rh antibodies around the seventh month of pregnancy and again just after delivering an Rh-positive baby. She is, in effect, passively immunized (artificially) to eliminate any fetal Rh-bearing red blood cells that cross the placenta before her own immune system responds to them and generates immunological memory that would endanger future Rh-positive babies.

Tissue and Organ Transplants

Major histocompatibility complex (MHC) molecules are responsible for stimulating the immune response that leads to rejection of tissue and organ transplants, or grafts. As you read earlier, the polymorphism of the MHC almost guarantees that no two people, except identical twins, have exactly the same set of MHC molecules. Thus, a rejection reaction is mounted in the vast majority of graft and transplant recipients because at least some MHC molecules on the donated tissue are foreign to the recipient. There is *no* danger of rejection if the donor and recipient are identical twins or if tissue is grafted from one part of an individual's body to another part.

To minimize the extent of rejection in nonidentical transplants, attempts are made to use donor tissue bearing MHC molecules that match those of the recipient as closely as possible. In addition, the recipient takes medicines that suppress immune responses. However, these medicines can leave the recipient more susceptible to infections and cancer during the course of treatment.

In a bone marrow transplant, the graft itself, rather than the recipient, is the source of potential immune rejection. Bone marrow transplants are used to treat leukemia and other cancers as well as various hematological (blood cell) diseases. As in any transplant, the MHC of the donor and recipient are matched as closely as possible. Prior to receiving transplanted bone marrow, the recipient is typically treated with irradiation to eliminate his or her own bone marrow cells, including any abnormal cells. This treatment effectively obliterates the recipient's immune system, leaving little chance of graft rejection. However, the great danger in bone marrow transplants is that lymphocytes in the donated marrow will react against the recipient. This graft versus host reaction is limited if the MHC molecules of the donor and recipient are well matched. Bone marrow donor programs around the world continually

seek volunteers; because of the great variability of the MHC, a diverse pool of potential donors is essential.

Concept Check 43.4

- Explain why a person who has type AB blood is considered a universal blood recipient.
- In bone marrow transplantation, there is a danger of a graft versus host reaction. Why is this reaction particular to a bone marrow transplant?
- Severely burned patients generally must receive numerous skin grafts. What is the advantage of using skin from an unburned part of a patient's own body (an autograft) rather than from another person?

For suggested answers, see Appendix A.

Concept 43.5

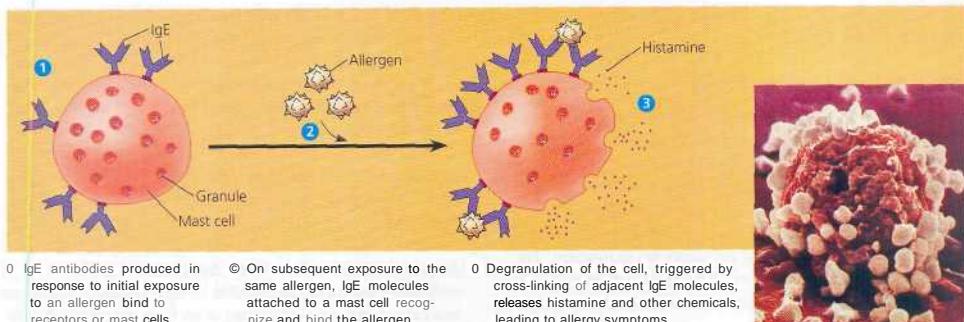

Exaggerated, self-directed, or diminished immune responses can cause disease

The highly regulated interplay of lymphocytes with foreign substances, with each other, and with other body cells provides extraordinary protection against many pathogens. However, if this delicate balance is disrupted by an immune system malfunction, the effects on the individual can range from the minor inconvenience of some allergies to the serious and often fatal consequences of certain autoimmune and immunodeficiency diseases.

Allergies

Allergies are exaggerated (hypersensitive) responses to certain antigens called *allergens*. One hypothesis to explain the origin of allergies is that they are evolutionary remnants of the immune system's response to parasitic worms. The humoral mechanism that combats worms is similar to the allergic response that causes such disorders as hay fever and allergic asthma.

The most common allergies involve antibodies of the IgE class (see Figure 43.18). Hay fever, for instance, occurs when plasma cells secrete IgE antibodies specific for antigens on the surface of pollen grains. Some of these antibodies attach by their tails to mast cells present in connective tissues. Later, when pollen grains again enter the body, they attach to the antigen-binding sites of mast cell-associated IgE, cross-linking adjacent antibody molecules. This induces the mast cell to release histamine and other inflammatory agents from their granules (vesicles), a process called *degranulation* (Figure 43.20). Recall that histamine causes dilation and increased permeability of small blood vessels.

A Figure 43.20 Mast cells, IgE, and the allergic response. The colorized SEM shows a degranulated mast cell that has released granules containing histamine and other inflammatory agents.

Such vascular changes lead to typical allergy symptoms: sneezing, runny nose, tearing eyes, and smooth muscle contractions that can result in breathing difficulty. Antihistamines diminish allergy symptoms by blocking receptors for histamine.

An acute allergic response sometimes leads to anaphylactic shock, a whole-body, life-threatening reaction that can occur within seconds of exposure to an allergen. Anaphylactic shock develops when widespread mast cell degranulation triggers abrupt dilation of peripheral blood vessels, causing a precipitous drop in blood pressure. Death may occur within a few minutes. Allergic responses to bee venom or penicillin can lead to anaphylactic shock in people who are extremely allergic to these substances. Likewise, people very allergic to peanuts, hsh, or other foods have died from eating only tiny amounts of these allergens. Some individuals with severe hypersensitivities carry syringes containing the hormone epinephrine, which counteracts this allergic response.

Autoimmune Diseases

In some individuals, the immune system loses tolerance for self and turns against certain molecules of the body, causing one of the many autoimmune diseases. In systemic lupus erythematosus (lupus), the immune system generates antibodies (known as autoantibodies) against a wide range of self molecules, including histones and DNA released by the normal breakdown of body cells. Lupus is characterized by skin rashes, fever, arthritis, and kidney dysfunction. Another antibody-mediated autoimmune disease, *rheumatoid arthritis*, leads to damage and painful inflammation of the cartilage and bone of joints (Figure 43.21). In insulin-dependent *diabetes mellitus*, the insulin-producing beta cells of the pancreas are the targets of autoimmune cytotoxic T cells. Yet another example is *multiple sclerosis*, the most common chronic neurological disease in developed countries. In this

disease, T cells infiltrate the central nervous system and destroy the myelin sheath that surrounds some neurons (see Figure 48.5). This results in a number of serious neurological abnormalities.

The mechanisms leading to autoimmunity are not fully understood. For a long time, it was thought that people with autoimmune diseases had self-reactive lymphocytes that had happened to escape elimination during their development. We now know that healthy people also have lymphocytes with the capacity to react against self. However, several regulatory mechanisms make these cells nonfunctional, so they cannot induce autoimmune reactions. Thus, autoimmune disease likely arises from some failure in immune system regulation.

A Figure 43.21 X-ray of a hand deformed by rheumatoid arthritis.

Immunodeficiency Diseases

The inability of the immune system to protect the body from pathogens or cancer cells that it should normally be able to defeat reflects some sort of deficiency in the system. An immunodeficiency disease caused by a genetic or developmental defect in the immune system is classified as an *inborn* or *primary immunodeficiency*. An immunodeficiency disease that develops later in life following exposure to various chemical and biological agents is classified as an *acquired* or *secondary immunodeficiency*. Whatever the cause and nature of the immunodeficiency, a person with this kind of disease

is subject to frequent and recurrent infections and also is more susceptible to cancer.

Inborn (Primary) Immunodeficiencies

Inborn immunodeficiencies result from defects in the development of various immune system cells or defects in the production of specific proteins, such as IgA antibodies or complement components. Depending on the specific genetic defect, innate defenses, acquired defenses, or both may be impaired. In *severe combined immunodeficiency (SCID)*, both the humoral and cell-mediated branches of acquired immunity fail to function. The long-term survival of people with this genetic disease usually requires a bone marrow transplant that will continue to supply functional lymphocytes.

In one type of SCID, a deficiency of the enzyme adenosine deaminase leads to accumulation of substances that are toxic to both B and T cells. Since the early 1990s, medical researchers have been testing a gene therapy for this disease in which the individual's own bone marrow cells are removed, engineered to contain a functional adenosine deaminase gene, and then returned to the body (see Figure 20.16). Recent successes include a child with SCID who received adenosine deaminase gene therapy when she was 2 years old. About two years after treatment, her T cells and B cells were still functioning normally. In fact, when a family member came down with chicken pox, the treated girl did not develop any sign of the disease, evidence that her immune system was working.

Acquired (Secondary) Immunodeficiencies

Immune dysfunction that develops later in life can be caused by exposure to a number of agents. Drugs used to fight autoimmune diseases or to prevent the rejection of a transplant suppress the immune system, leading to an immunodeficient state. In addition, the immune system is suppressed by certain cancers, especially Hodgkin's disease, which damages the lymphatic system. Acquired immunodeficiencies range from temporary states that may arise from physiological stress to the devastating **acquired immunodeficiency syndrome, or AIDS**, which is caused by a virus.

Stress and the Immune System. Healthy immune function appears to depend on both the endocrine system and the nervous systems. Nearly 2,000 years ago, the Greek physician Galen recorded that people suffering from depression were more likely than others to develop cancer. In fact, there is growing evidence that physical and emotional stress can harm immunity. Hormones secreted by the adrenal glands during stress affect the numbers of white blood cells and may suppress the immune system in other ways.

The association between emotional stress and immune function also involves the nervous system. Some neurotransmitters secreted when we are relaxed and happy may enhance

immunity. In one study, college students were examined just after a vacation and again during final exams. Their immune systems were impaired in various ways during exam week; for example, interferon levels were lower. These and other observations indicate that general health and state of mind affect immunity. Physiological evidence also points to an immune system-nervous system link: Receptors for neurotransmitters have been discovered on the surface of lymphocytes, and a network of nerve fibers penetrates deep into the thymus.

Acquired Immunodeficiency Syndrome (AIDS). People with AIDS are highly susceptible to opportunistic infections and cancers that take advantage of an immune system in collapse. For example, infection by *Pneumocystis carinii*, a ubiquitous fungus, can cause severe pneumonia in people with AIDS but is successfully rebuffed by individuals with a healthy immune system. Likewise, Kaposi's sarcoma is a rare cancer that occurs most commonly in AIDS patients. Such opportunistic diseases, as well as neurological damage and physiological wasting, can lead to death from AIDS.

Because AIDS arises from the loss of helper T cells, both humoral and cell-mediated immune responses are impaired. This loss of helper T cells results from infection by the **human immunodeficiency virus (HIV)**, a retrovirus (Figure 43.22). HIV gains entry into cells by making use of three proteins that participate in normal immune responses. The main receptor for HIV on helper T cells is the cell's CD4 molecule. The virus also infects other cell types, such as macrophages and brain cells, that have low levels of CD4. In addition to CD4, HIV entry requires a second cell-surface protein, a *co-receptor*. One co-receptor, called fusin, is present on all the cell types infected by HIV, while a different co-receptor is present only on macrophages and helper T cells. Both of these HIV co-receptors function as chemokine receptors in uninfected cells. In fact, these proteins were first recognized as HIV co-receptors after it was discovered that chemokines can block HIV entry into cells.

Once inside a cell, the HIV RNA genome is reverse-transcribed, and the product DNA is integrated into the host cell's genome. In this form, the viral genome can direct the production of new virus particles (see Figure 18.10). The infected cell's machinery for transcription and translation thus are hijacked for the benefit of the virus. The death of helper T cells in HIV infection is thought to occur in two ways: Infected cells may succumb to the damaging effects of virus reproduction, and both infected and uninfected cells may undergo inappropriately timed apoptosis triggered by the virus.

At this time, HIV infection cannot be cured, although certain drugs can slow HIV reproduction and the progression to AIDS. However, these drugs are very expensive and not available to all infected people. In addition, the mulitlational changes that occur in each round of virus reproduction can generate strains of HIV that are drug resistant. The impact of

A Figure 43.22 A T cell infected with HIV. Newly made virus particles (gray) are seen budding from the surface of the T cell in this colorized SEM.

viral drug resistance can be minimized by using a combination of drugs; viruses newly resistant to one drug can be defeated by another. But the appearance of strains resistant to multiple drugs reduces the effectiveness of multidrug "cocktails" in some patients. Frequent mutational changes in HIV surface antigens also have hampered efforts to develop an effective vaccine.

Transmission of HIV requires the transfer of body fluids containing infected cells, such as semen or blood, from person to person. Unprotected sex (that is, without a condom) among male homosexuals and transmission via HIV-contaminated needles (typically among intravenous drug users) account for

most of the HIV infections in the United States. However, transmission of HIV among heterosexuals is rapidly increasing as a result of unprotected sex with infected partners. In Africa and Asia, transmission occurs primarily by heterosexual sex.

In a December 2003 report, the joint United Nations Program on AIDS estimated that 40 million people worldwide are living with HIV/AIDS. The best approach for slowing the spread of HIV is to educate people about the practices that transmit the virus, such as using dirty needles and having sex without a condom. Although condoms do not completely eliminate the risk of transmitting HIV (or other similarly transmitted viruses, such as the hepatitis B virus), they do reduce it. Anyone who has sex—vaginal, oral, or anal—with a potentially infected partner risks exposure to the deadly virus.

Concept Check 43.5

- How would a macrophage deficiency likely affect a person's innate and acquired defenses?
- Many anti-allergy medications block responses by mast cells. Explain why these drugs are effective in treating allergies such as hay fever.
- In myasthenia gravis, antibodies bind to and block acetylcholine receptors at neuromuscular junctions, preventing muscle contraction. Is this disease best classified as an immunodeficiency disease, an autoimmune disease, or an allergic disease? Explain.
- People who have nonfunctional chemokine receptors because of a genetic mutation are immune to HIV infection. Explain this finding.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 43.1

Innate immunity provides broad defenses against infection

I* **External Defenses** (p. 899) Intact skin and mucous membranes form physical barriers that bar the entry of microorganisms and viruses. Mucus produced by cells in these membranes, the low pH of the skin and stomach, and degradation by lysozyme also deter infection by pathogens.

Internal Cellular and Chemical Defenses (pp. 899–902) Phagocytic cells ingest microbes that penetrate external innate defenses and help trigger an inflammatory response. Complement proteins, interferons, and other antimicrobial proteins also

act against invading microbes. In local inflammation, histamine and other chemicals released from injured cells promote changes in blood vessels that allow fluid, more phagocytes, and antimicrobial proteins to enter the tissues. Natural killer (NK) cells can induce the death of virus-infected or cancer cells via apoptosis.

► **Invertebrate Immune Mechanisms** (pp. 902–903) Insects defend themselves by mechanisms similar in many respects to vertebrate innate defenses.

Concept 43.2

In acquired immunity, lymphocytes provide specific defenses against infection

- Antigen Recognition by Lymphocytes** (pp. 903–905) Receptors on lymphocytes bind specifically to small regions of an antigen (epitopes). B cells recognize intact antigens, T cells recognize small antigen fragments (peptide antigens) that are complexed with cell-surface proteins called major histocompatibility (MHC) molecules. Class I MHC molecules, located on all

nucleated cells, display peptide antigens to cytotoxic T cells. Class II MHC molecules, located mainly on dendritic cells, macrophages, and B cells (antigen-presenting cells), display peptide antigens to helper T cells.

- **Lymphocyte Development** (pp. 905–908) Lymphocytes arise from stem cells in the bone marrow and complete their maturation in the bone marrow (B cells) or in the thymus (T cells). Early in development, random, permanent gene rearrangement forms functional genes encoding the B or T cell antigen receptor chains. All the antigen receptors produced by a single lymphocyte are specific for the same antigen. Self-reactive lymphocytes, whose receptors bind to normal body components, are destroyed or inactivated. In a primary immune response, binding of antigen to a mature lymphocyte induces the lymphocyte's proliferation and differentiation (clonal selection), generating a clone of short-lived activated effector cells and a clone of long-lived memory cells. These memory cells account for the faster, more efficient secondary immune response.

Concept 43.3

Humoral and cell-mediated immunity defend against different types of threats

- **Helper T Cells: A Response to Nearly All Antigens** (pp. 909–910) Helper T cells make CD4, a surface protein that enhances their binding to class II MHC molecule-antigen complexes on antigen-presenting cells. Activated helper T cells secrete several different cytokines that stimulate other lymphocytes.
- **Cytotoxic T Cells: A Response to Infected Cells and Cancer Cells** (pp. 910–911) Cytotoxic T cells make CD8, a surface protein that enhances their binding to class I MHC molecule-antigen complexes on infected cells, cancer cells, and transplanted tissues. Activated cytotoxic T cells secrete proteins that initiate destruction of their target cells.

- **B Cells: A Response to Extracellular Pathogens** (pp. 910–914) The clonal selection of B cells generates antibody-secreting plasma cells, the effector cells of humoral immunity. The five major antibody classes differ in their distributions and functions within the body. Binding of antibodies to antigens on the surface of pathogens leads to elimination of the microbes by phagocytosis and complement-mediated lysis.

- **Active and Passive Immunization** (p. 914) Active immunity develops naturally in response to an infection; it also develops artificially by immunization (vaccination). In immunization, a nonpathogenic form of a microbe or part of a microbe elicits an immune response to and immunological memory for that microbe. Passive immunity, which provides immediate, short-term protection, is conferred naturally when IgG crosses the placenta from mother to fetus or when IgA passes from mother to infant in breast milk. It also can be conferred artificially by injecting antibodies into a nonimmune person.

Activity *Immune Responses*

Concept 43.4

The immune system's ability to distinguish self from nonself limits tissue transplantation

- **Blood Groups and Transfusions** (pp. 915–916) Certain antigens on red blood cells determine whether a person has type A, B, AB, or O blood. Because antibodies to nonself blood antigens already exist in the body, transfusion with incompatible blood leads to destruction of the transfused cells. The Rh factor, another red blood cell antigen, creates difficulties when an Rh-negative mother carries successive Rh-positive fetuses.

- **Tissue and Organ Transplants** (p. 916) MHC molecules are responsible for stimulating the rejection of tissue grafts and organ transplants. The chances of successful transplantation are increased if the donor and recipient MHC tissue types are well matched and if immunosuppressive drugs are given to the recipient. Lymphocytes in bone marrow transplants may cause a graft versus host reaction in recipients.

Concept 43.5

Exaggerated, self-directed, or diminished immune responses can cause disease

- **Allergies** (pp. 916–917) In localized allergies such as hay fever, IgE antibodies produced after first exposure to an allergen attach to receptors on mast cells. The next time the same-allergen enters the body, it binds to mast cell-associated IgE molecules, inducing the cell to release histamine and other mediators that cause vascular changes and typical symptoms.
- **Autoimmune Diseases** (p. 917) Loss of the immune system's normal self-tolerance can lead to autoimmune diseases such as systemic lupus erythematosus (lupus), multiple sclerosis, rheumatoid arthritis, and insulin-dependent diabetes.
- **Immunodeficiency Diseases** (pp. 917–919) Inborn (primary) immunodeficiencies result from hereditary or congenital defects that prevent proper functioning of innate, humoral, and/or cell-mediated defenses. AIDS is an acquired (secondary) immunodeficiency caused by the human immunodeficiency virus (HIV). HIV infection leads to destruction of helper T cells, leaving the patient prone to opportunistic diseases owing to deficient humoral and cell-mediated immune responses.

TESTING YOUR KNOWLEDGE

Evolution Connection

One reason for the success of invertebrates, which make up more than 90% of living animal species, is their effective defense against microbes. Describe one mechanism by which invertebrates combat such invaders, and discuss how this mechanism comprises an evolutionary adaptation that is retained in the vertebrate immune system.

Scientific Inquiry

One effect of interferon- γ is to increase the number of class I MHC molecules on the cell surface. Suppose you want to test its effectiveness in treating viral infections and cancer. What effects would you predict interferon- γ to have on the immune response of laboratory animals against (a) virus-infected cells and (b) cancer cells?

Investigation *What Causes Infections in AIDS Patients?*

Investigation *Why Do AIDS Rates Differ Across the U.S.?*

Science, Technology, and Society

Both an injectable inactivated (killed) vaccine and an oral attenuated (live) vaccine are available for immunization against poliovirus, which can cause paralysis by destroying nerve cells in the brain and spinal cord. The oral vaccine is no longer recommended in western countries, where polio has been eradicated, because the live virus in this vaccine may mutate to a more virulent form, and be reintroduced into the population. However, the oral vaccine continues to be used in countries where polio persists because it is easy to administer (no needle!) and is highly effective. Moreover, the attenuated virus can spread to (and immunize) unvaccinated individuals. Do you feel this risk of mutation to virulence (about 1 in 12 million) is acceptable when compared with the benefits of oral vaccination? How do you think public health decisions of this type should be made?

- 44.6 Diverse adaptations of the vertebrate kidney have evolved in different environments

Overview

A Balancing Act

The physiological systems of animals, from cells and tissues to organs and organ systems, operate within a fluid **environment**. For such systems to function properly, this environment, particularly the relative concentrations of water and solutes, must be maintained within fairly narrow limits, often in the face of strong challenges from an animal's external environment. For example, freshwater animals, which live in an external environment that threatens to flood and dilute their body fluids, show adaptations that reduce water uptake, conserve solutes, and absorb salts from their surroundings. At the other extreme, desert and marine animals face desiccating environments with the potential to quickly deplete the animals' body water (Figure 44.1). Success in such environments depends on conservation of water and elimination of excess salts.

At the same time, metabolism presents organisms with the problem of waste disposal. The breakdown of proteins and nucleic acids is particularly problematic, since the primary metabolic waste product produced, ammonia, is very toxic. Studies of how animals meet these physiological challenges provide some of the most prominent examples of homeostasis. This chapter focuses on two key homeostatic processes: **osmoregulation**, how animals regulate solute concentrations and balance the gain and loss of water; and **excretion**, how animals get **rid of** the nitrogen-containing waste products of metabolism.

Concept 44.1

Osmoregulation balances the uptake and loss of water and solutes

Just as thermoregulation depends on balancing heat loss and gain (see Chapter 40), an animal's ability to regulate the chemical composition of its body fluids depends on balancing the uptake and loss of water and solutes. This osmoregulation is based largely on controlled movement of solutes between internal fluids and the external environment. The process also regulates the movement of water, which follows solutes by osmosis. An animal must also remove various metabolic waste products before they accumulate to harmful levels.

Osmosis

All animals—regardless of phylogeny, habitat, or type of waste produced—face the same central problem of osmoregulation: Over time, the rates of water uptake and loss must balance.

Lacking cell walls, animal cells swell and burst if there is a continuous net uptake of water or shrivel and die if there is a substantial net loss of water.

Water enters and leaves cells by osmosis. Recall from Chapter 7 that osmosis, a special case of diffusion, is the movement of water across a selectively permeable membrane. It occurs whenever two solutions separated by the membrane differ in osmotic pressure, or osmolarity (total solute concentration expressed as molarity, or moles of solute per liter of solution; see Chapter 3). The unit of measurement for osmolarity used in this chapter is milliosmoles per liter (mosm/L); 1 mosm/L is equivalent to a total solute concentration of 10^{-3} M. The osmolarity of human blood is about 300 mosm/L, while seawater has an osmolarity of about 1,000 mosm/L.

If two solutions separated by a selectively permeable membrane have the same osmolarity, they are said to be *isoosmotic*. There is no net movement of water by osmosis between isoosmotic solutions; although water molecules are continually crossing the membrane, they do so at equal rates in both directions. When two solutions differ in osmolarity, the one with the greater concentration of solutes is said to be *hyperosmotic* and the more dilute solution is said to be *hypoosmotic*. Water flows by osmosis from a hypoosmotic solution to a hyperosmotic one.*

Osmotic Challenges

There are two basic solutions to the problem of balancing water gain with water loss. One—available only to marine animals—is to be isoosmotic to the surroundings. Such an animal, which does not actively adjust its internal osmolarity, is known as an osmoconformer. Because an osmoconformers internal osmolarity is the same as that of its environment, there is no tendency to gain or lose water. Osmoconformers often live in water that has a very stable composition and hence have a very constant internal osmolarity. In contrast, an osmoregulator is an animal that must control its internal osmolarity because its body fluids are not isoosmotic with the outside environment. An osmoregulator must discharge excess water if it lives in a hypoosmotic environment or take in water to offset osmotic loss if it inhabits a hyperosmotic environment. Osmoregulation enables animals to live in environments that are uninhabitable for osmoconformers, such as freshwater and terrestrial habitats; it also allows many marine animals to maintain internal osmolarities different from that of seawater.

Whenever animals maintain an osmolarity difference between the body and the external environment, osmoregulation has an energy cost. Because diffusion tends to equalize

concentrations in a system, osmoregulators must expend energy to maintain the osmotic gradients that allow water to move in or out. They do so by using active transport to manipulate solute concentrations in their body fluids.

The energy cost of osmoregulation depends on how different an animal's osmolarity is from its surroundings, how easily water and solutes can move across the animals surface, and how much work is required to pump solutes across the membrane. Because of the difference in solute concentration between their body fluids (240-450 mosm/L), fresh water (0.5-15 mosm/L), and seawater (approximately 1,000 mosm/L), osmoregulation accounts for nearly 5% of the resting metabolic rate of many marine and freshwater bony fishes. For brine shrimp, small crustaceans that live in Utah Great Salt Lake and in other extremely salty lakes, the gradient between internal and external osmolarities is very large and the cost of osmoregulation is correspondingly high—as much as 30% of the resting metabolic rate. In contrast, marine osmoconformers, which are isoosmotic with seawater, expend little energy on osmoregulation.

Most animals, whether osmoconformers or osmoregulators, cannot tolerate substantial changes in external osmolarity and are said to be stenohalite (from the Greek *stenos*, narrow; *haline* refers to salt). In contrast, **eutraphine** animals (from the Greek *curys*, broad)—which include both certain osmoconformers and certain osmoregulators—can survive large fluctuations in external osmolarity. Familiar examples of eutraphine osmoregulators are the various species of salmon. A more extreme example is a fish called tilapia (a native of Africa widely grown in fish "farms" for human food), which can adjust to any salt concentration between fresh water and 2,000 mosm/L, twice that of seawater (Figure 44.2).

Next, we'll take a closer look at some of the adaptations for osmoregulation that have evolved in marine, freshwater, and terrestrial animals.

A Figure 44.2 Largemouth tilapia (*Tilapia mossambica*), an extreme eutraphine osmoregulator.

* In this chapter, we use the terms *isoosmotic*, *hypotonic*, and *hypertonie*, which refer specifically to osmolarity, instead of the more familiar terms *isotonic*, *hypotonic*, and *hypertonic*. The latter set of terms applies to the response of animal cells—whether they swell or shrink—in solutions of known solute concentrations.

Marine Animals

Animals first evolved in the sea, and more animal phyla are found there than in any other environment. Most marine invertebrates are osmoconformers. Their total osmolarity (the sum of the concentrations of all dissolved substances) is the same as that of seawater. However, they differ considerably from seawater in their concentrations of most specific solutes. Thus, even an animal that conforms to the osmolarity of its surroundings regulates its internal composition of solutes.

Marine vertebrates and some marine invertebrates are osmoregulators. For most of these animals, the ocean is a strongly dehydrating environment because it is much saltier than internal fluids, and water tends to be lost from their body by osmosis. Marine bony fishes, such as cod, are hypoosmotic to seawater and constantly lose water by osmosis and gain salt both by diffusion and from the food they eat (**Figure 44.3a**). The fishes balance the water loss by drinking large amounts of seawater. Their gills and skin dispose of sodium chloride; in the gills, specialized chloride cells actively transport chloride ions (Cl^-) out, and sodium ions (Na^+) follow passively. The kidneys of marine fishes dispose of excess calcium, magnesium, and sulfate ions while excreting only small amounts of water.

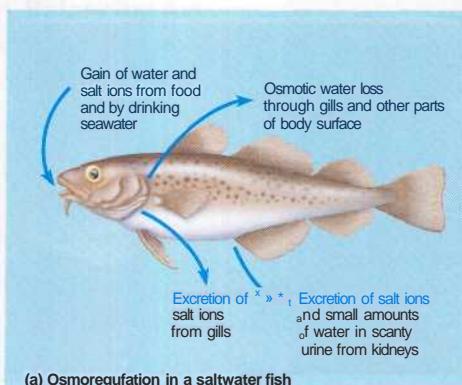

Marine sharks and most other chondrichthyans (cartilaginous animals; see Chapter 34) use a different osmoregulatory "strategy." Like bony fishes, their internal salt concentration is much less than that of seawater, so salt tends to diffuse into their body from the water, especially across their gills. The kidneys of sharks remove some of this salt load, and the rest is excreted by an organ called the rectal gland or is lost in feces. Unlike bony fishes, and despite relatively low internal salt concentration, marine sharks do not experience a large and continuous osmotic water loss. The explanation is that sharks

maintain high concentrations of the nitrogenous waste urea (a product of protein and nucleic acid metabolism produced by many animals; see Figure 44.8). Another organic solute, trimethylamine oxide (TMAO), protects proteins from damage by urea. (If you have ever prepared shark meat, you know it should be soaked in fresh water to remove urea before cooking.) A shark's total solute concentration of body fluids (salts, urea, TMAO, and other compounds) is somewhat greater than 1,000 mosm/L and therefore slightly hyperosmotic to seawater. Consequently, water slowly *enters* the shark's body by osmosis and in food (sharks do not drink), and this small influx of water is disposed of in urine produced by the kidneys.

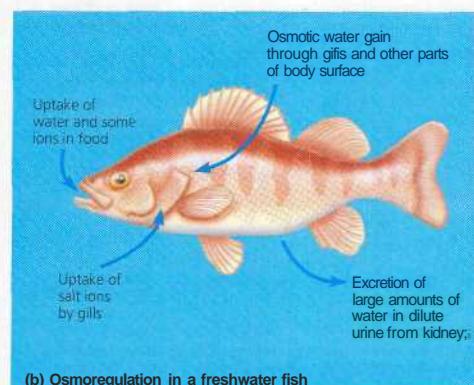

Freshwater Animals

The osmoregulatory problems of freshwater animals are opposite those of marine animals. Freshwater animals constantly gain water by osmosis and lose salts by diffusion because the osmolarity of their internal fluids is much higher than that of their surroundings. However, the body fluids of most freshwater animals do have lower solute concentrations compared to their marine relatives, an adaptation to their low-salinity freshwater habitat. For instance, whereas marine molluscs have body fluids with a solute concentration of approximately 1,000 mosm/L, some freshwater mussels maintain the solute concentration of their body fluids at about 40 mosm/L. The reduced osmotic difference between body fluids and the surrounding freshwater environment reduces the energy the animal expends for osmoregulation.

Many freshwater animals, including fishes such as perch, maintain water balance by excreting large amounts of very dilute urine. Salts lost by diffusion and in the urine are replenished by foods and by uptake across the gills; chloride cells in the gills actively transport Cl^- , and Na^+ follows (**Figure 44.3b**).

(a) Osmoregulation in a saltwater fish

(b) Osmoregulation in a freshwater fish

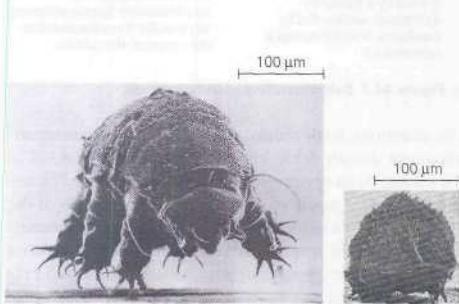

A **Figure 44.3** Osmoregulation in marine and freshwater bony fishes: a comparison.

salmon and other euryhaline fishes that migrate between seawater and fresh water undergo dramatic and rapid changes in osmoregulatory status. While in the ocean, salmon osmoregulate like other marine fishes by drinking seawater and excreting excess salt from the gills. When they migrate to fresh water, salmon cease drinking and begin to produce large amounts of dilute urine, and their gills start taking up salt from the dilute environment—just like fishes that spend their entire lives in fresh water.

Animals That Live in Temporary Waters

Dehydration is fatal for most animals, but some aquatic invertebrates living in temporary ponds and films of water around soil particles can lose almost all their body water and survive in a dormant state when their habitats dry up. This remarkable adaptation is called anhydrobiosis ("life without water"). Among the most striking examples are the tardigrades, or water bears, tiny invertebrates less than 1 mm long (**Figure 44.4**). In their active, hydrated state (see Figure 44.4a), these animals contain about 85% water by weight, but they can dehydrate to less than 2% water and survive in an inactive state (see Figure 44.4b), dry as dust, for a decade or more; just add water, and within minutes the rehydrated tardigrades are moving about and feeding.

Anhydrobiotic animals must have adaptations that keep their cells' membranes intact. Researchers are just beginning to learn how tardigrades survive drying out, but studies of anhydrobiotic roundworms (phylum Nematoda) show that dehydrated individuals contain large amounts of sugars. In particular, a disaccharide called trehalose seems to protect the cells by replacing the water that is normally associated with membranes and proteins. Many insects that survive freezing in the winter also utilize trehalose as a membrane protectant.

(a) Hydrated tardigrade

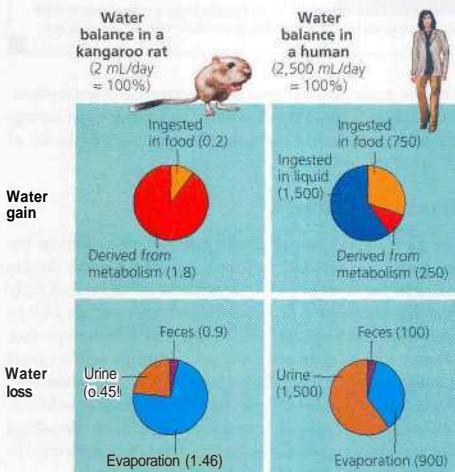

(b) Dehydrated tardigrade

A Figure 44.4 Anhydrobiosis. Tardigrades (water bears) inhabit temporary ponds and droplets of water in soil and on moist plants (SEM).

Land Animals

The threat of desiccation is a major regulatory problem for terrestrial plants and animals. Humans die if they lose about 12% of their body water; mammals that evolved in dry environments, such as camels, can withstand about twice that level of dehydration. Adaptations that reduce water loss are key to survival on land. Much as a waxy cuticle contributes to the success of land plants, most terrestrial animals have body coverings that help prevent dehydration. Examples are the waxy layers of insect exoskeletons, the shells of land snails, and the layers of dead, keratinized skin cells covering most terrestrial vertebrates. Many terrestrial animals, especially desert-dwellers, are nocturnal; this reduces evaporative water loss by taking advantage of the lower temperatures and higher relative humidity of night air.

Despite these adaptations, most terrestrial animals lose considerable water from moist surfaces in their gas exchange organs, in urine and feces, and across their skin. Land animals balance their water budgets by drinking and eating moist foods and by using metabolic water (water produced during cellular respiration). Some animals, such as many insect-eating desert birds and other reptiles, are so well adapted for minimizing water loss that they can survive in deserts without drinking. Kangaroo rats lose so little water that they can recover 90% of the loss by using metabolic water (**Figure 44.5**), gaining the remaining 10% from the small amount of water in their diet of

A Figure 44.5 Water balance in two terrestrial mammals. Kangaroo rats, which live in the American southwest, eat mostly dry seeds and do not drink water. A kangaroo rat loses water mainly by evaporation during gas exchange and gains water mainly from cellular metabolism. In contrast, a human loses a large amount of water in urine and regains it mostly in food and drink.

Figure 44.6

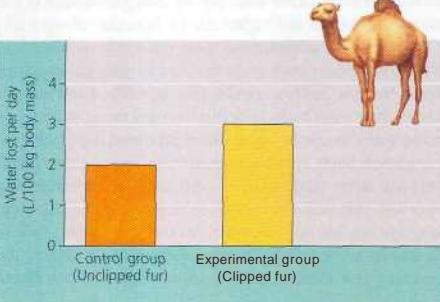

Inquiry What role does fur play in water conservation by camels?

EXPERIMENT

Knut and Bodil Schmidt-Nielsen and their colleagues from Duke University observed that the fur of camels exposed to full sun in the Sahara Desert could reach temperatures of over 70°C, while the animals' skin remained more than 30°C cooler. The Schmidt-Nielsens reasoned that insulation of the skin by fur may substantially reduce the need for evaporative cooling by sweating. To test this hypothesis, they compared the water loss rates of undipped and clipped camels.

RESULTS

Removing the fur of a camel increased the rate of water loss through sweating by up to 50%.

CONCLUSION

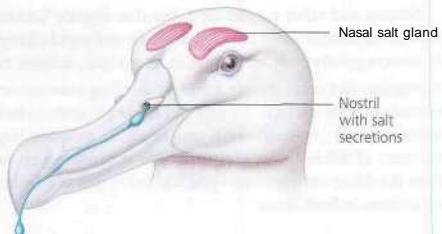

The fur of camels plays a critical role in their conserving water in the hot desert environments where they live.

seeds. In studying the adaptations of animals to desert environments, physiologists have discovered that major water savings can result from simple anatomical features, such as the fur of the camel (Figure 44.6).

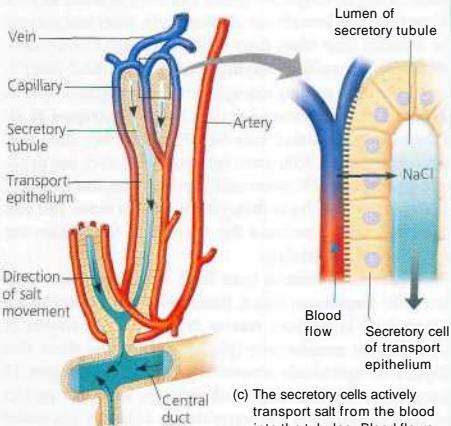

Transport Epithelia

The ultimate function of osmoregulation is to maintain the composition of cellular cytoplasm, but most animals do this indirectly by managing the composition of an internal body fluid that bathes the cells. In insects and other animals with an open circulatory system, this fluid is the hemolymph (see Chapter 42). In vertebrates and other animals with a closed circulatory system, the cells are bathed in an interstitial fluid that is controlled indirectly through the composition of blood. The maintenance of fluid composition depends on specialized structures ranging from cells that regulate solute movement to complex organs such as the vertebrate kidney.

In most animals, one or more different kinds of transport epithelia—a layer or layers of specialized epithelial cells that regulate solute movements—are essential components of osmotic regulation and metabolic waste disposal. Transport epithelia move specific solutes in controlled amounts in spe-

(a) An albatross's salt glands empty via a duct into the nostrils, and the salty solution either drips off the tip of the beak or is exhaled in a fine mist.

(b) One of several thousand secretory tubules in a salt-excreting gland. Each tubule is lined by a transport epithelium surrounded by capillaries, and drains into a central duct.

(c) The secretory cells actively transport salt from the blood into the tubules. Blood flows counter to the flow of salt secretion. By maintaining a concentration gradient of salt in the tubule (aqua), this countercurrent system enhances salt transfer from the blood to the lumen of the tube.

A Figure 44.7 Salt-excreting glands in birds.

cific directions. Some transport epithelia face the outside environment directly, while others line channels connected to the outside by an opening on the body surface, joined by impermeable tight junctions (see Figure 6.31), the cells of the epithelium form a barrier at the tissue-environment boundary. This arrangement ensures that any solutes moving between animal and environment must pass through a selectively permeable membrane.

In most animals, transport epithelia are arranged into complex tubular networks with extensive surface areas. We find some of the best examples in the salt glands of marine birds, which remove excess sodium chloride from the blood (Figure 44.7). For example, the albatross, which spends months or

years at sea and needs to obtain both food and water from the ocean, can drink seawater because its nasal salt glands secrete fluid much saltier than the ocean. Thus, even though drinking seawater brings in a lot of salt, the bird achieves a net gain of water. Humans who drink seawater, by contrast, must use more water to excrete the salt load than was gained by drinking.

The molecular structure of the plasma membrane determines the kinds and directions of solutes that move across a particular type of transport epithelium. In contrast to salt-excreting glands, transport epithelia in the gills of freshwater fishes use active transport to move salts from the dilute surrounding water into the blood. Transport epithelia in excretory organs often have the dual functions of maintaining water balance and disposing of metabolic wastes.

Concept Check 44.1

1. The movement of salt from the surrounding water to the blood of a freshwater fish requires the expenditure of energy in the form of ATP. Why?
2. Why are no freshwater animals osmoconformers?
3. How are sharks able to expend proportionately less energy for osmoregulation compared to marine bony fishes?

For suggested answers, see Appendix A.

Concept 44.2

An animal's nitrogenous wastes reflect its phylogeny and habitat

Because most metabolic wastes must be dissolved in water when they are removed from the body, the type and quantity of an animal's waste products may have a large impact on its water balance. In terms of their effect on osmoregulation, among the most important waste products are the nitrogenous (nitrogen-containing) breakdown products of proteins and nucleic acids (**Figure 44.8**). When these macromolecules are broken apart for energy or converted to carbohydrates or fats, enzymes remove nitrogen in the form of ammonia (NH_3), a very toxic molecule. Some animals excrete ammonia directly, in many species first convert the ammonia to other compounds that are less toxic but that require energy in the form of ATP to produce.

Forms of Nitrogenous Waste

Different animals excrete nitrogenous wastes in different forms—ammonia, urea, or uric acid—which vary in their toxicity and energy costs.

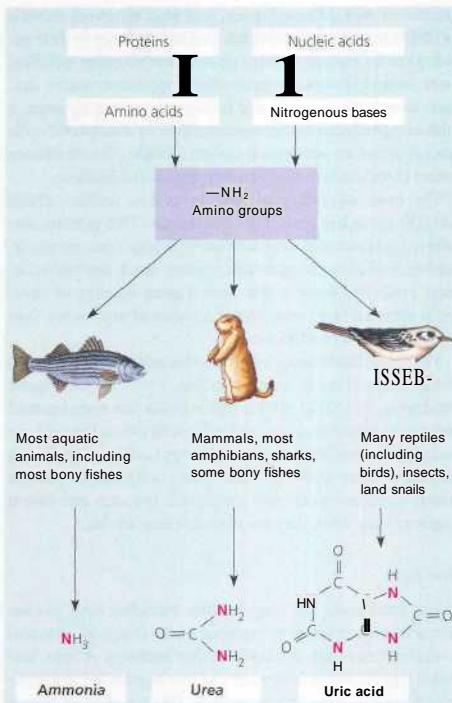

Figure 44.8 Nitrogenous wastes.

Ammonia

Because ammonia is very soluble but can only be tolerated at very low concentrations, animals that excrete nitrogenous wastes as ammonia need access to lots of water. Therefore, ammonia excretion is most common in aquatic species. Ammonia molecules easily pass through membranes and are readily lost by diffusion to the surrounding water. In many invertebrates, ammonia release occurs across the whole body surface. In fishes, most of the ammonia is lost as ammonium ions (NH_4^+) across the epithelium of the gills, with kidneys excreting only minor amounts of nitrogenous wastes. In freshwater fishes, the gill epithelium takes up Na^+ from the water in exchange for NH_4^+ , which helps to maintain a much higher Na^+ concentration in body fluids than in the surrounding water.

Urea

Although it works well in many aquatic species, ammonia excretion is much less suitable for land animals. Because ammonia is so toxic, it can be transported and excreted only in large

volumes of very dilute solutions, and most terrestrial animals and many marine species (which tend to lose water to their environment by osmosis) simply do not have access to sufficient water. Instead, mammals, most adult amphibians, sharks, and some marine bony fishes and turtles excrete mainly urea, a substance produced in the vertebrate liver by a metabolic cycle that combines ammonia with carbon dioxide. The circulatory system carries urea to the excretory organs, the kidneys.

The main advantage of urea is its low toxicity, about 100,000 times less than that of ammonia. This permits animals to transport and store urea safely at high concentrations. Further, a urea-excreting animal requires much less water, because much less water is lost when a given quantity of nitrogen is excreted in a concentrated solution of urea rather than a dilute solution of ammonia.

The main disadvantage of urea is that animals must expend energy to produce it from ammonia. From a bioenergetic standpoint, we would predict that animals that spend part of their lives in water and part on land would switch between excreting ammonia (thereby saving energy) and urea (reducing excretory water loss). In fact, many amphibians excrete mainly ammonia when they are aquatic tadpoles and switch largely to urea when they are land-dwelling adults.

Uric Acid

Insects, land snails, and many reptiles, including birds, excrete uric acid as their major nitrogenous waste. Like urea, uric acid is relatively nontoxic. But unlike either ammonia or urea, uric acid is largely insoluble in water and can be excreted as a semi-solid paste with very little water loss. This is a great advantage for animals with little access to water, but there is a cost: Uric acid is even more energetically expensive to produce than urea, requiring considerable ATP for synthesis from ammonia.

The Influence of Evolution and Environment on Nitrogenous Wastes

In general, the kinds of nitrogenous wastes excreted depend on an animal's evolutionary history and habitat—especially the availability of water (see Figure 44.8). For example, uric acid and urea represent different adaptations for excreting nitrogenous wastes with minimal water loss. One factor that seems to have been important in determining which of these alternatives evolved in a particular group of animals is the mode of reproduction. Soluble wastes can diffuse out of a shell-less amphibian egg or be carried away by the mother's blood in a mammalian embryo. However, the shelled eggs produced by birds and other reptiles are permeable to gases but not to liquids, which means that soluble nitrogenous wastes released by an embryo would be trapped within the egg and could accumulate to dangerous levels (although urea is much less harmful than ammonia, it does become toxic at very high concentrations). The evolution of uric acid as a

waste product conveyed a selective advantage because it precipitates out of solution and can be stored within the egg as a harmless solid left behind when the animal hatches.

The type of nitrogenous waste produced by vertebrates depends on habitat as well as on evolutionary lineage. For example, terrestrial turtles (which often live in dry areas) excrete mainly uric acid, whereas aquatic turtles excrete both urea and ammonia. In some species, individuals can change forms of nitrogenous wastes when environmental conditions change. For example, certain tortoises that usually produce urea shift to uric acid when temperature increases and water becomes less available. This is another example of how response to the environment occurs on two levels: Over generations, evolution determines the limits of physiological responses for a species, but during their lives, individual organisms make physiological adjustments within these evolutionary constraints.

The amount of nitrogenous waste produced is coupled to the energy budget, as it strongly depends on how much and what kind of food an animal eats. Because they use energy at high rates, endotherms eat more food—and therefore produce more nitrogenous wastes—per unit volume than ectotherms. Predators, which derive much of their energy from dietary proteins, excrete more nitrogen than animals that rely mainly on lipids or carbohydrates as energy sources.

Concept Check 44.2

- Dragonfly larvae, which are aquatic, excrete ammonia, whereas adult dragonflies, which are terrestrial, excrete uric acid. Explain.
- What role does the vertebrate liver play in the body's processing of nitrogenous waste?
- What advantage does uric acid offer as a nitrogenous waste in arid environments?

For suggested answers, see Appendix A.

Concept 44.3

Diverse excretory systems are variations on a tubular theme

Although the problems of water balance are very different on land, in salt water, and in fresh water, solving them all depends on the regulation of solute movement between internal fluids and the external environment. Much of this movement is handled by excretory systems, which are central to homeostasis because they dispose of metabolic wastes and control body fluid composition by adjusting rates of solute loss. Before we describe particular excretory systems, let's consider the basic process of excretion.

Excretory Processes

Although excretory systems are diverse, nearly all produce the fluid waste urine in a process that involves several steps (Figure 44.9). First, body fluid (blood, coelomic fluid, or hemolymph) is collected. The initial fluid collection usually involves **filtration** through selectively permeable membranes consisting of a single layer of transport epithelium. These membranes retain cells as well as proteins and other large molecules in the body fluid; hydrostatic pressure (blood pressure in many animals) forces water and small solutes, such as salts, sugars, amino acids, and nitrogenous wastes, into the excretory system. This fluid is called the filtrate.

Even when filtration occurs, fluid collection is largely non-selective; thus, it is important that essential small molecules are recovered from the filtrate and returned to the body fluids. In the second step of the process, selective reabsorption, excretory systems use active transport to reabsorb valuable solutes such as glucose, certain salts, and amino acids from the filtrate. Nonessential solutes and wastes (for example, excess salts and toxins) are left in the filtrate or are added to it by selective secretion, which also uses active transport. The pumping of various solutes also adjusts the osmotic movement

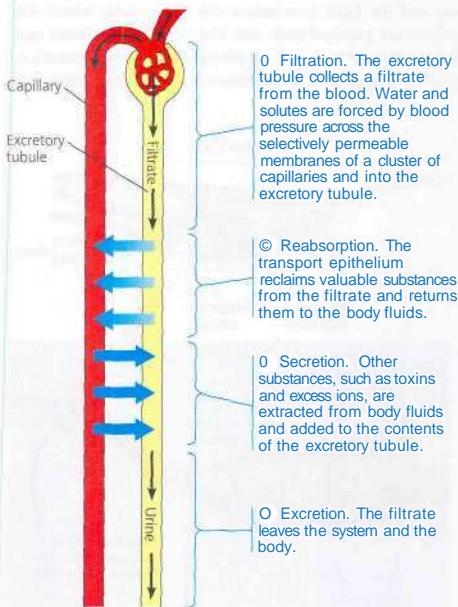

of water into or out of the filtrate. The processed filtrate is then excreted from the system and from the body as urine.

Survey of Excretory Systems

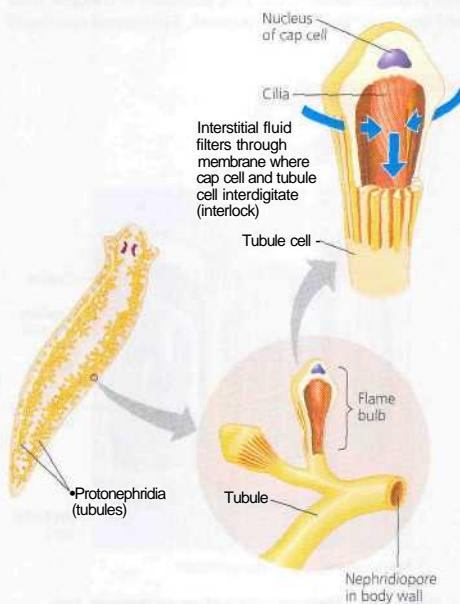

The systems that perform basic excretory functions vary widely among animal groups. However, they are generally built on a complex network of tubules that provide a large surface area for the exchange of water and solutes, including nitrogenous wastes.

Protonephridia: Flame-Bulb Systems

Flatworms (phylum Platyhelminthes) have excretory systems called protonephridia (singular, *protonephridium*). A protonephridium is a network of dead-end tubules lacking internal openings. As shown in Figure 44.10, the tubules branch throughout the body, and the smallest branches are capped by a cellular unit called a flame bulb. The flame bulb has a tuft of cilia projecting into the tubule. (The beating cilia resemble a flickering flame, hence, the name flame bulb.) The beating of the cilia draws water and solutes from the interstitial fluid through the flame bulb (filtration) into the tubule system and then moves the urine outward through the tubules until they empty to the external environment through openings called

▲ **Figure 44.9 Key functions of excretory systems: an overview.** Most excretory systems produce a filtrate by pressure-filtering body fluids and then modify the filtrate's contents. This diagram is modeled after the vertebrate excretory system.

▲ **Figure 44.10 Protonephridia: the flame-bulb system of a planarian.** Protonephridia are branching internal tubules that function mainly in osmoregulation.

volumes of very dilute solutions, and most terrestrial animals and many marine species (which tend to lose water to their environment by osmosis) simply do not have access to sufficient

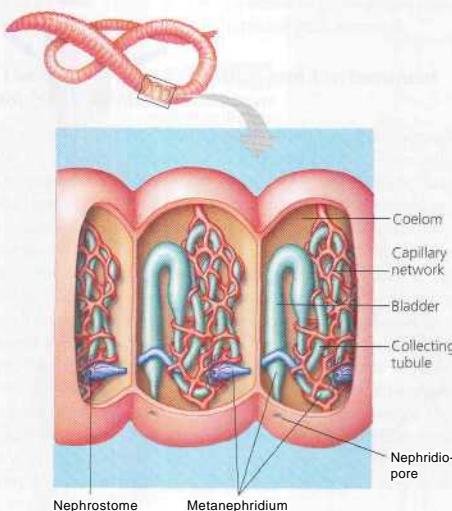

waste product conveyed a selective advantage because it precipitates out of solution and can be stored within the egg as a harmless solid left behind when the animal hatches.

nephridiopores. Excreted urine is very dilute in freshwater flatworms, helping balance the osmotic uptake of water from the environment. Apparently, the tubules reabsorb most solutes before the urine exits the body.

The flame-bulb systems of freshwater flatworms seem to function mainly in osmoregulation; most metabolic wastes diffuse out of the animal across the body surface or are excreted into the gastrovascular cavity and eliminated through the mouth (see Figure 33.10). However, in some parasitic flatworms, which are isoosmotic to the surrounding fluids of their host organisms, protonephridia mainly dispose of nitrogenous wastes. This difference in function shows how structures common to a group of organisms can be adapted in diverse ways by evolution in different environments. Protonephridia are also found in rotifers, some annelids, the larvae of molluscs, and lancelets, which are invertebrate chordates. (See Chapters 33 and 34 to review these animal phyla.)

Metanephridia

Another type of tubular excretory system, metanephridia (singular, *metanephridium*), has internal openings that collect body fluids (Figure 44.11). Metanephridia are found in most annelids, including earthworms. Each segment of a worm has a pair of metanephridia, which are immersed in coelomic fluid and enveloped by a capillary network. The internal opening of

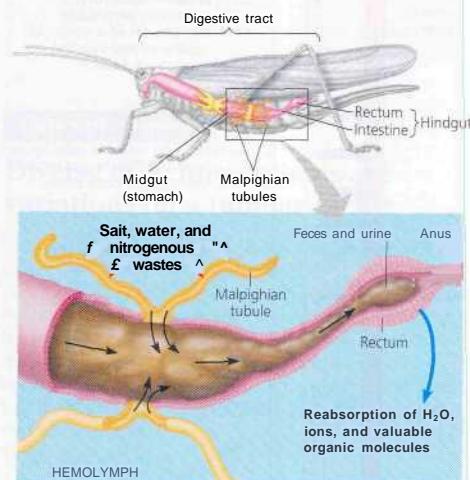

A Figure 44.11 Metanephridia of an earthworm. Each segment of the worm contains a pair of metanephridia, which collect coelomic fluid from the adjacent anterior segment. (Only one metanephridium of each pair is shown here.)

a metanephridium is surrounded by a ciliated funnel, the nephrostome. Fluid enters the nephrostome and passes through a coiled collecting tubule, which includes a storage bladder that opens to the outside through the nephridiopore.

An earthworm's metanephridia have both excretory and osmoregulatory functions. As urine moves along the tubule, the transport epithelium bordering the lumen reabsorbs most solutes and returns them to the blood in the capillaries. Nitrogenous wastes remain in the tubule and are excreted to the outside. Earthworms inhabit damp soil and usually experience a net uptake of water by osmosis through the skin. Their metanephridia balance the water influx by producing dilute urine (hypotonic to the body fluids).

Malpighian Tubules

Insects and other terrestrial arthropods have organs called Malpighian tubules that remove nitrogenous wastes and also function in osmoregulation (Figure 44.12). The malpighian tubules open into the digestive tract and dead-end at tips that are immersed in hemolymph (circulatory fluid). The transport epithelium lining the tubules secretes certain solutes, including nitrogenous wastes, from the hemolymph into the lumen of the tubule. Water follows the solutes into the tubule by osmosis, and the fluid then passes into the rectum, where most solutes are pumped back into the hemolymph. Water again follows the solutes, and the nitrogenous wastes—mainly insoluble uric acid—are eliminated as nearly dry matter along

A Figure 44.12 Malpighian tubules of insects. Malpighian tubules are outpocketings of the digestive tract that remove nitrogenous wastes and function in osmoregulation.

with the feces. Highly effective in conserving water, the insect excretory system is one of several key adaptations contributing to the tremendous success of these animals on land.

Vertebrate Kidneys

The kidneys of vertebrates usually function in both osmoregulation and excretion. Like the excretory organs of most animal phyla, kidneys are built of tubules. Since the osmoconforming hagfishes, which are not vertebrates but are among the most primitive living chordates, have kidneys with segmentally arranged excretory tubules, it is likely that the excretory structures of vertebrate ancestors were segmented. The kidneys of most vertebrates, however, are compact, nonsegmented organs containing numerous tubules arranged in a highly organized manner. A dense network of capillaries intimately associated with the tubules is also an integral part of the vertebrate excretory system, as are the ducts and other structures that carry urine out of the tubules and kidney and eventually out of the body.

In the next two sections, we will focus on the mammalian excretory system, using humans as our primary example. We will then end the chapter by comparing the excretory organs of the various vertebrate classes to see how evolutionary modifications function in different environments.

Concept Check 44.3

1. What are the fundamental processes involved in all excretory systems, regardless of their anatomical differences or evolutionary origins?
2. Describe some advantages of an excretory system built around a network of fine tubules.

for suggested answers, see Appendix A.

Concept 44.4

Nephrons and associated blood vessels are the functional units of the mammalian kidney

The excretory system of mammals centers on the kidneys, which are also the principal site of water balance and salt regulation. Mammals have a pair of kidneys. Each kidney, bean-shaped and about 10 cm long in humans, is supplied with blood by a renal artery and drained by a renal vein (Figure 44.13a, on the following page). Blood flow through the kidneys is voluminous. In humans, the kidneys account for less than 1% of body weight, but they receive about 20% of resting cardiac output. Urine exits each kidney through a duct called the ureter, and both ureters drain into a common

urinary bladder. During urination, urine is expelled from the urinary bladder through a tube called the urethra, which empties to the outside near the vagina in females or through the penis in males. Sphincter muscles near the junction of the urethra and the bladder, which are under nervous system control, regulate urination.

Structure and Function of the Nephron and Associated Structures

The mammalian kidney has two distinct regions, an outer renal cortex and an inner renal medulla (Figure 44.13b). Packing both regions are microscopic excretory tubules and their associated blood vessels. The nephron—the functional unit of the vertebrate kidney—consists of a single long tubule and a ball of capillaries called the glomerulus (Figure 44.13c and d). The blind end of the tubule forms a cup-shaped swelling, called Bowman's capsule, which surrounds the glomerulus. Each human kidney contains about a million nephrons, with a total tubule length of 80 km.

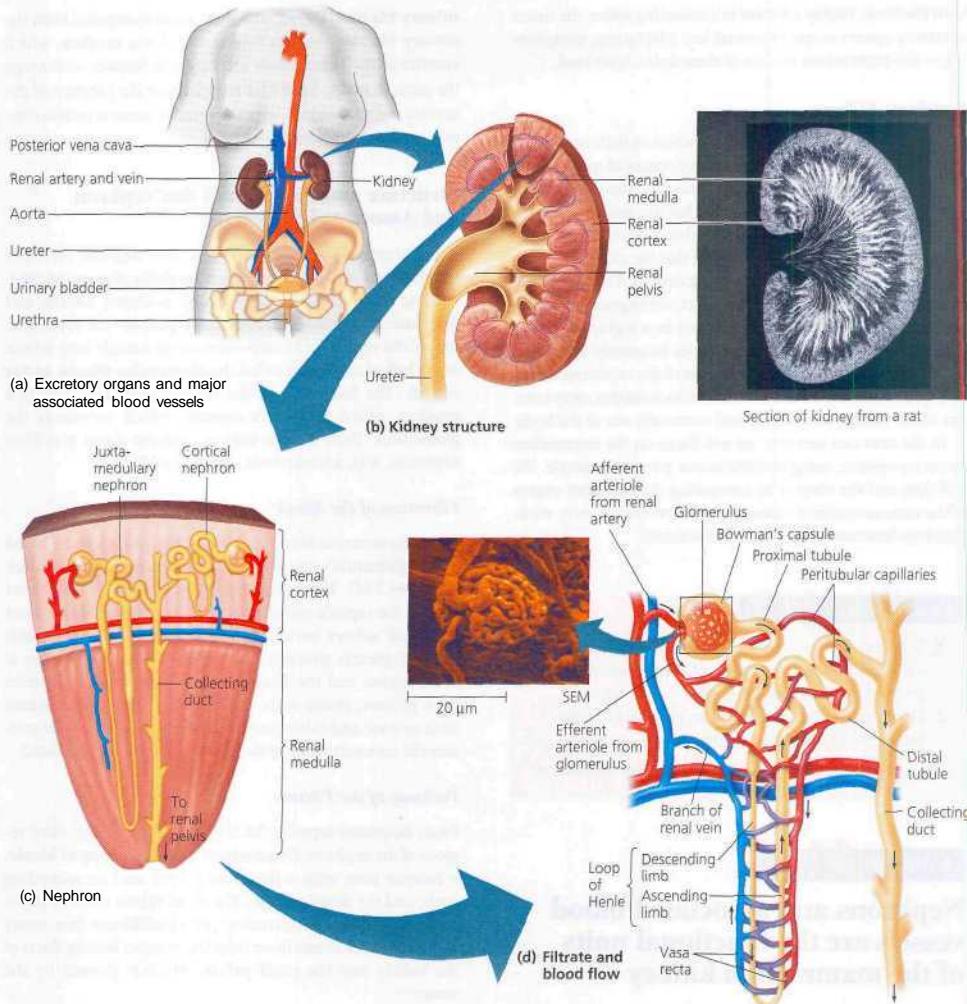

Filtration of the Blood

Filtration occurs as blood pressure forces fluid from the blood in the glomerulus into the lumen of Bowman's capsule (see Figure 44.13d). The porous capillaries, along with specialized cells of the capsule called podocytes, are permeable to water and small solutes but not to blood cells or large molecules such as plasma proteins. Filtration of small molecules is nonselective, and the filtrate in Bowman's capsule contains salts, glucose, amino acids, and vitamins; nitrogenous wastes such as urea; and other small molecules—a mixture that mirrors the concentrations of these substances in blood plasma.

Pathway of the Filtrate

From Bowman's capsule, the filtrate passes through three regions of the nephron: the proximal tubule; the loop of Henle, a hairpin turn with a descending limb and an ascending limb; and the distal tubule. The distal tubule empties into a collecting duct, which receives processed filtrate from many nephrons. This filtrate flows from the many collecting ducts of the kidney into the renal pelvis, which is drained by the ureter.

In the human kidney, approximately 80% of the nephrons, the cortical nephrons, have reduced loops of Henle and are almost entirely confined to the renal cortex. The other 20%, the juxtamedullary nephrons, have well-developed loops that extend deeply into the renal medulla. Only mammals and birds have juxtamedullary nephrons; the nephrons of other vertebrates lack loops of Henle. It is the juxtamedullary nephrons that enable mammals to produce urine that is hyperosmotic to body fluids, an adaptation that is extremely important for water conservation.

A Figure 44.13 The mammalian excretory system.

The nephron and the collecting duct are lined by a transport epithelium that processes the filtrate to form the urine. One of this epithelium's most important tasks is reabsorption of solutes and water. Between 1,100 and 2,000 L of blood flows through a pair of human kidneys each day a volume about 275 times the total volume of blood in the body. From

this enormous traffic of blood, the nephrons and collecting ducts process about 180 L of initial filtrate, equivalent to two or three times the body weight of an average person. Of this, nearly all of the sugar, vitamins, and other organic nutrients and about 99% of the water are reabsorbed into the blood, leaving only about 1.5 L of urine to be voided.

Blood Vessels Associated with the Nephrons

Each nephron is supplied with blood by an afferent arteriole, a branch of the renal artery that subdivides into the capillaries of the glomerulus (see Figure 44.13d). The capillaries converge as they leave the glomerulus, forming an efferent arteriole. This vessel subdivides again, forming the peritubular capillaries, which surround the proximal and distal tubules. More capillaries extend downward and form the vasa recta, the capillaries that serve the loop of Henle. The vasa recta also form a loop, with descending and ascending vessels conveying blood in opposite directions.

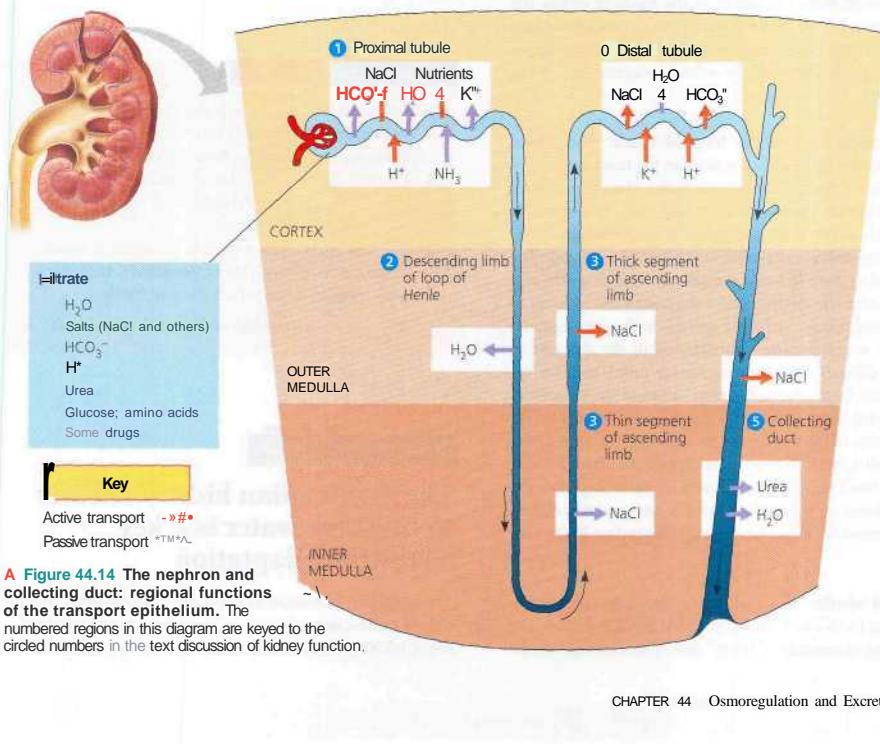

Although the excretory tubules and their surrounding capillaries are closely associated, they do not exchange materials directly. The tubules and capillaries are immersed in interstitial fluid, through which various substances diffuse between the plasma within capillaries and the filtrate within the nephron tube. This exchange is facilitated by the relative direction of blood flow and filtrate flow in the nephrons.

From Blood Filtrate to Urine: A Closer Look

In this section we will concentrate on how the filtrate becomes urine as it flows through the mammalian nephron and col-

lecting duct. The circled numbers correspond to the numbers in Figure 44.14.

O Proximal tubule. Secretion and reabsorption in the proximal tubule substantially alter the volume and composition of filtrate. For example, the cells of the transport epithelium help maintain a relatively constant pH in body fluids by the controlled secretion of H^+ . The cells also synthesize and secrete ammonia, which neutralizes the acid and keeps the filtrate from becoming too acidic. The more acidic the filtrate, the more ammonia the cells produce and secrete, and the urine of a mammal usually contains some ammonia from this source (even though most nitrogenous waste is excreted as urea). The proximal tubules also reabsorb about 90% of the important buffer bicarbonate (HCO_3^-). Drugs and other poisons that have been processed in the liver pass from the peritubular capillaries into the interstitial fluid, and then are secreted across the epithelium of the proximal tubule into the nephron's lumen. Conversely, valuable nutrients, including glucose, amino acids, and potassium (K^+), are actively or passively transported from the filtrate to the interstitial fluid and then are moved into the peritubular capillaries.

One of the most important functions of the proximal tubule is reabsorption of most of the NaCl (salt) and water from the huge initial filtrate volume. Salt in the filtrate diffuses into the cells of the transport epithelium, and the membranes of the cells actively transport Na^+ into the interstitial fluid. This transfer of positive charge is balanced by the passive transport of Cl^- out of the tubule. As salt moves from the filtrate to the interstitial fluid, water follows by osmosis. The exterior side of the epithelium has a much smaller surface area than the side facing the lumen, minimizing leakage of salt and water back into the tubule. Instead, the salt and water now diffuse from the interstitial fluid into the peritubular capillaries.

© **Descending limb of the loop of Henle.** Reabsorption of water continues as the filtrate moves into the descending limb of the loop of Henle. Here the transport epithelium is freely permeable to water but not very permeable to salt and other small solutes. For water to move out of the tubule by osmosis, the interstitial fluid bathing the tubule must be hyperosmotic to the filtrate. The osmolarity of the interstitial fluid does in fact become progressively greater from the outer cortex to the inner medulla of the kidney. Thus, filtrate moving downward from the cortex to the medulla within the descending limb of the loop of Henle continues to lose water to interstitial fluid of greater and greater osmolarity, which increases the solute concentration of the filtrate.

© **Ascending limb of the loop of Henle.** The filtrate reaches the tip of the loop, deep in the renal medulla in the case of juxamedullary nephrons, then moves back to the cortex within the ascending limb. In contrast to the descending limb, the transport epithelium of the ascending limb is permeable to salt but not to water. The ascending limb has two specialized regions: a thin segment near the loop tip and a thick segment adjacent to the distal tubule. As filtrate ascends in the thin segment, NaCl, which became concentrated in the descending limb, diffuses out of the permeable tubule into the interstitial fluid. This movement increases the osmolarity of the interstitial fluid in the medulla. The exodus of salt from the filtrate continues in the thick segment of the ascending limb, but here the epithelium actively transports NaCl into the interstitial fluid. By losing salt without giving up water, the filtrate is progressively diluted as it moves up to the cortex in the ascending limb of the loop.

0 **Distal tubule.** The distal tubule plays a key role in regulating the K^+ and NaCl concentration of body fluids by varying the amount of the K^+ that is secreted into the fil-

trate and the amount of NaCl reabsorbed from the filtrate. Like the proximal tubule, the distal tubule also contributes to pH regulation by the controlled secretion of H^+ and reabsorption of bicarbonate (HCO_3^-).

@ **Collecting duct.** The collecting duct carries the filtrate through the medulla to the renal pelvis. By actively reabsorbing NaCl, the transport epithelium of the collecting duct plays a large role in determining how much salt is actually excreted in the urine. Though its degree of permeability is under hormonal control, the epithelium is permeable to water. However, it is not permeable to salt or, in the renal cortex, to urea. Thus, as the collecting duct traverses the gradient of osmolarity in the kidney, the filtrate becomes increasingly concentrated as it loses more and more water by osmosis to the hyperosmotic interstitial fluid. In the inner medulla, the duct becomes permeable to urea. Because of the high urea concentration in the filtrate at this point, some urea diffuses out of the duct and into the interstitial fluid. Along with NaCl, this urea contributes to the high osmolarity of the interstitial fluid in the medulla. This high osmolarity enables the mammalian kidney to conserve water by excreting urine that is hyperosmotic to the general body fluids.

Concept Check 44.4

- How would a decrease in blood pressure in the afferent arteriole leading to a glomerulus affect the rate of filtration of blood within Bowman's capsule?
- A variety of drugs make the epithelium of the collecting duct less permeable to water. How would this affect kidney function?
- List these parts of a nephron in the order in which filtrate moves through them: proximal tubule, Bowman's capsule, distal tubule, loop of Henle

For suggested answers, see Appendix A.

Concept 44.5

The mammalian kidney's ability to conserve water is a key terrestrial adaptation

The osmolarity of human blood is about 300 mosm/L, but the kidney can excrete urine up to four times as concentrated—about 1,200 mosm/L. Some mammals can do even better. For

example, Australian hopping mice, which live in dry desert regions, can produce urine concentrated to 9,300 mosm/L—9 times as concentrated as seawater and 25 times as concentrated as the animal's body fluid.

Solute Gradients and Water Conservation

In a mammalian kidney, the cooperative action and precise arrangement of the loops of Henle and the collecting ducts are largely responsible for the osmotic gradient that concentrates the urine. But even with this highly organized structure, the maintenance of osmotic differences and the production of hyperosmotic urine are possible only because considerable energy is expended for the active transport of solutes against concentration gradients. In essence, the nephrons—especially the loops of Henle—can be thought of as tiny energy-consuming machines whose function is to produce a region of high osmolarity in the kidney, which can then be used to extract water from the filtrate in the collecting duct. The two primary solutes in this osmolarity gradient are NaCl, which is deposited in the renal medulla by the loop of Henle, and urea, which leaks across the epithelium of the collecting duct in the inner medulla (see Figure 44.14).

To better understand the physiology of the mammalian kidney as a water-conserving organ, let's retrace the flow of filtrate through the excretory tubule, this time focusing on how the juxtamedullary nephrons maintain an osmolarity gradient in the kidney and use that gradient to excrete a hyperosmotic urine (Figure 44.15). Filtrate passing from Bowman's capsule to the proximal tubule has an osmolarity of about 300 mosm/L, the same as blood. As the filtrate flows through the proximal tubule in the renal cortex, a large amount of water and salt is reabsorbed; thus, the volume of filtrate decreases substantially, but because of the salt loss, its osmolarity remains about the same.

As the filtrate flows from cortex to medulla in the descending limb of the loop of Henle, water leaves the tubule by osmosis, and osmolarity of the filtrate increases as solutes, including NaCl, become more concentrated. The highest osmolarity (about 1,200 mosm/L) occurs at the elbow of the loop of Henle. This maximizes the diffusion of salt out of the

tubule as the nitrate rounds the curve and enters the ascending limb, which, remember, is permeable to salt but not to water. Thus, the two limbs of the loop of Henle cooperate in maintaining the gradient of osmolarity in the interstitial fluid of the kidney. The descending limb produces a progressively saltier filtrate, and then NaCl diffuses from the ascending limb to help maintain a high osmolarity in the interstitial fluid of the renal medulla.

Notice that the loop of Henle has several qualities of a countercurrent system, similar in principle to the countercurrent mechanisms that maximize oxygen absorption by fish gills (see Figure 42.21) or reduce heat loss in endotherms (see Figure 40.15). In these cases, the countercurrent mechanisms involve passive movement along either an oxygen concentration gradient or a heat gradient. In contrast, the countercurrent system involving the loop of Henle expends energy to

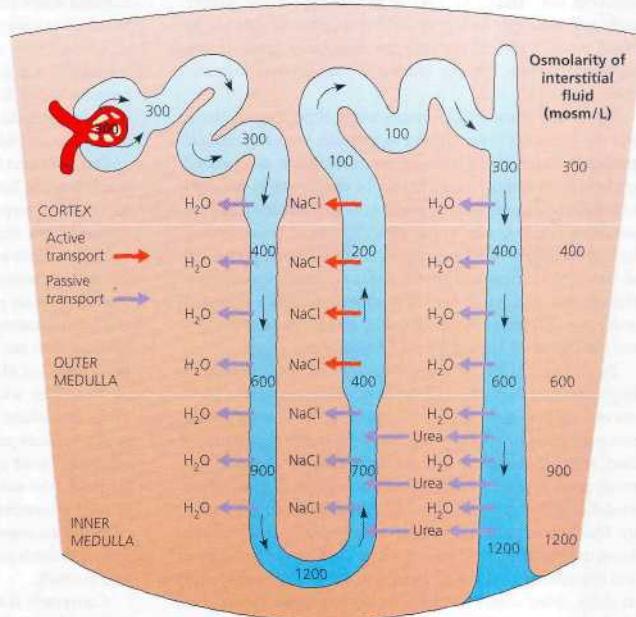

Figure 44.15 How the human kidney concentrates urine: the two-solute model. Two solutes contribute to the osmolarity of the interstitial fluid: NaCl and urea. The loop of Henle maintains the interstitial gradient of NaCl, which increases in the descending limb and decreases in the ascending limb. Urea diffuses into the interstitial fluid of the medulla from the collecting duct (most of the urea in the filtrate remains in the collecting duct and is excreted). The filtrate moves first down, then up, and then down again in the collecting duct. As the filtrate flows in the collecting duct past interstitial fluid of increasing osmolarity, more water moves out of the duct by osmosis, thereby concentrating the solutes, including urea, that are left behind in the filtrate.

actively transport NaCl from the filtrate in the upper part of the ascending limb of the loop. Such countercurrent systems, which expend energy to create concentration gradients, are called **countercurrent multiplier systems**. The countercurrent multiplier system involving the loop of Henle maintains a high salt concentration in the interior of the kidney, enabling the kidney to form concentrated urine.

What prevents the capillaries of the vasa recta from dissipating the gradient by carrying away the high concentration of NaCl in the medulla's interstitial fluid? Notice in Figure 44.13 that the vasa recta is also a countercurrent system, with descending and ascending vessels carrying blood in opposite directions through the kidney's osmolarity gradient. As the descending vessel conveys blood toward the inner medulla, water is lost from the blood and NaCl diffuses into it. These fluxes are reversed as blood flows back toward the cortex in the ascending vessel, with water reentering the blood and salt diffusing out. Thus, the vasa recta can supply the kidney with nutrients and other important substances carried by blood without interfering with the osmolarity gradient that makes it possible for the kidney to excrete hyperosmotic urine.

The countercurrent-like characteristics of the loop of Henle and the vasa recta make it easier to maintain the steep osmotic gradient between the medulla and cortex. However, any osmotic gradient in an animal will eventually be eliminated by diffusion unless energy is expended to preserve it. In the kidney, this expenditure largely occurs in the thick segment of the ascending limb of the loop of Henle, where NaCl is actively transported out of the tubule. Even with the benefits of countercurrent exchange, this process—along with other renal active transport systems—consumes considerable ATP, and for its size, the kidney has one of the highest metabolic rates of any organ.

By the time the filtrate reaches the distal tubule, it is actually hypoosmotic to body fluids because of active transport of NaCl out of the thick segment of the ascending limb. Now the filtrate descends again toward the medulla, this time in the collecting duct, which is permeable to water but not to salt. Therefore, osmosis extracts water from the filtrate as it passes from cortex to medulla and encounters interstitial fluid of increasing osmolarity. This concentrates salt, urea, and other solutes in the filtrate. Some urea leaks out of the lower portion of the collecting duct and contributes to the high interstitial osmolarity of the inner medulla. (This urea is recycled by diffusion into the loop of Henle, but continual leakage from the collecting duct maintains a high interstitial urea concentration.) Before leaving the kidney, the urine may attain the osmolarity of the interstitial fluid in the inner medulla, which can be as high as 1,200 mosm/L. Although *isoosmotic* to the inner medulla's interstitial fluid, the urine is *hyperosmotic* to blood and interstitial fluid elsewhere in the body. This high osmolarity allows the solutes remaining in the urine to be excreted from the body with minimal water loss.

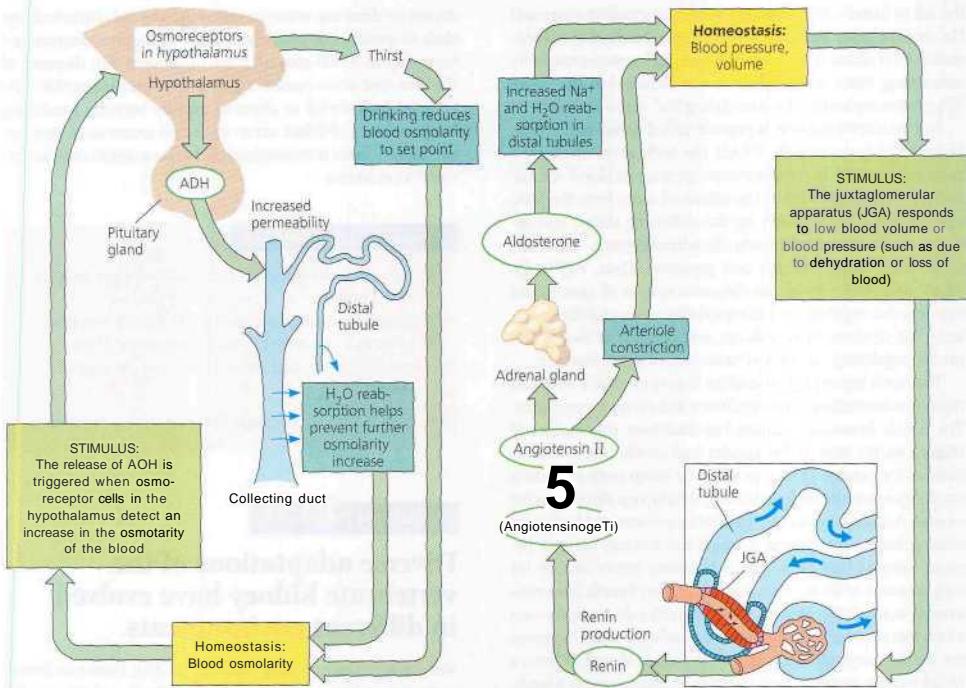

The juxtapamedullary nephron, with its urine-concentrating features, is a key adaptation to terrestrial life, enabling mammals to get rid of salts and nitrogenous wastes without squandering water. As we have seen, the remarkable ability of the mammalian kidney to produce hyperosmotic urine is completely dependent on the precise arrangement of the tubules and collecting ducts in the renal cortex and medulla. In this respect, the kidney is one of the clearest examples of how the function of an organ is inseparably linked to its structure.

Regulation of Kidney Function

One of the most important aspects of the mammalian kidney is its ability to adjust both the volume and osmolarity of urine, depending on the animal's water and salt balance and the rate of urea production. In situations of high salt intake and low water availability, a mammal can excrete urea and salt with minimal water loss in small volumes of hyperosmotic urine. But if salt is scarce and fluid intake is high, the kidney can get rid of the excess water with little salt loss by producing large volumes of hypoosmotic urine (as dilute as 70 mosm/L, compared to about 300 mosm/L for human blood). This versatility in osmoregulatory function is managed with a combination of nervous and hormonal controls.

One hormone that is important in regulating water balance is antidiuretic hormone (ADH) (**Figure 44.16a**). ADH is produced in the hypothalamus of the brain and is stored in and released from the posterior pituitary gland, which is positioned just below the hypothalamus. Osmoreceptor cells in the hypothalamus monitor the osmolarity of blood; when it rises above a set point of 300 mosm/L (perhaps due to water loss from sweating or to ingestion of salty food), more ADH is released into the bloodstream and reaches the kidney. The main targets of ADH are the distal tubules and collecting ducts of the kidney, where the hormone increases the permeability of the epithelium to water. This amplifies water reabsorption, which reduces urine volume and helps prevent further increase of blood osmolarity above the set point. By negative feedback, the subsiding osmolarity of the blood reduces the activity of osmoreceptor cells in the hypothalamus, and less ADH is then secreted. But only the gain of additional water in food and drink can bring osmolarity all the way back down to 300 mosm/L.

Conversely, if a large intake of water has reduced blood osmolarity below the set point, very little ADH is released. This decreases the permeability of the distal tubules and collecting ducts, so water reabsorption is reduced, resulting in increased discharge of dilute urine. (Increased urination is called diuresis, and it is because ADH opposes this state that it is called antidiuretic hormone.) Alcohol can disturb water balance by inhibiting the release of ADH, causing excessive urinary water loss and dehydration (which may cause some of the symptoms of a hangover). Normally, blood osmolarity, ADH

A **Figure 44.16** Hormonal control of the kidney by negative feedback circuits.

please, and water reabsorption in the kidney are all linked in a feedback loop that contributes to homeostasis.

A second regulatory mechanism involves a specialized tissue called the **juxtaglomerular apparatus (JGA)**, located near the afferent arteriole that supplies blood to the glomerulus (**Figure 44.16b**). When blood pressure or blood volume in the afferent arteriole drops (for instance, as a result of reduced salt intake or loss of blood), the enzyme renin initiates chemical reactions that convert a plasma protein called angiotensinogen to a peptide called **angiotensin II**. Functioning as a hormone, angiotensin II raises blood pressure by constricting arterioles, decreasing blood flow to many capillaries, including those of the kidney. Angiotensin II also stimulates the proximal tubules of the nephrons to reabsorb more NaCl and water. This reduces the amount of salt and water excreted in the urine and consequently raises blood volume and pressure. Another effect of angiotensin II is stimulation of the adrenal glands to release a hormone called **aldosterone**. This hormone acts on the

nephrons' distal tubules, making them reabsorb more sodium (Na^+) and water and increasing blood volume and pressure. In summary, the **renin-angiotensin-aldosterone system (RAAS)** is part of a complex feedback circuit that functions in homeostasis. A drop in blood pressure and blood volume triggers renin release from the JGA. In turn, the rise in blood pressure and volume resulting from the various actions of angiotensin II and aldosterone reduce the release of renin.

The functions of ADH and the RAAS may seem to be redundant, but this is not the case. Both increase water reabsorption, but they counter different osmoregulatory problems. The release of ADH is a response to an increase in the osmolarity of the blood, as when the body is dehydrated from excessive water loss or inadequate intake of water. However, a situation that causes an excessive loss of both salt and body fluids—an injury, for example, or severe diarrhea—will reduce blood volume *without* increasing osmolarity. This will not induce a change in ADH release, but the RAAS will respond to

the fall in blood volume and pressure by increasing water and Na^+ reabsorption. ADH and the RAAS are partners in homeostasis; ADH alone would lower blood Na^+ concentration by stimulating water reabsorption in the kidney, but the RAAS helps maintain balance by stimulating Na^+ reabsorption.

Still another hormone, a peptide called atrial natriuretic factor (ANF), opposes the RAAS. The walls of the atria of the heart release ANF in response to an increase in blood volume and pressure. ANF inhibits the release of renin from the JGA, inhibits NaCl reabsorption by the collecting ducts, and reduces aldosterone release from the adrenal glands. These actions lower blood volume and pressure. Thus, ADH, the RAAS, and ANF provide an elaborate system of checks and balances that regulate the kidney's ability to control the osmolarity, salt concentration, volume, and pressure of blood. The precise regulatory role of ANF is an area of active research.

The flexibility of the mammalian kidney enables it to adjust rapidly to contrasting osmoregulatory and excretory problems. The South American vampire bat illustrates this versatility (**Figure 44.17**). Bats of this species feed on the blood of large birds and mammals. The bats use their sharp teeth to make a small incision in the victim's skin and then lap up blood from the wound. Anticoagulants in the bat's saliva prevent the blood from clotting, but the prey animal is usually not seriously harmed. Because vampire bats often search for many hours and fly for long distances to locate a suitable victim, they benefit from consuming as much blood as possible when they do find prey—so much that after feeding, a bat could be too heavy to fly. However, the bat's kidneys offload much of the water absorbed from a blood meal by excreting large volumes of dilute urine as it feeds, up to 24% of body mass per hour. Having lost enough weight to take off, the bat can fly back to its roost in a cave or hollow tree, where it spends the day. In the roost, the bat faces a very different regulatory problem. Its food is mostly protein, which generates large quantities of urea—but roosting bats don't have

A Figure 44.17 A vampire bat (*Desmodus rotundus*), a mammal with a unique excretory situation.

access to drinking water to dilute it. Instead, their kidneys shift to producing small quantities of highly concentrated urine (up to 4,600 mosm/L), an adjustment that disposes of the urea load while conserving as much water as possible. The vampire bat's ability to alternate rapidly between producing large amounts of dilute urine and small amounts of very hyperosmotic urine is an essential part of its adaptation to an unusual food source.

Concept Check 44.5

- How does alcohol affect regulation of water balance in the body?
- How does eating salty food affect kidney function?
- Identify a major functional consequence of the countercurrent-like characteristics of the loop of Henle.

For suggested answers, see Appendix A.

Concept 44.6

Diverse adaptations of the vertebrate kidney have evolved in different environments

Vertebrate animals occupy habitats ranging from rain forests to deserts and from some of the saltiest bodies of water to the dilute waters of high mountain lakes. Variations in nephron structure and function equip the kidneys of different vertebrates for osmoregulation in their various habitats. The adaptations of the vertebrate kidney are most clearly revealed by comparing species that inhabit a wide range of environments or by comparing the responses of different vertebrate groups to similar environmental conditions (**Figure 44.18**).

In all animals, the intricate physiological machines we call organs work continuously, maintaining solute and water balance and excreting nitrogenous wastes. The details that we have reviewed in this chapter only hint at the great complexity of the neural and hormonal mechanisms involved in regulating these homeostatic processes. The next chapter further explores the hormonal control of homeostasis.

Concept Check *44.6

- What do the number and length of nephrons indicate about the habitat of fishes? What do they indicate about rates of urine production?

For suggested answers, see Appendix A.

Exploring Environmental Adaptations of the Vertebrate Kidney

MAMMALS

Mammals that excrete the most hyperosmotic urine, such as Australian hopping mice, North American kangaroo rats, and other desert mammals, have exceptionally long loops of Henle. Long loops maintain steep osmotic gradients in the kidney, resulting in urine becoming very concentrated as it passes from cortex to medulla in the collecting ducts.

Bannertail Kangaroo rat
(Dipodomys spectabilis)

In contrast, beavers, muskrats, and other aquatic mammals that spend much of their time in fresh water and rarely face problems of dehydration, have nephrons with very short loops, resulting in a

Beaver (*Castor canadensis*)

much lower ability to concentrate urine. Terrestrial mammals living in moist conditions have loops of Henle of intermediate length and the capacity to produce urine intermediate in concentration to that produced by freshwater and desert mammals.

FRESHWATER FISHES AND AMPHIBIANS

Rainbow trout
(Oncorhynchus mykiss)

from the filtrate in their distal tubules, leaving water behind.

Amphibian kidneys function much like those of freshwater fishes. When in fresh water, the skin of the frog accumulates certain salts from the water by active transport, and the kidneys excrete dilute urine. On land, where dehydration is the most pressing problem of osmoregulation, frogs conserve body fluid by reabsorbing water across the epithelium of the urinary bladder.

Frog (*Rana temporaria*)

BIRDS AND OTHER REPTILES

Roadrunner
(Geococcyx californianus)

Birds, like mammals, have kidneys with juxtaglomerular nephrons that specialize in conserving water. However, the nephrons of birds have much shorter loops of Henle; thus, bird kidneys cannot concentrate urine to the high osmolalities achieved by mammalian kidneys. Although they can produce hyperosmotic urine, the main water conservation adaptation of birds is uric acid, which can be excreted as a paste, as the nitrogen waste molecule, thereby reducing urine volume.

The kidneys of other reptiles, having only cortical nephrons, produce urine that is, at most, isoosmotic to body fluids. However, the epithelium of the cloaca (see Chapter 34) helps conserve fluid by reabsorbing some of the water present in urine and feces. Also like birds, most other terrestrial reptiles excrete nitrogenous wastes as uric acid.

Desert iguana
(Dipsosaurus dorsalis)

MARINE BONY FISHES

Northern bluefin tuna (*Thunnus thynnus*)

Because they are hypoosmotic to seawater, marine bony fishes lose body water and gain excess salts from their surroundings, environmental challenges opposite those faced by their freshwater relatives. Compared to freshwater fishes, marine fishes have fewer and smaller nephrons, which lack a distal tubule. In addition, the kidneys of most marine fishes have small glomeruli, and some lack glomeruli entirely. Thus, the kidneys of marine fishes have low filtration rates and excrete very little urine. The main function of the kidneys is to get rid of double-charged ions such as calcium (Ca^{2+}), magnesium (Mg^{2+}), and sulfate (SO_4^{2-}), which the fish takes in by its incessant drinking of seawater. Marine fishes rid themselves of these ions by secreting them into the proximal tubules of the nephrons and excreting them with the urine.

SUMMARY OF KEY CONCEPTS

Concept 44.1

Osmoregulation balances the uptake and loss of water and solutes

- Osmoregulation is based largely on the controlled movement of solutes between internal fluids and the external environment, and the movement of water, which follows by osmosis (p. 922).
- **Osmosis** (pp. 922–923) Cells require a balance between osmotic gain and loss of water. Water uptake and loss are balanced by various mechanisms of osmoregulation in different environments.
- **Osmotic Challenges** (pp. 923–926) Osmoconformers, which are only marine animals, are isoosmotic with their surroundings and do not regulate their osmolarity. Osmoregulators expend energy to control water uptake and loss in a hyperosmotic or hypoosmotic environment. Among marine animals, most invertebrates are osmoconformers. Sharks have an osmolarity slightly higher than seawater because they retain urea. Marine bony fishes lose water to their hyperosmotic environment and drink seawater. Marine vertebrates excrete excess salt through rectal glands, gills, salt-excreting glands, or kidneys. Freshwater animals, which constantly take in water from their hypoosmotic environment, excrete dilute urine. Lost salt is replaced by eating or by ion uptake by gills. Terrestrial animals combat desiccation through behavioral adaptations, water-conserving excretory organs, and drinking and eating food with high water content. Animals in temporary waters may be anhydrobiotic.
- **Transport Epithelia** (pp. 926–927) Water balance and waste disposal depend on transport epithelium, layers of specialized epithelial cells that regulate the solute movements required for waste disposal and for tempering changes in body fluids.

Concept 44.2

An animal's nitrogenous wastes reflect its phylogeny and habitat

- **Forms of Nitrogenous Waste** (pp. 927–928) Protein and nucleic acid metabolism generates ammonia, a toxic waste product excreted in three forms. Most aquatic animals excrete ammonia across the body surface or gill epithelia into the surrounding water. The liver of mammals and most adult amphibians converts ammonia to the less toxic urea, which is carried to the kidneys, concentrated, and excreted with a minimal loss of water. Uric acid is an insoluble, paste-like precipitate excreted in the paste-like urine of land snails, insects, and many reptiles, including birds.
- **The Influence of Evolution and Environment on Nitrogenous Wastes** (p. 928) The kinds of nitrogenous wastes excreted depend on an animal's evolutionary history and habitat. The amount of nitrogenous waste produced is coupled to the animal's energy budget.

Concept 44.3

Diverse excretory systems are variations on a tubular theme

- **Excretory Processes** (p. 929) Most excretory systems produce urine by refining a filtrate derived from body fluids.

Key functions of most excretory systems are filtration (pressure-filtering of body fluids, producing a filtrate) and the production of urine from the filtrate by selective reabsorption, (reclaiming valuable solutes from the filtrate) and secretion (addition of toxins and other solutes from the body fluids to the filtrate).

- **Survey of Excretory Systems (pp. 929–931)** Extracellular fluid is filtered into the protonephridia of the flame-bell system in flatworms; these tubules excrete a dilute fluid and also function in osmoregulation. Each segment of an earthworm has a pair of open-ended metanephridia, tubules that collect coelomic fluid and produce dilute urine for excretion. In insects, Malpighian tubules function in osmoregulation and removal of nitrogenous wastes from the hemolymph. Insects produce a relatively dry waste matter, an important adaptation to terrestrial life. Kidneys, the excretory organs of vertebrates, function in both excretion and osmoregulation.

Concept 44.4

Nephrons and associated blood vessels are the functional units of the mammalian kidney

- **Structure and Function of the Nephron and Associate! Structures (pp. 931–933)** Excretory tubules (consisting of nephrons and collecting ducts) and associated blood vessels pack the kidney. Filtration occurs as blood pressure forces fluid from the blood in the glomerulus into the lumen of Bowman's capsule. Filtration of small molecules is nonselective and the filtrate in Bowman's capsule contains a mixture of small molecules that mirrors the concentrations of these substances in blood plasma. Fluid from several nephrons flows into a collecting duct. A ureter conveys urine from the renal pelvis to the urinary bladder.

- **From Blood Filtrate to Urine: A Closer Look**

(pp. 933–934) Nephrons control the composition of the blood by filtration, secretion, and reabsorption. Secretion and reabsorption in the proximal tubule substantially alter the volume and composition of filtrate. The descending limb of the loop of Henle is permeable to water but not to salt; water moves by osmosis into the hyperosmotic interstitial fluid. Salt diffuses out of the concentrated filtrate as it moves through the salt-permeable ascending limb of the loop of Henle. The distal tubule plays a key role in regulating the K⁺ and NaCl concentration of body fluids. The collecting duct carries the filtrate through the medulla to the renal pelvis and reabsorbs NaCl.

Activity Structure of the Human Excretory System

Activity Nephron Function

Concept 44.5

The mammalian kidney's ability to conserve water is a key terrestrial adaptation

- **Solute Gradients and Water Conservation (pp. 935–936)** In a mammalian kidney, the cooperative action and precise arrangement of the loops of Henle and the collecting ducts are largely responsible for the osmotic gradient that concentrates the urine. The countercurrent multiplier system involving the loop of Henle maintains a high salt concentration in the interior of the kidney, which enables the kidney to form concentrated urine. The collecting duct, permeable to water but not to salt, conducts the filtrate through the kidney's osmolarity gradient, and more water exits the filtrate by osmosis. Urea, which diffuses out of the collecting duct as it traverses the inner medulla, forms, along with NaCl, the osmotic gradient that enables the kidney to produce urine that is hyperosmotic to the blood.

- **Regulation of Kidney Function** (pp. 936–938) The osmolarity of the urine is regulated by nervous system and hormonal control of water and salt reabsorption in the kidneys. This regulation involves the actions of antidiuretic hormone (ADH), the renin-angiotensin-aldosterone system (RAAS), and atrial natriuretic factor (ANF).

Activity *Control of Water Reabsorption*
Investigation *What Affects Urine Production?*

Concept 44.6

Diverse adaptations of the vertebrate kidney have evolved in different environments

- The form and function of nephrons in the various vertebrate classes are related primarily to the requirements for osmoregulation in the animal's habitat. Desert mammals, which excrete the most hyperosmotic urine, have exceptionally long loops of Henle, while animals living in moist or aquatic habitats have short loops and excrete less concentrated urine. Although birds can produce a hyperosmotic urine, the main water conservation adaptation of birds is removal of nitrogen as uric acid, which can be excreted as a paste. Most other terrestrial reptiles excrete uric acid. Freshwater fishes and amphibians produce large volumes of very dilute urine. The kidneys of marine bony fishes have low filtration rates and excrete very little urine, (pp. 938–939)

TESTING YOUR KNOWLEDGE

Evolution Connection

A large part of the evolutionary success of arthropods and vertebrates on land is attributable to their osmoregulatory capabilities. Compare and contrast the Malpighian tubule with the nephron in regard to anatomy, relationship to circulation, and physiological mechanisms for conserving body water.

Scientific Inquiry

Merriam's kangaroo rats (*Dipodomys merriami*) are native to western North America, where they live in a wide range of habitats ranging from moist, cool woodlands to the hottest and driest places on the continent. Assuming that natural selection acting on local populations has resulted in differences in water conservation among Merriam's kangaroo rat populations, propose a hypothesis concerning the relative rates of evaporative water loss by populations that live in dry versus moist environments. Using a humidity sensor to detect evaporative water loss by kangaroo rats, how could you test your hypothesis?

Investigation *What Affects Urine Production?*

Science, Technology, and Society

Kidneys were the first organs to be successfully transplanted. A donor can live a normal life with a single kidney, making it possible for individuals to donate a kidney to an ailing relative or even an unrelated individual with a similar tissue type. In some countries, two people sell kidneys to transplant recipients through organ brokers. What are some of the ethical issues associated with this organ commerce?

45 Hormones and the Endocrine System

A Figure 45.1 An anise swallowtail butterfly emerging from its chrysalis.

Key Concepts

- 45.1 The endocrine system and the nervous system act individually and together in regulating an animal's physiology
- 45.2 Hormones and other chemical signals bind to target cell receptors, initiating pathways that culminate in specific cell responses
- 45.3 The hypothalamus and pituitary integrate many functions of the vertebrate endocrine system
- 45.4 Nonpituitary hormones help regulate metabolism, homeostasis, development, and behavior
- 4S 3 Invertebrate regulatory systems also involve endocrine and nervous system interactions

Overview

The Body's Long-Distance Regulators

People offer hormones as an explanation for the howling of alley cats and the moodiness of teenagers. In the United States more than a million people with diabetes take the hormone insulin, and other hormones are used in cosmetics to keep the skin smooth or in livestock feed to fatten cattle. These powerful substances are also involved in even more dramatic transformations. In becoming an adult, a butterfly like the one in **Figure 45.1** undergoes a complete change of body form, a metamorphosis regulated by hormones. Internal communication involving those hormones enables different parts of the insects adult body to develop in concert.

An animal hormone (from the Greek *horman*, to excite) is a chemical signal that is secreted into the circulatory system (usually the blood) and communicates regulatory messages within the body. A hormone may reach all parts of the body, but only certain types of cells, the target cells, are equipped to respond. Thus, a given hormone traveling in the bloodstream elicits specific responses—such as a change in metabolism—from its target cells, while other cell types are unaffected by that particular hormone.

In this chapter, we will describe how the basic concepts of biological control systems apply to hormonal pathways and how hormones act on target cells. Here we will focus on hormones that help maintain homeostasis; in Chapters 46 and 47 we will discuss the role of hormones in regulating growth, development, and reproduction. This chapter will examine the major types of hormones in vertebrates, including where they are formed in the body and their major effects. In addition, we will consider comparable regulatory mechanisms in invertebrates.

Concept 45.1

The endocrine system and the nervous system act individually and together in regulating an animal's physiology

Animals have two systems of internal communication and regulation, the nervous system and the endocrine system. The nervous system, which we will discuss in Chapter 48, conveys high-speed electrical signals along specialized cells called neurons. These rapid messages control the movement of body

parts in response to sudden environmental changes, such as occur when you jerk your hand away from a hot pan or when your pupils dilate as you enter a dark room.

Collectively, all of an animal's hormone-secreting cells constitute its endocrine system. Hormones coordinate slower but longer-acting responses to stimuli such as stress, dehydration, and low blood glucose levels. Hormones also regulate long-term developmental processes by informing different parts of the body how fast to grow or when to develop the characteristics that distinguish male from female or juvenile from adult. Hormone-secreting organs, called endocrine glands, are referred to as ductless glands because they secrete their chemical messengers directly into extracellular fluid. From there, the chemicals diffuse into the circulation.

Overlap Between Endocrine and Nervous Regulation

While it is convenient to distinguish between the endocrine and nervous systems, in reality the lines between these two regulatory systems are blurred. In particular, certain specialized nerve cells known as neurosecretory cells release hormones into the blood. In animals as distinct as insects and vertebrates, a part of the brain called the hypothalamus contains neurosecretory cells. The hormones produced by neurosecretory cells are sometimes called *neurohormones* to distinguish them from the "classic" hormones released by endocrine glands.

A few chemicals serve both as hormones in the endocrine system and as chemical signals in the nervous system. Epinephrine, for example, functions in the vertebrate body as the so-called "fight-or-flight" hormone (produced by the adrenal medulla, an endocrine gland) and as a neurotransmitter, a local chemical signal that conveys messages between neurons in the nervous system (see Chapter 48). In addition, the nervous system plays a role in certain sustained responses—for example, controlling day/night cycles and reproductive cycles in many animals—often by increasing or decreasing secretion from endocrine glands.

Thus, although the endocrine and nervous systems are anatomically distinct, they interact functionally in regulating a number of physiological processes.

Control Pathways and Feedback Loops

Let's review the fundamental concepts of biological control systems introduced in Chapter 40 and apply them to regulation by hormones. A *receptor*, or *sensor* detects a stimulus—for example, a change in blood calcium level—and sends the information to a *control center*. After comparing the incoming information to a set point, or "desired" value, the control center sends out a signal that directs an *effector* to respond. In endocrine and neuroendocrine pathways, this outgoing signal,

called an *efferent signal*, is a hormone or neurohormone, which acts on particular effector tissues and elicits specific physiological or developmental changes. The three types of simple hormonal pathways depicted in Figure 45.2 include these basic functional components of a control system. Not depicted in this figure are complex neuroendocrine pathways in which a hormone secreted by one endocrine tissue acts on another endocrine tissue, controlling its release of a different hormone, which then acts on target tissues. Regulation by each of the 20 or so different hormones you will learn about in this and other chapters involves one of these general types of simple or complex pathways.

Another common feature of control pathways is a feedback loop connecting the response to the initial stimulus. In negative feedback, the effector response reduces the initial stimulus, and eventually the response ceases. This feedback mechanism prevents overreaction by the system and wild fluctuations in the variable being regulated. Negative feedback operates in many endocrine and nervous pathways, especially those involved in maintaining homeostasis (see Chapter 40). Later in this chapter, we will examine how negative feedback contributes to the hormonal control of blood calcium and glucose levels.

In contrast to negative feedback, which dampens the stimulus, positive feedback reinforces the stimulus and leads to an even greater response. The neurohormone pathway that regulates the release of milk by a nursing mother is an example of positive feedback (see Figure 45.2b). Suckling stimulates sensory nerve cells in the nipples, which send nervous signals that eventually reach the hypothalamus, the control center. An outgoing signal from the hypothalamus triggers the release of the neurohormone oxytocin from the posterior pituitary gland. Oxytocin then causes the mammary glands to secrete milk. The release of milk in turn leads to more suckling and stimulation of the pathway, until the baby is satisfied.

Concept Check 45.1

- How do neurohormones differ from "classic" hormones? How are they similar?
- Different biological control systems exhibit common features: a receptor/sensor, a control center, an efferent signal, and an effector. Draw two sketches showing how these components are arranged in a simple endocrine pathway and a simple neurohormone pathway
- Explain why, unlike negative feedback, positive feedback is not a common feature of hormonal pathways that help maintain homeostasis.

For suggested answers, see Appendix A.

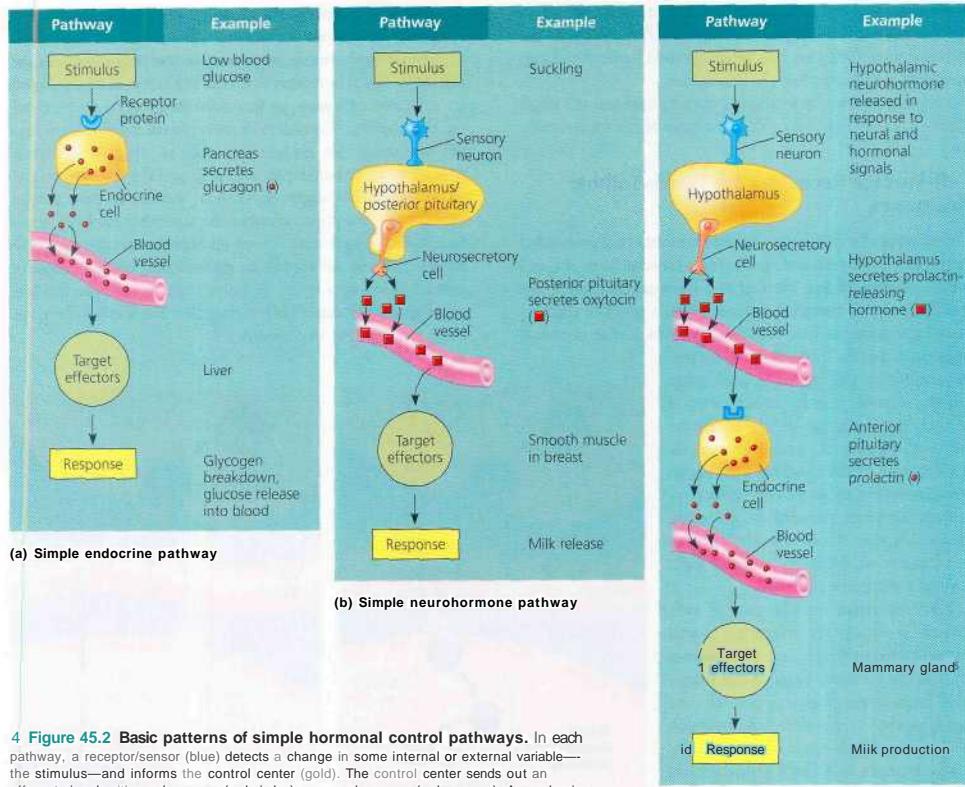

Figure 45.2 Basic patterns of simple hormonal control pathways. In each pathway, a receptor/sensor (blue) detects a change in some internal or external variable—the stimulus—and informs the control center (gold). The control center sends out an efferent signal, either a hormone (red circles) or neurohormone (red squares). An endocrine cell carries out both the receptor and control center functions.

IConcept 45.2

Hormones and other chemical signals bind to target cell receptors, initiating pathways that culminate in specific cell responses

Hormones, the body's long-distance chemical regulators, convey information via the bloodstream to target cells throughout the body. Other chemical signals, called local regulators, transmit information to target cells near the secreting cells. Still other chemical signals, called pheromones, carry messages between different individuals of a species, as in mate at-

traction. In this chapter, as mentioned earlier, we will concentrate on hormones (and neurohormones) that are not directly involved in reproduction.

Three major classes of molecules function as hormones in vertebrates: proteins and peptides (small polypeptides containing up to 30 amino acids); amines derived from amino acids; and steroids. Most protein/peptide and amine hormones are water-soluble, whereas steroid hormones are not.

Regardless of their chemical nature, however, signaling by any of these molecules involves three key events: reception, signal transduction, and response (see Chapter 11). Reception of the signal occurs when the signal molecule binds to a specific receptor protein in or on the target cell. Each signal molecule has a specific shape that can be recognized by that signal's receptors. Receptors may be located in the plasma membrane of a target cell or inside the cell. The binding of a signal molecule

to a receptor protein triggers events within the target cell—*signal transduction*—that result in a *response*, a change in the cell's behavior. Cells that lack receptors for a particular chemical signal are unresponsive to that signal.

Let's take a closer look at signal transduction and the kinds of cell responses induced by different types of chemical signals.

Cell-Surface Receptors for Water-Soluble Hormones

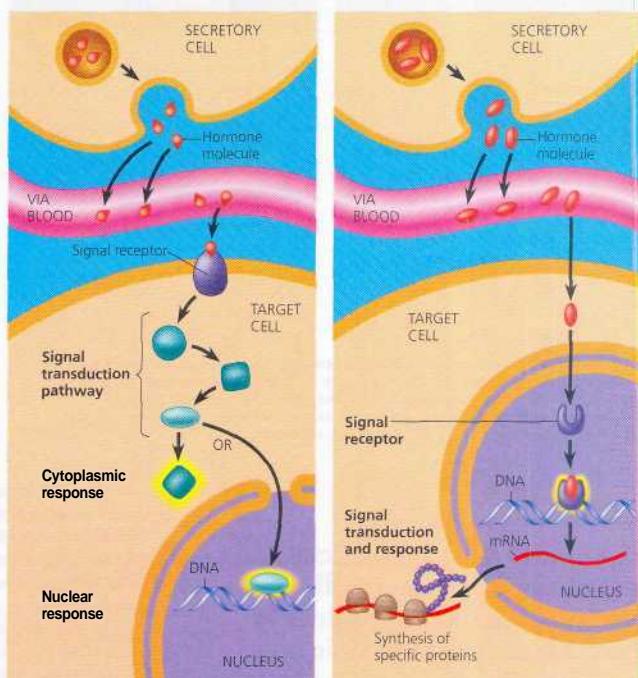

The receptors for most water-soluble hormones are embedded in the plasma membrane, projecting outward from the cell surface (**Figure 45.3a**). Binding of a hormone to its receptor initiates a signal transduction pathway, a series of changes in cellular proteins that converts an extracellular chemical signal to a specific intracellular response. Depending on the hormone and target cell, the response may be the activation of an enzyme, a change in the uptake or secretion of specific molecules, or rearrangement of the cytoskeleton. Signal transduction from some cell-surface receptors activates proteins in the cytoplasm that then move into the nucleus and directly or indirectly regulate transcription of specific genes.

Early evidence for the role of cell-surface receptors in triggering signal transduction pathways came from studies on how the hormone epinephrine stimulates breakdown of glycogen to glucose (see Chapter 11). Another demonstration of the role of cell-surface receptors involves changes in a frog's skin color, an adaptation that helps camouflage the frog in changing light. Skin cells called melanocytes contain the dark brown pigment melanin in cytoplasmic organelles called melanosomes. The frog's skin appears light when melanosomes cluster tightly around the cell nuclei and darker when melanosomes spread throughout the cytoplasm. A peptide hormone called melanocyte-stimulating hormone controls the arrangement of melanosomes and thus the frog's skin color. Adding melanocyte-stimulating hormone to the interstitial fluid surrounding the pigment-containing cells causes the melanosomes to disperse. However, direct microinjection of melanocyte-stimulating hormone

into individual melanocytes does not induce melanosome dispersion—evidence

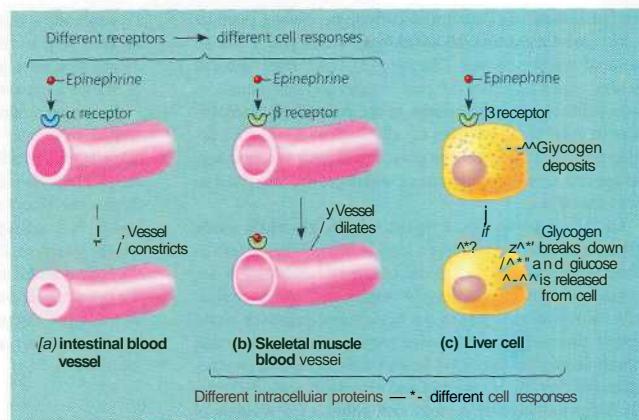

that interaction between the hormone and a *surface* receptor is required for hormone action.

A particular hormone may cause diverse responses in target cells with different receptors for the hormone, different signal transduction pathways, and/or different proteins for carrying out the response. Consider the multiple effects of epinephrine in mediating the body's response to short-term stress (**Figure 45.4**). For example, liver cells and the smooth muscle of blood vessels supplying skeletal muscle contain β -type epinephrine receptors, whereas the smooth muscle of intestinal blood vessels have α -type epinephrine receptors. These tissues respond differently to epinephrine, resulting in decreased blood flow to the digestive tract and increased delivery of glucose to major skeletal muscles. These effects help the body react quickly in emergencies.

A Figure 45.3 Mechanisms of hormonal signaling: a review. (a) A water-soluble hormone binds to a receptor protein on the surface of a target cell. This interaction triggers a signal transduction pathway that leads to a change in a cytoplasmic function or a change in gene transcription in the nucleus. (b) A lipid-soluble hormone penetrates the target cell's plasma membrane and binds to an intracellular receptor, either in the cytoplasm or in the nucleus (shown here). The signal-receptor complex acts as a transcription factor, typically activating gene expression.

> Figure 45.4 One chemical signal, different effects. Epinephrine, the primary “fight-or-flight” hormone, produces different responses in different target cells. Responses of target cells may differ if they have different receptors for a hormone [compare (a) with (b)]. Target cells with the same receptor exhibit different responses if they have different signal transduction pathways and/or effector proteins [compare (b) with (c)].

Intracellular Receptors for Lipid-Soluble Hormones

The first indication that the receptors for some hormones are located inside target cells came from studying the vertebrate hormones estrogen and progesterone. For most mammals, including humans, these steroid hormones are necessary for the normal development and function of the female reproductive system. In the early 1960s, researchers demonstrated that estrogen and progesterone accumulate within the nuclei of cells in the reproductive tract of female rats. By contrast, no estrogen accumulated in the cells of tissues that do not respond to estrogen. These observations led to the hypothesis that cells sensitive to a steroid hormone contain internal receptor molecules that bind specifically to that hormone.

Researchers later identified the intracellular proteins that function as receptors for steroid hormones, thyroid hormones, and the hormonal form of vitamin D. All of these hormones are small, mostly nonpolar (lipid-soluble) molecules that diffuse easily through the phospholipid interior of cellular membranes.

Intracellular receptors usually perform the entire task of transducing a signal within a target cell. The chemical signal activates the receptor, which then directly triggers the cell's response. In almost all cases, the intracellular receptor activated by a lipid-soluble hormone is a transcription factor, and the response is a change in gene expression.

Most intracellular receptors are already located in the nucleus (**Figure 45.3b**, on page 946) when they bind hormone molecules, which have diffused in from the bloodstream. The resulting hormone-receptor complexes bind, in turn, to specific sites in the cell's DNA and stimulate the transcription of specific genes. Some steroid hormone receptors, however, are trapped in the cytoplasm when no hormone is present. Binding of a steroid hormone to its cytoplasmic receptor forms a

hormone-receptor complex that can move into the nucleus and stimulate transcription of specific genes (see Figure 11.6). In both cases, mRNA produced in response to hormone stimulation is translated into new protein in the cytoplasm. For example, estrogen induces cells in the reproductive system of a female bird to synthesize large amounts of ovalbumin, the main protein of egg white.

As with hormones that bind to cell-surface receptors, hormones that bind to intracellular receptors may exert different effects on different target cells. The estrogen that stimulates a bird's reproductive system to make ovalbumin causes the bird's liver to make other proteins. The same hormone also may have different effects in different species. For instance, thyroxine produced by the thyroid gland regulates metabolism in humans and other vertebrates. But in frogs, thyroxine has additional effects: it triggers the metamorphosis of a tadpole into an adult, stimulating resorption of the tadpole's tail and other changes.

Paracrine Signaling by Local Regulators

Before continuing our discussion of the endocrine system and hormonal regulation, let us briefly consider local regulators. In contrast to long-distance endocrine signaling by hormones, local regulators convey messages between neighboring cells—a process referred to as paracrine signaling (see Figure 11.4). Once secreted by the cells that make them, local regulators act on nearby target cells within seconds or even milliseconds, eliciting cell responses more quickly than hormones can. Some local regulators have cell-surface receptors; others have intracellular receptors. Binding of local regulators to their specific receptors triggers events within target cells similar to those elicited by hormones (see Figure 45.3).

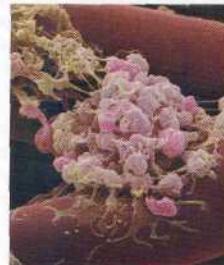

Several types of chemical compounds function as local regulators. Many neurotransmitters, the key local regulators in the

nervous system, are amino acid derivatives. Among peptide/protein local regulators are **cytokines**, which play a role in immune responses (see Chapter 43), and most **growth factors**, which stimulate cell proliferation and differentiation. Growth factors must be present in the extracellular environment in order for many types of cells to grow, divide, and develop normally. The functions of various growth factors in regulating cell division and tissue development are described in other chapters.

Another important local regulator is the gas **nitric oxide (NO)**. When the blood oxygen level falls, endothelial cells in blood vessel walls synthesize and release NO. Nitric oxide activates an enzyme that relaxes the neighboring smooth muscle cells, which in turn dilates the vessels and improves blood flow to tissues. Nitric oxide also plays a role in male sexual function by increasing blood flow into the penis and producing an erection. Highly reactive and potentially toxic, NO usually triggers changes in a target cell within a few seconds of contact and then breaks down. The drug Viagra (sildenafil citrate), a treatment for male erectile dysfunction, sustains an erection by interfering with this breakdown of NO. Nitric oxide has other functions as well: In the nervous system, it can function as a neurotransmitter, and NO secreted by certain white blood cells can kill bacteria and cancer cells in body fluids.

A group of local regulators called **prostaglandins (PGs)** are modified fatty acids, often derived from lipids in the plasma membrane. They are so named because they were first discovered in prostate-gland secretions that contribute to semen. Released from most types of cells into interstitial fluid, prostaglandins regulate nearby cells in various ways, depending on the tissue. In semen that reaches the reproductive tract of a female, prostaglandins stimulate smooth muscles of the female's uterine wall to contract, helping sperm reach an egg. During childbirth, prostaglandins secreted by cells of the female's placenta cause the nearby muscles of the uterus to become more excitable, helping to induce labor (see Figure 46.18).

In the immune system, various prostaglandins help induce fever and inflammation and also intensify the sensation of pain. These responses contribute to the body's defense by sounding an alarm that something harmful is occurring. The anti-inflammatory effects of aspirin and ibuprofen are due to the drugs' inhibition of prostaglandin synthesis,

A Figure 45.5 Activated platelets aggregating, a process regulated in part by prostaglandins. Following injury to a blood vessel wall, platelets (pink and purple) develop a sticky outer surface and adhere to each other, as shown in this colorized SEM.

Prostaglandins also help regulate the aggregation of platelets, an early step in the formation of blood clots (Figure 45.5). This is why some physicians recommend that people who are at risk for a heart attack take aspirin on a regular basis.

In the respiratory system, two prostaglandins with very similar molecular structures have opposite effects on the smooth muscle cells in the walls of blood vessels serving the lungs. Prostaglandin E signals the muscle cells to relax, which dilates the blood vessels and promotes oxygenation of the blood. Prostaglandin F signals the muscle cells to contract, which constricts the vessels and reduces blood flow through the lungs. Shifts in the relative concentrations of these two antagonistic (opposing) signals help maintain homeostasis in changing circumstances. Later in the chapter, we will encounter other antagonistic signals that counterbalance each other.

Concept Check 45.2

- How do the mechanisms for inducing responses in target cells differ for water-soluble hormones and steroid hormones?
- Explain how a single hormone, such as epinephrine, can cause different responses in different tissues.
- Why do local regulators, such as prostaglandins, generally elicit responses in their target cells more rapidly than hormones?

For suggested answers, see Appendix A.

Concept 45.3

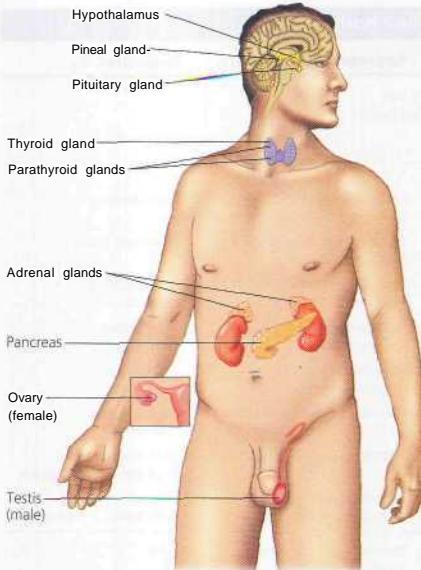

The hypothalamus and pituitary integrate many functions of the vertebrate endocrine system

So far, we have looked at the basic components of hormonal regulatory pathways and how a hormonal signal is converted to a cellular response. Now we turn to the physiological effects of the primary vertebrate hormones and the role of the endocrine system in adjusting the body's activities to shifting environmental and developmental conditions. We begin with the hypothalamus and pituitary gland, which control much of the endocrine system.

As you read, you may want to refer to **Table 45.1**, which summarizes the actions of major human hormones, and to **Figure 45.6**, on page 950, which illustrates the major endocrine glands in the human body. Small reference diagrams accompanying each section of the text will help you recall each gland's location.

Table 45.1 Major Human Endocrine Glands and Some of Their Hormones

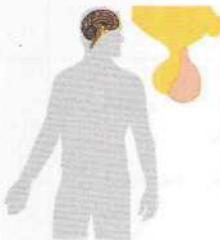

| Gland | Hormone | Chemical Class | Representative Actions | Regulated By |
|--|--|---|---|---|
| Hypothalamus | | | Hormones released from the posterior pituitary and hormones that regulate the anterior pituitary (see below) | |
| Pituitary gland Posterior pituitary (releases neurohormones made in hypothalamus) | Oxytocin Antidiuretic hormone (ADH) | Peptide Peptide | Stimulates contraction of uterus and mammary gland cells Promotes retention of water by kidneys | Nervous system Water/salt balance |
| Anterior pituitary | Growth hormone (GH) Prolactin (PRL) Follicle-stimulating hormone (FSH) Luteinizing hormone (LH) Thyroid-stimulating hormone (TSH) Adrenocorticotrophic hormone (ACTH) | Protein Protein Glycoprotein Glycoprotein Glycoprotein Peptide | Stimulates growth (especially bones) and metabolic functions Stimulates milk production and secretion Stimulates production of ova and sperm Stimulates ovaries and testes Stimulates thyroid gland Stimulates adrenal cortex to secrete glucocorticoids | Hypothalamic hormones Hypothalamic hormones Hypothalamic hormones Hypothalamic hormones Thyroxine in blood; hypothalamic hormones Glucocorticoids; hypothalamic hormones |
| Thyroid gland | Triiodothyronine (T_3) and thyroxine (T_4) Calcitonin | Amine Peptide | Stimulates and maintains metabolic processes Lowers blood calcium levels | TSH |
| Parathyroid glands | Parathyroid hormone (PTH) | Peptide | Raises blood calcium level | Calcium in blood |
| Pancreas | Insulin Glucagon | Protein Protein | Lowers blood glucose level Raises blood glucose level | Glucose in blood Glucose in blood |
| Adrenal glands Adrenal medulla | Epinephrine and norepinephrine | Amine | Raise blood glucose level; increase metabolic activities; constrict certain blood vessels | Nervous system |
| Adrenal cortex | Glucocorticoids Mineralocorticoids | Steroid Steroid | Raise blood glucose level Promote reabsorption of Na^+ and excretion of K^+ in kidneys | ACTH K^+ in blood |
| Gonads | | | | |
| Testes | Androgens | Steroid | Support sperm formation; promote development and maintenance of male secondary sex characteristics | FSH and LH |
| Ovaries | Estrogens Progesterone | Steroid | Stimulate uterine lining growth; promote development and maintenance of female secondary sex characteristics Promotes uterine lining growth | FSH and LH |
| Pineal gland | Melatonin | Amine | Involved in biological rhythms | Light/dark cycles |

A Figure 45.6 Human endocrine glands surveyed in this chapter. In addition to the glands shown here, many organs with primarily nonendocrine functions also secrete hormones.

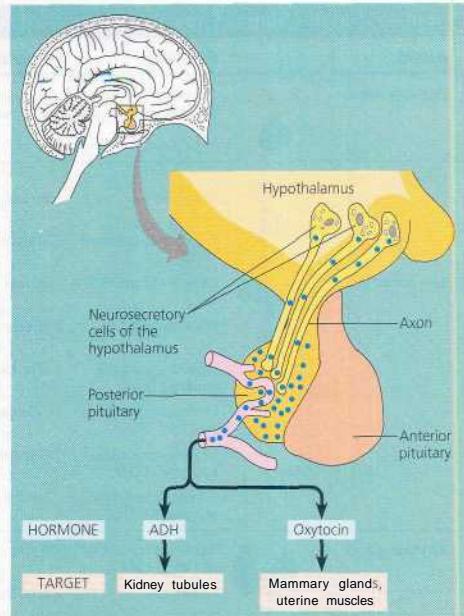

Note that hormone-secreting cells are present in many organs belonging to other systems, including the heart, thymus, liver, stomach, small intestine, kidney, and placenta. Some of the hormones released by these nonendocrine organs are discussed in other chapters.

Relationship Between the Hypothalamus and Pituitary Gland

The **hypothalamus** plays an important role in integrating the vertebrate endocrine and nervous systems. This region of the lower brain receives information from nerves throughout the body and from other parts of the brain, then initiates endocrine signals appropriate to environmental conditions. In many

vertebrates, for example, the brain passes sensory information about seasonal changes and the availability of a mate to the hypothalamus by means of nerve signals; the hypothalamus then triggers the release of reproductive hormones required for breeding.

A Figure 45.7 Production and release of posterior pituitary hormones. The posterior pituitary gland is an extension of the hypothalamus. Certain neurosecretory cells in the hypothalamus make antidiuretic hormone (ADH) and oxytocin, which are transported to the posterior pituitary where they are stored. Nervous signals from the brain trigger release of these neurohormones.

The hypothalamus contains two sets of neurosecretory cells whose hormonal secretions are stored in or regulate the activity of the **pituitary gland**, a lima bean-sized organ located at the base of the hypothalamus. No organ illustrates the close structural, functional, and developmental relationship between the endocrine and nervous systems better than the pituitary gland. It has discrete posterior and anterior parts, which are actually two fused glands that develop from separate regions of the embryo and perform very different functions.

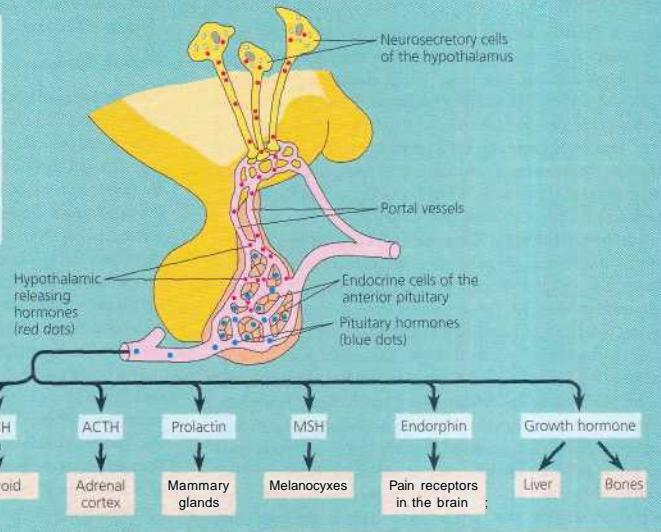

The **posterior pituitary**, or **neurohypophysis**, is an extension of the hypothalamus that grows downward toward the mouth during embryonic development. It stores and secretes two hormones that are made by certain neurosecretory cells located in the hypothalamus; the long processes (axons) of these cells carry the hormones to the posterior pituitary (**Figure 45.7**).

The **anterior pituitary**, or **adenohypophysis**, develops from a fold of tissue at the roof of the embryonic mouth; this tissue grows upward toward the brain and eventually loses its connection to the mouth. The anterior pituitary consists of endocrine cells that synthesize and secrete at least six

Tropic Effects Only
 FSH, follicle-stimulating hormone
 LH, luteinizing hormone
 TSH, thyroid-stimulating hormone
 ACTH, adrenocorticotrophic hormone

Non tropic Effects Only
 Prolactin
 MSH, melanocyte-stimulating hormone
 Endorphin

Nontropic and Tropic Effects
 Growth hormone

A Figure 45.8 Production and release of anterior pituitary hormones. The release of hormones synthesized in the anterior pituitary gland is controlled by hypothalamic

tropic hormones. The hypothalamic releasing and inhibiting hormones are secreted by neurosecretory cells into a capillary network within the hypothalamus. These capillaries drain

into portal vessels that connect with a second capillary network in the anterior pituitary. Each hormone made in the anterior pituitary is secreted in response to a specific releasing hormone.

different hormones directly into the blood. Several of these hormones have other endocrine glands as their targets. Hormones that regulate the function of endocrine organs, called **tropic hormones**, are particularly important in coordinating endocrine signaling throughout the body.

The anterior pituitary itself is regulated by tropic hormones produced by a set of neurosecretory cells in the hypothalamus. Some hypothalamic tropic hormones (called releasing hormones) stimulate the anterior pituitary to release its hormones, while others (called inhibiting hormones) inhibit its hormone secretion. The hypothalamic releasing and inhibiting hormones are secreted into capillaries at the base of the hypothalamus (**Figure 45.8**). The capillaries drain into short blood vessels, called portal vessels, that subdivide into a second capillary bed within the anterior pituitary. In this way, the hypothalamic tropic hormones have direct access to the gland they control. Every anterior pituitary hormone is controlled by at least one releasing hormone, and some have both a releasing hormone and an inhibiting hormone.

Posterior Pituitary Hormones

As shown in Figure 45.7, the posterior pituitary releases two hormones, antidiuretic hormone (ADH) and oxytocin. Both

are peptides made by neurosecretory cells in the hypothalamus and thus strictly speaking are neurohormones. They function in simple neurohormone pathways (see Figure 45.2b).

Antidiuretic hormone (ADH) acts on the kidneys, increasing water retention and thus decreasing urine volume. It is part of the elaborate mechanism that helps regulate the osmolarity of the blood. This mechanism illustrates the importance of negative feedback in maintaining homeostasis and the central role of the hypothalamus as a member of both the endocrine system and the nervous system. See Figure 44.16 to review the function of ADH in this complex regulatory circuit.

Oxytocin induces target cells in the uterine muscles to contract during childbirth. As described earlier, it also causes the mammary glands to eject milk during nursing. Oxytocin signaling in both cases exhibits positive feedback.

Anterior Pituitary Hormones

The anterior pituitary produces many different hormones (see Figure 45.8). Four function strictly as tropic hormones, stimulating the synthesis and release of hormones from the thyroid gland, adrenal glands, and gonads. Several others exert only direct, nontropic effects on nonendocrine organs. And one, growth hormone, has both tropic and nontropic actions.

Tropic Hormones

Three of the exclusively tropic hormones secreted by the anterior pituitary are closely related in their chemical structures. Follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH) are all similar glycoproteins, protein molecules with carbohydrates attached to them. FSH and LH are also called gonadotropins because they stimulate the activities of the male and female gonads, the testes and ovaries. TSH promotes normal development of the thyroid gland and the production of thyroid hormones.

Adrenocorticotrophic hormone (ACTH), the fourth anterior pituitary tropic hormone, is unrelated structurally to the others. It is a peptide hormone derived by cleavage of a large precursor protein. ACTH stimulates the production and secretion of steroid hormones by the adrenal cortex.

All four anterior pituitary tropic hormones participate in complex neuroendocrine pathways. In each pathway, signals to the brain stimulate release of a hypothalamic neurohormone that in turn stimulates release of an anterior pituitary tropic hormone. The anterior pituitary tropic hormone then acts on its target endocrine tissue, stimulating secretion of yet another hormone that exerts systemic metabolic or developmental effects. We will take a closer look at the hormonal pathways involving TSH and ACTH later in this chapter. In Chapter 46, we will discuss how FSH and LH regulate reproductive functions. As you will see, negative-feedback loops are crucial in regulating these complex pathways.

Nontropic Hormones

Nontropic hormones produced by the anterior pituitary include prolactin, melanocyte-stimulating hormone (MSH), and β -endorphin. These peptide/protein hormones, whose secretion is controlled by hypothalamic hormones, function in simple neuroendocrine pathways (see Figure 45.2c).

The most remarkable characteristic of prolactin (PRL) is the great diversity of effects it produces in different vertebrate species. For example, prolactin stimulates mammary gland growth and milk synthesis in mammals; regulates fat metabolism and reproduction in birds; delays metamorphosis in amphibians, where it may also function as a larval growth hormone; and regulates salt and water balance in freshwater fishes. This list suggests that prolactin is an ancient hormone whose functions have diversified during the evolution of the various vertebrate groups.

As described earlier, melanocyte-stimulating hormone (MSH) regulates the activity of pigment-containing cells in the skin of some fishes, amphibians, and reptiles. In mammals, MSH appears to act on neurons in the brain, inhibiting hunger.

β -Endorphin belongs to a class of chemical signals called endorphins. Certain neurons in the brain also produce endorphins (see Chapter 48). All the endorphins bind to receptors in the brain and dull the perception of pain. Some researchers speculate that the so-called "runner's high" results partly from the release of endorphins when stress and pain in the body

reach critical levels. Both MSH and β -endorphin are formed by cleavage of the same precursor protein that gives rise to ACTH.

GrowthHormone

Growth hormone (GH) is so similar structurally to prolactin that scientists hypothesize that the genes directing their production evolved from the same ancestral gene. GH acts on a wide variety of target tissues and has both tropic and nontropic effects. Its major tropic action is to signal the liver to release insulin-like growth factors (IGFs), which circulate in the blood and (indirectly) stimulate bone and cartilage growth. In the absence of GH, the skeleton of an immature animal stops growing. Injecting the hormone into an animal experimentally deprived of its own supply partially restores the animal's growth. GH also exerts diverse metabolic effects that tend to raise blood glucose, thus opposing the effects of insulin (discussed later in this chapter).

Abnormal production of GH in humans can result in several disorders, depending on when the problem occurs and whether it involves hypersecretion (too much) or hyposecretion (too little). Hypersecretion of GH during childhood can lead to gigantism, in which the person grows unusually tall—as tall as 8 feet (2.4 m)—though body proportions remain relatively normal. Excessive production of GH in adulthood, a condition known as acromegaly stimulates bony growth in a few tissues that are still responsive to the hormone, such as in the face, hands, and feet.

Hyposecretion of GH in childhood retards long-bone growth and can lead to pituitary dwarfism. Individuals with this disorder generally reach a height of only about 4 feet (1.2 m), though body proportions remain relatively normal. If diagnosed before puberty, pituitary dwarfism can be treated successfully with human GH. For many years, the supply of GH isolated from cadaver pituitaries fell far short of demand. In the mid-1980s, genetic engineers learned to produce human GH by inserting DNA encoding the hormone into bacteria (see Chapter 20). Therapy with genetically engineered GH is now fairly routine for children with pituitary dwarfism.

Some athletes take GH in the belief that it can improve athletic performance. However, research has shown that in healthy adults who are not hormone-deficient, GH has little impact on muscle mass and strength.

Concept Check 45.3

- How do the two fused glands of the pituitary gland differ in origin and function?
- Discuss the role of tropic hormones in regulating the endocrine system.
- Which pathway of hormonal control (see Concept 45.1) is characteristic of (a) prolactin, (b) adrenocorticotrophic hormone (ACTH), and (c) oxytocin?

For suggested answers, see Appendix A.

Concept 45.4

Nonpituitary hormones help regulate metabolism, homeostasis, development, and behavior

Next, let's survey the major functions of several nonpituitary hormones and the endocrine glands that produce them. Tropic hormones from the anterior pituitary control secretion of some, but not all, of these hormones.

Thyroid Hormones

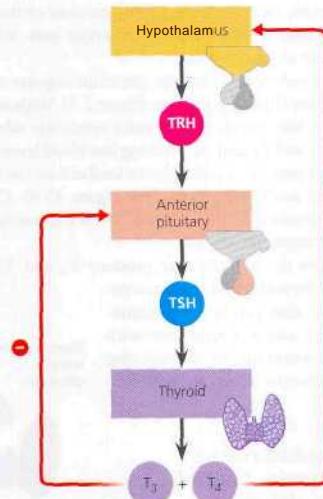

In humans and other mammals, the thyroid gland consists of two lobes located on the ventral surface of the trachea (see Figure 42-23). In many other vertebrates, the two halves of the gland are separated on the two sides of the pharynx.

The thyroid gland produces two very similar hormones derived from the amino acid tyrosine; triiodothyronine (T_3), which contains three iodine atoms, and tetraiodothyronine, or thyroxine (T_4), which contains four iodine atoms. In mammals, the thyroid secretes mainly T_4 , but target cells convert most of it to T_3 by removing one iodine atom. Although both hormones are bound by the same receptor protein located in the cell nucleus, the receptor has greater affinity for T_3 than for T_4 . Thus, it is mostly T_3 that brings about responses in target cells.

The hypothalamus and anterior pituitary control the secretion of thyroid hormones and hence their effects in an animal's body. This process involves a complex neuroendocrine pathway with two negative-feedback loops (Figure 45.9).

The thyroid gland plays a crucial role in vertebrate development and maturation. A striking example is the thyroid control of the metamorphosis of a tadpole into a frog, which involves massive reorganization of many different tissues. Studies with other nonhuman animals have shown that thyroid hormones are required for the normal functioning of bone-forming cells and the branching of nerve cells during embryonic development of the brain. The thyroid is equally important in human development. Cretinism, an inherited condition of thyroid deficiency, results in markedly retarded skeletal growth and poor mental development. These defects can often be prevented, at least partially, if treatment with thyroid hormones begins early in life.

The thyroid gland also has important homeostatic functions. In adult mammals, for instance, thyroid hormones help maintain normal blood pressure, heart rate, muscle tone, digestion, and reproductive functions. Throughout the body, T_3 and T_4

A Figure 45.9 Feedback regulation of T_3 and T_4 secretion from the thyroid gland. The hypothalamus secretes TSH-releasing hormone (TRH), which stimulates the anterior pituitary to secrete thyroid-stimulating hormone (TSH). TSH then stimulates the thyroid gland to synthesize and release the thyroid hormones T_3 and T_4 . These hormones exert negative feedback on the hypothalamus and anterior pituitary by inhibiting release of TRH and TSH.

A Figure 45.10 Graves' disease, the most common form of hyperthyroidism in humans. Tissue behind the eyes can become swollen and fibrous, causing the characteristic symptom of bulging eyes.

are important in bioenergetics, generally increasing the rate of oxygen consumption and cellular metabolism. Too much or too little of these hormones in the blood can result in serious metabolic disorders. In humans, excessive secretion of thyroid hormones, known as hyperthyroidism, can lead to high body temperature, profuse sweating, weight loss, irritability, and high blood pressure. The most common form of hyperthyroidism is Graves' disease; protruding eyes, caused by fluid accumulation behind the eyes, are a typical symptom (Figure 45.10).

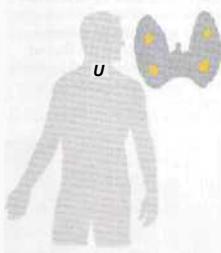

Hypothyroidism, the opposite condition, can cause cretinism in infants and produce symptoms such as weight gain, lethargy, and intolerance to cold in adults.

A deficiency of iodine in the diet can result in goiter, an enlargement of the thyroid gland (see Figure 2.3). Without sufficient iodine, the thyroid gland cannot synthesize adequate amounts of T_3 and T_4 , and the resulting low blood levels of T_3 and T_4 cannot exert the usual negative feedback on the hypothalamus and anterior pituitary (see Figure 45.9). Consequently, the pituitary continues to secrete TSH, elevating TSH levels and enlarging the thyroid.

In addition to the cells that produce T_3 and T_4 , the mammalian thyroid gland contains endocrine cells that produce calcitonin. This hormone acts in conjunction with

parathyroid hormone in maintaining calcium homeostasis, as we will describe next.

Parathyroid Hormone and Calcitonin: Control of Blood Calcium

Rigorous homeostatic control of the blood calcium level is critical because calcium ions (Ca^{2+}) are essential to the normal functioning of all cells. If blood Ca^{2+} level falls substantially, skeletal muscles begin to contract convulsively, a condition known as tetany. If not corrected, tetany is fatal. In mammals, two hormones with opposite actions—parathyroid hormone and calcitonin—play a major role in maintaining blood Ca^{2+} level near a set point of about 10 mg/100 mL (Figure 45.11).

When blood Ca^{2+} level falls below this set point, parathyroid hormone (PTH) is released. PTH is produced by four small structures, the parathyroid glands, that are embedded in the surface of the thyroid.

reach critical levels. Both MSH and p-endorphin are formed by floivanc nf tThe Samp nrprnrsnr nrnrfin iTiaLaiVPs rise in ACTH_

PTH raises the level of blood Ca^{2+} by direct and indirect effects. In bone, PTH induces specialized cells called osteoclasts to decompose the mineralized matrix of bone and release Ca^{2+} into the blood. In the kidneys, it directly stimulates reabsorption of Ca^{2+} through the renal tubules. PTH also has an indirect effect on the kidneys, promoting the conversion of vitamin D to its active hormonal form. An inactive form of vitamin D, a steroid-derived molecule, is obtained from food or synthesized in the skin. Activation of vitamin D begins in the liver and is completed in the kidneys, a process stimulated by PTH. The active form of vitamin D acts directly on the intestines, stimulating the

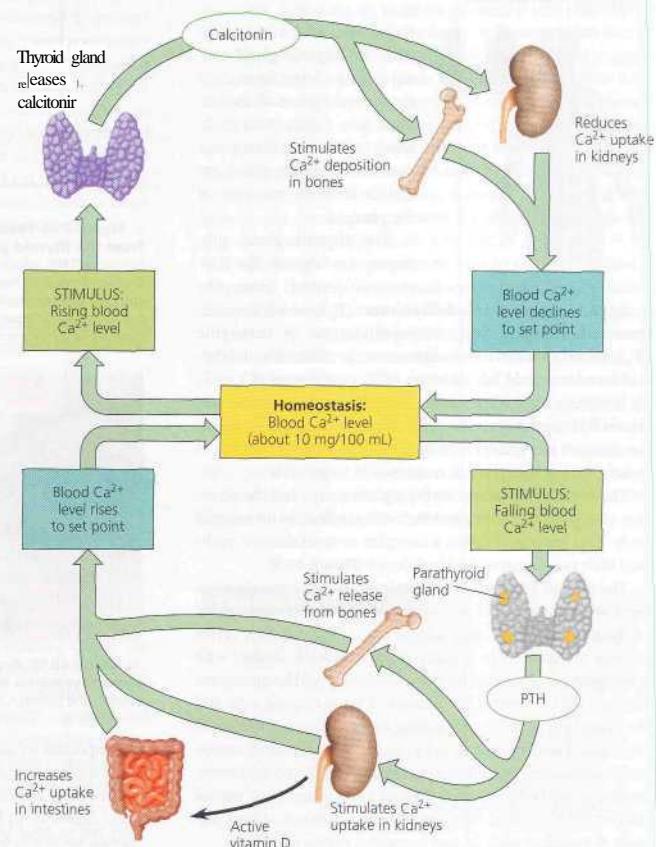

Figure 45.11 Hormonal control of calcium homeostasis in mammals. A negative-feedback system involving two antagonistic hormones, calcitonin and parathyroid hormone (PTH), maintains the blood Ca^{2+} concentration near its set point.

uptake of Ca^{2+} from food and thus augmenting the effect of PTH.

A rise in blood Ca^{2+} level above the set point promotes release of **calcitonin** from the thyroid gland. Calcitonin exerts effects on bone and kidneys opposite to those of PTH and thus lowers the blood Ca^{2+} level.

The regulation of blood Ca^{2+} level illustrates how two hormones with opposite effects—in this case, PTH and calcitonin—balance each other, exerting tight regulation and maintaining homeostasis. Each hormone functions in a simple endocrine pathway in which the hormone-secreting cells themselves monitor the variable being regulated (see Figure 45.2a). In classic feedback fashion, the response to either hormone triggers release of the antagonistic hormone, thereby minimizing fluctuations in the concentration of Ca^{2+} in the blood.

Insulin and Glucagon: Control of Blood Glucose

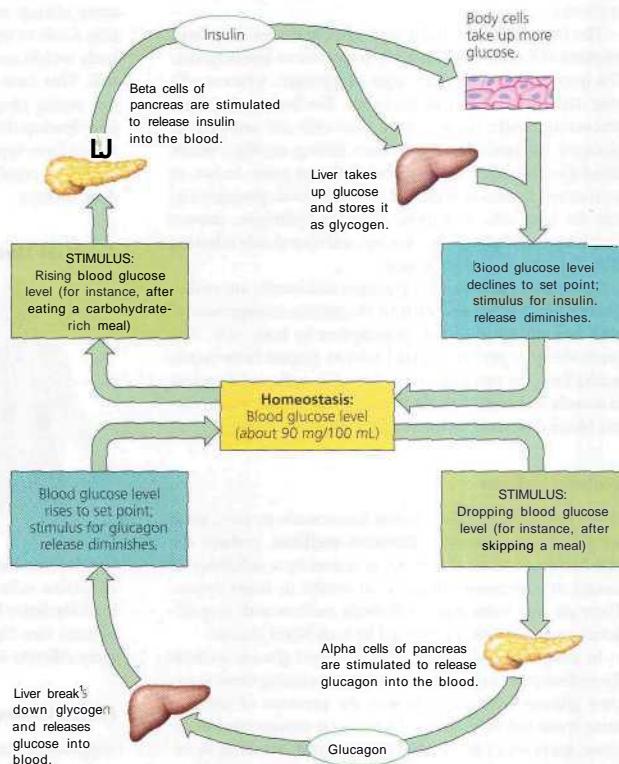

Although the **pancreas** is considered a major endocrine gland, hormone-secreting cells make up only 1–2% of its weight. The rest of the pancreas produces bicarbonate ions and digestive enzymes, which are released into small ducts and carried to the small intestine via the pancreatic duct (see figure 41.20). Tissues and glands that discharge secretions into ducts are described as *exocrine*. Thus, the pancreas is a dual endocrine and exocrine gland with important functions in both the endocrine and digestive systems.

Clusters of endocrine cells, the **islets of Langerhans**, are scattered throughout the exocrine tissue of the pancreas. Each islet has a population of **alpha cells**, which produce the hormone **glucagon**, and a population of **beta cells**, which produce the hormone **insulin**. Both of these protein

hormones, like all endocrine signals, are secreted into the circulatory system.

Insulin and glucagon are antagonistic hormones that regulate the concentration of glucose in the blood (Figure 45.12). This is a critical bioenergetic and homeostatic function, because glucose is a major fuel for cellular respiration and a key source of carbon skeletons for the synthesis of other organic compounds. Metabolic balance depends on maintaining blood glucose concentrations near a set point, which is about 90 mg/100 mL in humans. When blood glucose exceeds this level, insulin is released, and its effects lower blood glucose concentration. When blood glucose drops below the set point, glucagon is released, and its effects increase blood

K Figure 45.12 Maintenance of glucose homeostasis by insulin and glucagon.

The antagonistic effects of insulin and glucagon help maintain the blood glucose level near its set point. A rise in blood glucose level above the set point promotes insulin release from the pancreas, leading to removal of excess glucose from the blood and its storage as glycogen. A fall in blood glucose level below the set point stimulates the pancreas to secrete glucagon, which acts on the liver to raise the blood glucose level.

glucose concentration. Each hormone operates in a simple endocrine pathway that is regulated by negative feedback. The combination of the two pathways permits precise regulation of blood glucose.

Target Tissues for Insulin and Glucagon

Insulin lowers blood glucose levels by stimulating virtually all body cells except those of the brain to take up glucose from the blood. (Brain cells are unusual in being able to take up glucose without insulin; as a result, the brain has access to circulating fuel almost all the time.) Insulin also decreases blood glucose by slowing glycogen breakdown in the liver and inhibiting the conversion of amino acids and glycerol (from fats) to glucose.

The liver, skeletal muscles, and adipose tissues store large amounts of fuel and are especially important in bioenergetics. The liver and muscles store sugar as glycogen, whereas adipose tissue cells convert sugars to fats. The liver is a key fuel-processing center because only liver cells are sensitive to glucagon. Normally, glucagon starts having an effect before blood glucose levels even drop below the set point. In fact, as soon as excess glucose is cleared from the blood, glucagon signals the liver cells to increase glycogen hydrolysis, convert amino acids and glycerol to glucose, and start slowly releasing glucose back into the circulation.

The antagonistic effects of glucagon and insulin are vital to glucose homeostasis and thus to the precise management of both fuel storage and fuel consumption by body cells. The liver's ability to perform its vital roles in glucose homeostasis results from the metabolic versatility of its cells and its access to absorbed nutrients via the hepatic portal vessel, which carries blood directly from the small intestine to the liver.

Diabetes Mellitus

When the mechanisms of glucose homeostasis go awry, there are serious consequences. Diabetes mellitus, perhaps the best-known endocrine disorder, is caused by a deficiency of insulin or a decreased response to insulin in target tissues. There are two major types of diabetes mellitus with very different causes, but each is marked by high blood glucose.

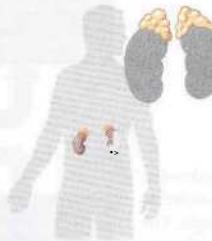

In people with diabetes, elevated blood glucose exceeds the reabsorption capacity of the kidneys, causing them to excrete glucose. This explains why the presence of sugar in urine is one test for diabetes. As glucose is concentrated in the urine, more water is excreted along with it, resulting in excessive volumes of urine and persistent thirst. (*Diabetes*, from the Greek *diabainein*, to pass through, refers to this copious urination; and *mellitus*, from the Greek *meli*, honey, refers to the presence of sugar in urine.) Without sufficient glucose available to meet the needs of most body cells, fat becomes the main substrate for cellular respiration. In severe cases,

acidic metabolites formed during fat breakdown accumulate in the blood, threatening life by lowering blood pH.

Type I diabetes mellitus (insulin-dependent diabetes) is an autoimmune disorder in which the immune system destroys the beta cells of the pancreas. Type I diabetes, which usually appears during childhood, destroys the person's ability to produce insulin. Treatment consists of insulin injections, usually several times daily. In the past, insulin for injections was extracted from animal pancreases, but now human insulin can be obtained from genetically engineered bacteria, a relatively inexpensive source (see Figure 20.2).

Type II diabetes mellitus (non-insulin-dependent diabetes) is characterized either by a deficiency of insulin or, more commonly, by reduced responsiveness of target cells due to some change in insulin receptors. Although heredity can play a role in type II diabetes, research indicates that excess body weight and lack of exercise significantly increase the risk. This form of diabetes generally appears after age 40, but young people who are overweight and sedentary can also develop the disease. More than 90% of people with diabetes have type II. Many can manage their blood glucose level with regular exercise and a healthy diet; some require drug therapy.

Adrenal Hormones: Response to Stress

The adrenal glands are adjacent to the kidneys. In mammals, each adrenal gland is actually made up of two glands with different cell types, functions, and embryonic origins: the *adrenal cortex*, the outer portion, and the *adrenal medulla*, the central portion. Like the pituitary gland, each adrenal gland is a fused endocrine

and neuroendocrine gland. The adrenal cortex consists of true endocrine cells, whereas the secretory cells of the adrenal medulla derive from the neural crest during embryonic development (see Figure 34.7). Nonmammalian vertebrates have quite different arrangements of the same tissues.

Catecholamines from the Adrenal Medulla

Suppose you sense danger or approach a stressful situation, such as speaking in public. Your heart beats faster and your skin develops goose bumps. What causes these reactions? They are part of the so-called fight-or-flight response stimulated by two hormones of the adrenal medulla, epinephrine (also known as adrenaline) and norepinephrine (noradrenaline). These hormones are members of a class of compounds,

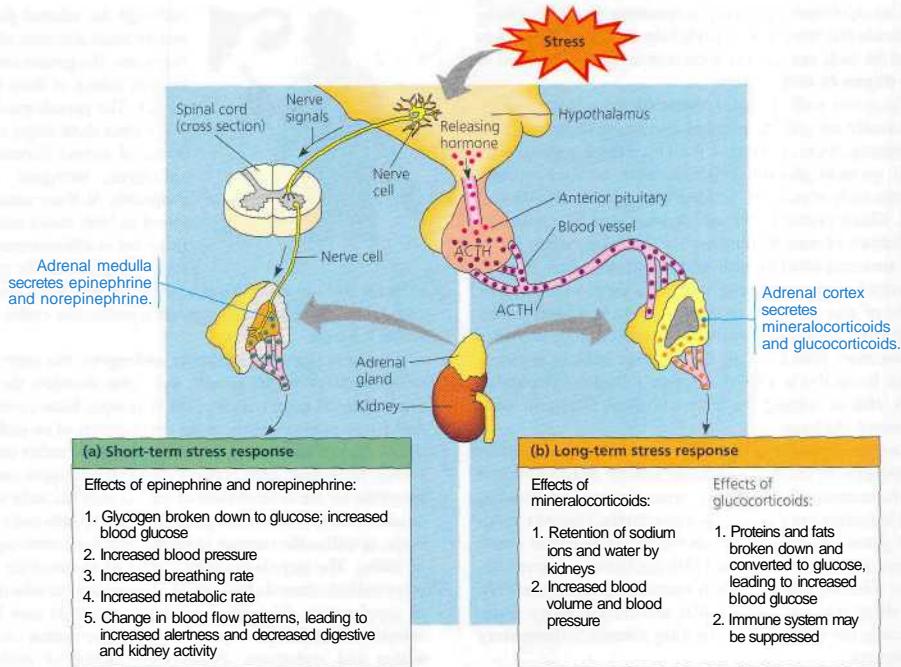

the catecholamines, that are synthesized from the amino acid tyrosine. Both epinephrine and norepinephrine also function as neurotransmitters in the nervous system.

Either positive or negative stress—ranging from extreme pleasure to a drop in temperature to life-threatening danger—stimulates the adrenal medulla to secrete epinephrine and norepinephrine. These hormones act directly on several target tissues and give the body a rapid bioenergetic boost. They increase the rate of glycogen breakdown in the liver and skeletal muscles, promote glucose release by liver cells, and stimulate the release of fatty acids from fat cells. The released glucose and fatty acids circulate in the blood and can be used by body cells as fuel.

In addition to increasing the availability of energy sources, epinephrine and norepinephrine exert profound effects on the cardiovascular and respiratory systems. For example, they increase both the rate and the stroke volume of the heartbeat and dilate the bronchioles in the lungs, actions that increase the rate of oxygen delivery to body cells. (This is why doctors

prescribe epinephrine as a heart stimulant and to open breathing tubes during asthma attacks.) The catecholamines also cause smooth muscles of some blood vessels to contract and muscles of other vessels to relax, with an overall effect of shunting blood away from the skin, digestive organs, and kidneys while increasing the blood supply to the heart, brain, and skeletal muscles (see Figure 45.4). Epinephrine generally has a stronger effect on heart and metabolic rates, while the primary role of norepinephrine is in sustaining blood pressure.

As shown in Figure 45.13a, secretion by the adrenal medulla is stimulated by nerve signals carried from the brain via the sympathetic division of the autonomic nervous system (discussed in Chapter 48). In response to a stressful stimulus, nerve impulses from the hypothalamus travel to the adrenal medulla, where they trigger the release of epinephrine. Norepinephrine is released independently of epinephrine. The adrenal medulla hormones provide another example of a simple neurohormone pathway (see Figure 45.2b). In this

▲ **Figure 45.13 Stress and the adrenal gland.** Stressful stimuli cause the hypothalamus to activate the adrenal medulla via nerve impulses (a) and the adrenal cortex via hormonal signals (b). The adrenal medulla mediates short-term responses to stress by secreting the catecholamine hormones epinephrine and norepinephrine. The adrenal cortex controls more prolonged responses by secreting corticosteroids.

case, the neurosecretory cells are modified peripheral nerve cells rather than the hypothalamic neurosecretory cells that release hormones in the posterior pituitary.

Steroid Hormones from the Adrenal Cortex

Hormones from the adrenal cortex also function in the body's response to stress. But in contrast to the adrenal medulla, which reacts to nervous input, the adrenal cortex responds to endocrine signals. Stressful stimuli cause the hypothalamus to secrete a releasing hormone that stimulates the anterior pituitary to release the tropic hormone ACTH. When ACTH reaches the adrenal cortex via the bloodstream, it stimulates the endocrine cells to synthesize and secrete a family of steroids called corticosteroids. In another case of negative feedback, elevated levels of corticosteroids in the blood suppress the secretion of ACTH.

The two main types of corticosteroids in humans are the glucocorticoids, such as cortisol, and the mineralocorticoids, such as aldosterone. Evidence is mounting that both glucocorticoids and mineralocorticoids help maintain homeostasis when the body experiences stress over an extended period of time (**Figure 45.13b**).

The primary effect of glucocorticoids is on bioenergetics, specifically on glucose metabolism. Augmenting the fuel-mobilizing effects of glucagon from the pancreas, glucocorticoids promote glucose synthesis from noncarbohydrate sources such as proteins, making more glucose available as fuel. Glucocorticoids act on skeletal muscle, causing a breakdown of muscle proteins. The resulting carbon skeletons are transported to the liver and kidneys, where they are converted to glucose and released into the blood. The synthesis of glucose from muscle proteins is a homeostatic mechanism providing circulating fuel when body activities require more than the liver can mobilize from its glycogen stores. It can also be part of a broader role of the glucocorticoids, that of helping the body withstand long-term environmental challenge.

Cortisol and other glucocorticoids also suppress certain components of the body's immune system. Because of their anti-inflammatory effect, glucocorticoids have been used to treat inflammatory diseases such as arthritis. However, long-term glucocorticoid use can have serious side effects owing to their metabolic actions and also can increase susceptibility to infection owing to their immunosuppressive effects. For these reasons, nonsteroidal anti-inflammatory drugs generally are preferred for treating chronic inflammatory conditions.

Mineralocorticoids act principally on salt and water balance. Aldosterone, for example, stimulates cells in the kidneys to reabsorb sodium ions and water from filtrate, raising blood pressure and volume. Aldosterone secretion is stimulated primarily by angiotensin II, as part of the regulatory pathway that

controls the kidneys' ability to maintain the ion and water homeostasis of the blood (see Figure 44.13). However, when an individual is under severe stress, the resulting rise in blood ACTH levels can increase the rate at which the adrenal cortex secretes aldosterone as well as glucocorticoids.

The adrenal cortex produces a third group of corticosteroids that function as sex hormones. All the steroid hormones are synthesized from cholesterol (see Figure 5.15), and their structures differ in only minor ways. However, these differences are associated with major differences in their effects. The sex hormones produced by the adrenal cortex are mainly male hormones (androgens), with small amounts of female hormones (estrogens and progestins). There is evidence that adrenal androgens account for the sex drive in adult females, but otherwise the physiological roles of the adrenal sex hormones are not well understood.

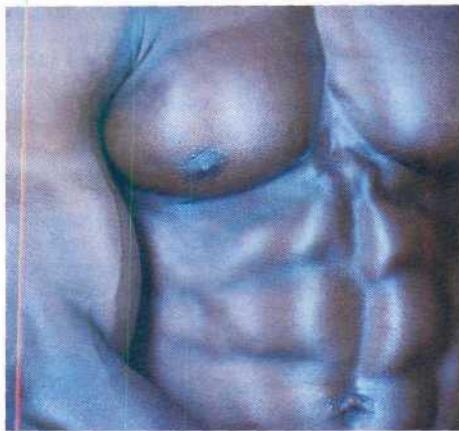

Gonadal Sex Hormones

Although the adrenal glands secrete small amounts of sex hormones, the gonads are the primary source of these hormones. The gonads produce and secrete three major categories of steroid hormones: androgens, estrogens, and progestins. All three types are found in both males and females but in different proportions. Produced in the testes of males and ovaries of females, these steroids affect growth and development and also regulate reproductive cycles and sexual behavior.

The testes primarily synthesize androgens, the main one being testosterone. In general, androgens stimulate the development and maintenance of the male reproductive system. Androgens produced early in the development of an embryo determine that the fetus will develop as a male rather than a female. At puberty, high concentrations of androgens are responsible for the development of human male secondary sex characteristics, such as male patterns of hair growth and a low voice, as well as the increase in muscle and bone mass typical of males. The muscle-building action of testosterone and other anabolic steroids has enticed some athletes to take them as supplements, although these drugs appear to give little competitive advantage in sports requiring fine muscle coordination and endurance. Furthermore, abuse of anabolic steroids carries many health risks (**Figure 45.14**), and they are banned in most competitive sports.

Estrogens, of which the most important is estradiol, are responsible for the maintenance of the female reproductive system and for the development of female secondary sex

A Figure 45.14 Male breast enlargement due to anabolic steroids. Steroid abuse disrupts the body's normal production of hormones, which causes both short- and long-term health risks. Men may also experience infertility and testicular atrophy. Women may undergo masculinizing effects such as breast shrinkage, voice deepening, and excessive growth of body hair. Both sexes can develop acne and male-pattern baldness. Potential long-term health risks include heart and liver damage.

characteristics. In mammals, **progesterins**, which include progesterone, are primarily involved in preparing and maintaining the uterus, which supports the growth and development of an embryo.

Both estrogens and androgens are components of complex neuroendocrine pathways. Their synthesis is controlled by gonadotropins (FSH and LH) from the anterior pituitary gland (see Figure 45.8). FSH and LH secretion in turn is controlled by a releasing hormone from the hypothalamus, GnRH (gonadotropin-releasing hormone). In Chapter 46 we will examine in detail the feedback relationships that regulate the secretion of gonadal steroids.

Melatonin and Biorhythms

We conclude our discussion of the vertebrate endocrine system with the **pineal gland**, a small mass of tissue near the center of the mammalian brain (it is found closer to the brain surface in some other vertebrates). The pineal gland synthesizes and secretes the hormone **melatonin**, a modified amino acid. Depending on the species,

the pineal gland contains light-sensitive cells or has nervous connections from the eyes that control its secretory activity.

Melatonin regulates functions related to light and to seasons marked by changes in day length. Although melatonin affects skin pigmentation in many vertebrates, its primary functions are related to biological rhythms associated with reproduction. Melatonin is secreted at night, and the amount secreted depends on the length of the night. In winter, for example, the days are short and the nights are long, so more melatonin is secreted. Thus, melatonin production is a link between a biological clock and daily or seasonal activities, such as reproduction. Recent evidence suggests that the main target cells of melatonin are in the part of the brain called the suprachiasmatic nucleus (SCN), which functions as a biological clock. Melatonin seems to decrease the activity of neurons in the SCN, and this may be related to its role in mediating rhythms. However, much remains to be learned about the precise role of melatonin and about biological clocks in general.

Concept Check 45.4

- How does thyroxine (T_4) control its own production and secretion?
- How do calcitonin and parathyroid hormone (PTH) maintain blood Ca^{2+} level near the set point?
- In a glucose tolerance test, a person's blood glucose level is measured periodically following ingestion of a glucose-containing solution. In a healthy individual, the blood glucose rises moderately at first but then falls to near normal within 2–3 hours. Predict the results of this test in a person with diabetes mellitus. Explain your answer.
- How would a decrease in the number of corticosteroid receptors in the hypothalamus likely affect levels of corticosteroids in the blood?

For suggested answers, see Appendix A.

Concept 45.5

Invertebrate regulatory systems also involve endocrine and nervous system interactions

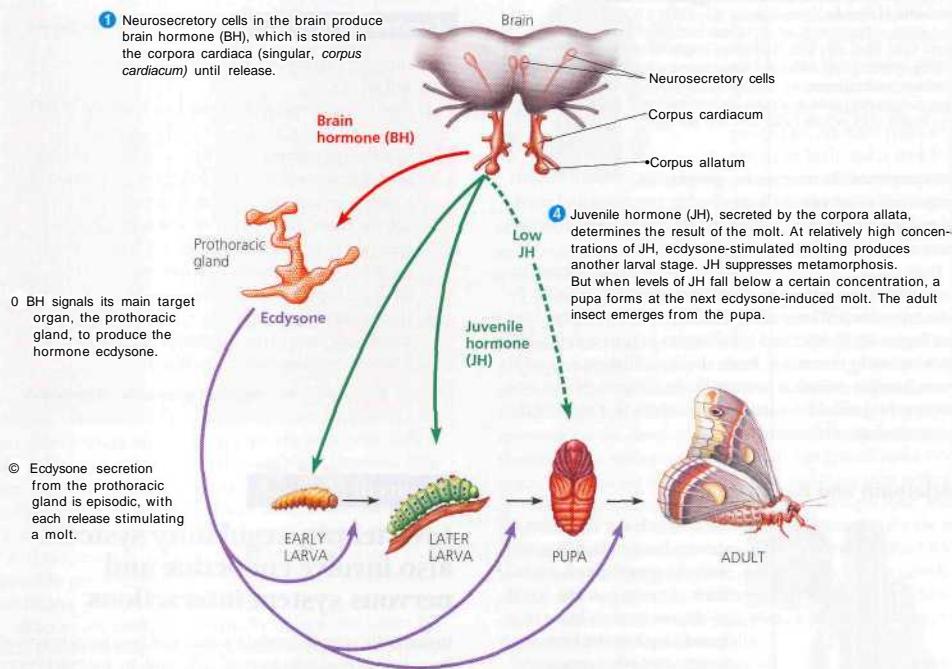

Invertebrate animals produce a variety of hormones in typical hormone-secreting endocrine cells and in neurosecretory cells. Some invertebrate hormones have homeostatic functions, such as regulation of water balance. However, we know the most about hormones that function in reproduction and development. In a hydra, for example, one hormone stimulates

growth and budding (asexual reproduction) but prevents sexual reproduction. In more complex invertebrates, the endocrine and nervous systems are generally integrated in the control of reproduction and development. In the mollusc *Aplysia*, for instance, specialized nerve cells secrete a neurohormone that stimulates the laying of thousands of eggs and also inhibits feeding and locomotion, activities that interfere with reproduction.

All groups of arthropods possess extensive endocrine systems. Crustaceans have hormones that function in growth and reproduction, water balance, movement of pigments in the integument and eyes, and regulation of metabolism. Having exoskeletons that cannot stretch, crustaceans and insects appear to grow in spurts, shedding the old exoskeleton and secreting a new one with each molt. Further, most insects acquire their adult characteristics in a single terminal molt. In insects and crustaceans (and most likely in all arthropods with exoskeletons), molting is triggered by a hormone.

The hormonal regulation of insect development has been studied extensively. Three hormones play major roles in molting and metamorphosis into the adult form (**Figure 45.15**). Brain hormone, produced by neurosecretory cells in the insect brain, stimulates the release of ecdysone from the prothoracic glands, a pair of endocrine glands just behind the head. Ecdysone promotes molting and the development of adult characteristics, as in the change from a caterpillar to a butterfly. Brain hormone and ecdysone are balanced by the third hormone in this system, juvenile hormone. Juvenile hormone is secreted by a pair of small endocrine glands just behind the brain, the corpora allata (singular, *corpus allatum*), which are somewhat analogous to the anterior pituitary gland in vertebrates. As its name suggests, juvenile hormone promotes the retention of larval (juvenile) characteristics.

In the presence of a relatively high concentration of juvenile hormone, ecdysone can still stimulate molting, but the product is simply a larger larva. Only when the level of juvenile hor-

A Figure 45.15 Hormonal regulation of insect development. Most insects go through a series of larval stages, with each molt (shedding of the old exoskeleton) leading to a larger larva. Molting of the final larval stage gives rise to a pupa, in which metamorphosis produces the adult form of the insect. Hormones control the progression of stages, as shown here.

mone wanes can ecdysone-induced molting produce a developmental stage called a pupa. Within the pupa, metamorphosis replaces larval anatomy with the insect's adult form. Synthetic versions of juvenile hormone are now being used as insecticides to prevent insects from maturing into reproducing adults.

In the next chapter, we will look at reproduction in both vertebrates and invertebrates. There we will see that the endocrine system is central not only to the survival of the individual but also to the propagation of the species.

Concept Check 45.5

- How does the nervous system contribute to molting in insects?
- Juvenile hormone is sometimes used commercially as an insecticide. What effects does it have on insect populations? Explain.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 45.1

The endocrine system and the nervous system act individually and together in regulating an animal's physiology

► **Overlap Between Endocrine and Nervous Regulation** (pp. 944) The endocrine and nervous systems often function together in maintaining homeostasis, development, and reproduction. Endocrine glands and various organs with primarily nonendocrine functions secrete hormones, and specialized secretory cells derived from nervous tissue secrete neurohormones. Both classes of hormonal signals circulate in the blood to their target tissues, functioning as long-distance regulators.

► **Control Pathways and Feedback Loops** (pp. 944–945) There are three major types of hormonal control pathways: endocrine, neurohormone, and neuroendocrine. The basic components of a biological regulatory system are present in each kind of pathway. Negative feedback regulates many hormonal pathways involved in homeostasis.

Concept 45.2

Hormones and other chemical signals bind to target cell receptors, initiating pathways that culminate in specific cell responses

• **Cell-Surface Receptors for Water-Soluble Hormones** (pp. 946–947) Peptide/protein hormones and most of those derived from amino acids bind to receptors embedded in the plasma membrane. Hormone binding triggers an intracellular signal transduction pathway leading to specific responses in the cytoplasm or changes in gene expression. The same hormone may have different effects on target cells that have different receptors for the hormone, different signal transduction pathways, or different effector proteins.

Activity Overview of Cell Signaling

Activity Peptide Hormone Action

• **intracellular Receptors for Lipid-Soluble Hormones** (p. 947) Steroid hormones, thyroid hormones, and the hormonal form of vitamin D enter target cells and bind LO-

specific protein receptors in the cytoplasm or nucleus. The hormone-receptor complexes then act as transcription factors in the nucleus, regulating transcription of specific genes.

Activity Steroid Hormone Action

► **Paracrine Signaling by Local Regulators** (pp. 947–948) Various types of chemical signals elicit responses in nearby target cells. Local regulators include neurotransmitters, cytokines and growth factors (proteins/peptides), nitric oxide (a gas), and prostaglandins (modified fatty acids).

Concept 45.3

The hypothalamus and pituitary integrate many functions of the vertebrate endocrine system

• **Relationship Between the Hypothalamus and Pituitary Gland** (pp. 950–951) The hypothalamus, a region of the lower brain, contains different sets of neurosecretory cells. Some produce direct-acting hormones that are stored in and released from the posterior pituitary. Other hypothalamic cells produce tropic hormones that are secreted into the blood and transported to the anterior pituitary, a true endocrine gland. These tropic hormones control release of hormones from the anterior pituitary.

• **Posterior Pituitary Hormones** (p. 951) The two hormones released from the posterior pituitary act directly on nonendocrine tissues. Oxytocin induces uterine contractions and milk ejection, and antidiuretic hormone (ADH) enhances water reabsorption in the kidneys.

• **Anterior Pituitary Hormones** (pp. 951–952) Both tropic and nontropic hormones are produced by the anterior pituitary. The four strictly tropic hormones are thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and adrenocorticotrophic hormone (ACTH). Each acts on its target endocrine tissue to stimulate release of hormone(s) with direct metabolic or developmental effects. Prolactin, melanocyte-stimulating hormone (MSH), and 3-endorphin are nontropic anterior pituitary hormones. Prolactin stimulates lactation in mammals but has diverse effects in different vertebrates. MSH influences skin pigmentation in some vertebrates and fat metabolism in mammals. Endorphins inhibit the perception of pain. Growth hormone (GH) promotes growth directly and has diverse metabolic effects; it also stimulates the production of growth factors by other tissues (a tropic effect).

Concept 45.4

Nonpituitary hormones help regulate metabolism, homeostasis, development, and behavior

- **Thyroid Hormones** (pp. 953–954) The Thyroid gland produces iodine-containing hormones (T₃ and T₄) that stimulate metabolism and influence development and maturation. Secretion of T₃ and T₄ is controlled by the hypothalamus and pituitary in a complex neuroendocrine pathway involving two negative-feedback loops. The thyroid also secretes calcitonin, which functions in calcium homeostasis.

Investigation How Do Thyroxine and TSH Affect Metabolism?

- **Parathyroid Hormone and Calcitonin: Control of Blood Calcium** (pp. 954–955) Two amagousic hormones, calcitonin and parathyroid hormone (PTH), play the major role in calcium (Ca^{2+}) homeostasis in mammals. Calcitonin, secreted by the thyroid, stimulates Ca^{2+} deposition in bones and excretion by kidneys, thereby decreasing blood Ca^{2+} levels. PTH, secreted by the parathyroid glands, has the opposite effects on bones and kidneys, thereby increasing blood Ca^{2+} levels. PTH also has an indirect effect, stimulating the kidneys to activate vitamin D, which in turn promotes intestinal uptake of Ca^{2+} from food.

- **Insulin and Glucagon: Control of Blood Glucose** (pp. 955–956) Two types of endocrine cells in the pancreas secrete insulin and glucagon, antagonistic hormones that help maintain glucose homeostasis. Insulin (from beta cells) reduces blood glucose levels by promoting die cellular uptake of glucose, glycogen formation in the liver, protein synthesis, and fat storage. Glucagon (from alpha cells) increases blood glucose levels by stimulating the conversion of glycogen to glucose in the liver and the breakdown of fat and protein to glucose. Diabetes mellitus, which is marked by elevated blood glucose levels, may be caused by inadequate production of insulin (type I) or loss of responsiveness of target cells w insulin (type II).

- **Adrenal Hormones: Response to Stress** (pp. 956–958) Neurosecretory cells in the adrenal medulla release epinephrine and norepinephrine in response to stress-activated impulses from the nervous system. These hormones mediate various fight-or-flight responses. The adrenal cortex releases three functional classes of steroid hormones. Glucocorticoids, such as cortisol, influence glucose metabolism and the immune system; mineralocorticoids, primarily aldosterone, affect salt and water balance. The adrenal cortex also produces small amounts of sex hormones.

- **Gonadal Sex Hormones** (pp. 958–959) The gonads—testes and ovaries—produce most of the body's sex hormones; androgens, estrogens, and progestins. All three types are produced in males and females but in different proportions.

Activity Human Endocrine Glands and Hormones

- **Melatonin and Biorhythms** (p. 959) The pineal gland, located within the brain, secretes melatonin. Release of melatonin is controlled by light/dark cycles. Its primary functions appear to be related to biological rhythms associated with reproduction.

Concept 45.5

Invertebrate regulatory systems also involve endocrine and nervous system interactions

- Diverse hormones regulate different aspects of homeostasis in invertebrates. In insects, molting and development are controlled by three main hormones: brain hormone, a tropic neurohormone; ecdysone, whose release is triggered by brain hormone; and juvenile hormone (pp. 959–961).

TESTING YOUR KNOWLEDGE**Evolution Connection**

The intracellular receptors used by all the steroid and thyroid hormones are similar enough in structure that they are all considered members of one "superfamily" of proteins. Propose a hypothesis for how the genes encoding these receptors may have evolved. (Hint: See Figure 19.19.)

Scientific Inquiry

In your response to the Evolution Connection question on this page, you came up with a hypothesis. How could you test your hypothesis using DNA sequence data?

Investigation How Do Thyroxine and TSH Affect Metabolism?

Science, Technology, and Society

Growth hormone (GH) treatments have enabled hundreds of children with pituitary dwarfism to reach a stature within the normal range. Some parents of children who are extremely short, but who do not suffer from an endocrine disorder, also request GH treatment so that their children will grow faster and taller. There can be potentially harmful effects, such as a reduction in body fat and an increase in muscle mass. And no one yet knows if GH injections could have seriously harmful long-term effects in individuals who do not have a hypopituitary condition. What guidelines would you propose for the use of GH in children? Explain your reasoning.

new government's success in the local referendum will probably depend largely on its ability to demonstrate that the proposed changes will improve the quality of life for most citizens.

THE FUTURE

International finance and the future multilateral monetary system

The collapse of Soviet communism has now made it increasingly clear that the international financial system must move to a more effective relationship between the political integration of Europe, energy, financial and monetary issues. However, this process of integration must be undertaken in a way that respects the principles of personal freedom, free markets, property rights, free enterprise, individual initiative and the rule of law. It is important that the role of business in the economy, through private banks, should be clarified and given enough time to work out the new rules of capital accumulation and wage creation. This will take a short time, allowing a change in the political integration of institutions among states and monetary issues, but not necessarily changing the methods of financing governments. In addition, a period of political stability will allow the introduction of a single currency and a single tax base, thus creating a single market. The question of the principles of money should be forgotten.

International finance, by establishing a new institutional plan, can help to stabilize the world economy. It shall first establish a funding institution

to support the development of the European Union and its members.

International finance can also help to stabilize the world economy by helping to maintain a balance of payments equilibrium between countries.

International finance can also help to maintain a balance of payments equilibrium between countries by helping to maintain a balance of payments equilibrium between countries.

46 Animal Reproduction

A Figure 46.1 Earthworms mating.

Key Concepts

- 46.1 Both asexual and sexual reproduction occur in the animal kingdom
- 46.2 Fertilization depends on mechanisms that help sperm meet eggs of the same species
- 46.3 Reproductive organs produce and transport gametes: focus on humans
- 46.4 In humans and other mammals, a complex interplay of hormones regulates gametogenesis
- 46.5 In humans and other placental mammals, an embryo grows into a newborn in the mother's uterus

Overview

Doubling Up for Sexual Reproduction

The two earthworms in **Figure 46.1** are mating. Unless disturbed, they will remain above the ground and joined like this for several hours. Each worm produces both sperm and eggs, each donates and receives sperm during mating, and each will produce fertilized eggs. In a few weeks, sexual reproduction will be completed when new worms hatch.

The many aspects of animal form and function we have studied in earlier chapters can be viewed, in the broadest context, as adaptations contributing to reproductive success. Individuals are transient. A population transcends finite life spans only by reproduction, the creation of new individuals from existing ones. Animal reproduction is the subject of this chapter. We will first compare the diverse reproductive mechanisms that have evolved in the animal kingdom and then examine the details of mammalian, particularly human, reproduction. Deferring the

cellular and molecular details of embryonic development until the next chapter, we focus here on the physiology of reproduction, mostly from the perspective of the parents.

Concept 46.1

Both asexual and sexual reproduction occur in the animal kingdom

There are two principal modes of animal reproduction. **Asexual** (from the Greek, "without sex") **reproduction** is the creation of new individuals whose genes all come from one parent without the fusion of egg and sperm. In most cases, asexual reproduction relies entirely on mitotic cell division. **Sexual reproduction** is the creation of offspring by the fusion of haploid **gametes** to form a **zygote** (fertilized egg), which is diploid. Animal gametes arise by meiosis (see Figure 13.8). The female gamete, the unfertilized **egg** (also called an **ovum**), is a relatively large cell and not motile. The male gamete, the **sperm**, is generally a much smaller, motile cell. Sexual reproduction increases genetic variability among offspring by generating unique combinations of genes inherited from two parents. By producing offspring having a variety of phenotypes, sexual reproduction may enhance the reproductive success of parents when environmental factors (including pathogens) change relatively rapidly (see Chapter 23, p. 469).

Mechanisms of Asexual Reproduction

Many invertebrates can reproduce asexually by **fission**, the separation of a parent into two or more individuals of approximately

A Figure 46.2 Asexual reproduction of a sea anemone (*Anthopleura elegantissima*). The individual in the center of this photograph is undergoing fission, a type of asexual reproduction. Two smaller individuals will form as the parent divides approximately in half. The offspring will be genetic copies of the parent.

equal size (**Figure 46.2**). Also common among invertebrates is budding, in which new individuals arise from outgrowths of existing ones. For example, in certain cnidarians and tunicates, new individuals grow out from the body of a parent (see Figure 13.2). The offspring may either detach from the parent or remain joined, eventually forming extensive colonies. Stony corals, which may be more than 1 m across, are cnidian colonies of several thousand connected individuals. In another form of asexual reproduction, some invertebrates, such as sponges, release specialized groups of cells that can grow into new individuals.

Yet another type of asexual reproduction starts with the process of fragmentation, the breaking of the body into several pieces, some or all of which develop into complete adults. For an animal to reproduce this way, fragmentation must be accompanied by regeneration, the regrowth of lost body parts. Reproduction by fragmentation and regeneration occurs in many sponges, cnidarians, polychaete annelids, and tunicates. Many animals can also replace lost appendages by regeneration—most sea stars can grow new arms when injured, for example—but this is not reproduction because new individuals are not created. In sea stars of the genus *Linckia*, a whole new individual may develop from an isolated arm. Thus, a single animal with five arms, if broken apart, could asexually give rise to five offspring.

Asexual reproduction has several potential advantages. For instance, it enables animals living in isolation to produce offspring without locating mates. It can also create numerous offspring in a short amount of time, which is ideal for colonizing a habitat rapidly. Theoretically, asexual reproduction is most advantageous in stable, favorable environments because it perpetuates successful genotypes precisely.

Reproductive Cycles and Patterns

Most animals exhibit cycles in reproductive activity, often related to changing seasons. The periodic nature of reproduction allows animals to conserve resources and reproduce when more energy is available than is needed for maintenance and when environmental conditions favor the survival of offspring. Ewes (female sheep), for example, have 15-day reproductive cycles and ovulate at the midpoint of each cycle. These cycles generally occur during fall and early winter, ensuring that most lambs are born in the late winter or spring. Even animals that live in relatively unvarying habitats, such as the tropics or the ocean, generally reproduce only at certain times of the year. Reproductive cycles are controlled by a combination of hormonal and environmental cues, the latter including seasonal temperature, rainfall, day length, and lunar cycles.

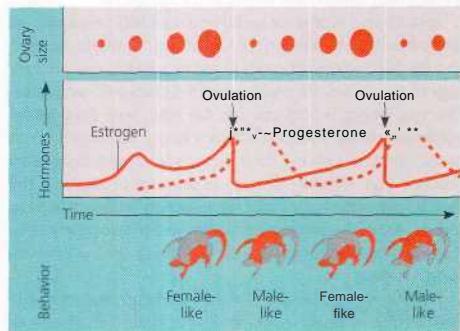

Animals may reproduce exclusively asexually or sexually, or they may alternate between the two modes. In aphids, rotifers, and the freshwater crustacean *Daphnia*, a female can produce eggs of two types, depending on environmental conditions. One type of egg is fertilized, but the other type develops by parthenogenesis, a process in which an egg develops without being fertilized. Haploid adults arising from parthenogenesis produce eggs without meiosis. In the case of *Daphnia*, the switch from sexual to asexual reproduction is often related to season. Asexual reproduction occurs under favorable conditions, and sexual reproduction occurs during times of environmental stress.

Parthenogenesis has a role in the social organization of certain species of bees, wasps, and ants. Male honeybees, or drones, are produced parthenogenetically, whereas females, both sterile workers and reproductive females (queens), develop from fertilized eggs.

Among vertebrates, several genera of fishes, amphibians, and lizards reproduce exclusively by a complex form of parthenogenesis that involves the doubling of chromosomes after meiosis to create diploid "zygotes." For example, about 15 species of whiptail lizards (genus *Cnemidophorus*) reproduce exclusively by parthenogenesis. There are no males in these species, but the lizards imitate courtship and mating behavior typical of sexual species of the same genus. During the breeding season, one female of each mating pair mimics a male (**Figure 46.3a**). The roles change two or three times during the season, female behavior occurring when the level of the female sex hormone estrogen is high, prior to ovulation (the release of eggs), and male behavior occurring after ovulation, when the level of estrogen drops (**Figure 46.3b**). Ovulation is more likely to occur if one individual is mounted by another during the critical time of the hormone cycle; isolated lizards lay fewer eggs than those that go through the motions of sex. Apparently, these parthenogenetic lizards, which evolved from species having two sexes, still require certain sexual stimuli for maximum reproductive success.

(a) Both lizards in this photograph are *C. uniparens* females. The one on top is playing the role of a male. Every two or three weeks during the breeding season, individuals switch sex roles.

(b) The sexual behavior of *C. uniparens* is correlated with the cycle of ovulation mediated by sex hormones. As blood levels of estrogen rise, the ovaries grow, and the lizard behaves like a female. After ovulation, the estrogen level drops abruptly, and the progesterone level rises; these hormone levels correlate with male behavior.

A Figure 46.3 Sexual behavior in parthenogenetic lizards.
The desert-grassland whiptail lizard (*Cnemidophorus uniparens*) is an all-female species. These reptiles reproduce by parthenogenesis, the development of an unfertilized egg. However, ovulation is stimulated by mating behavior.

Sexual reproduction presents a special problem for sessile or burrowing animals and for parasites, such as tapeworms, which may seldom encounter a member of the opposite sex. One solution to this problem is hermaphroditism, in which each individual has both male and female reproductive systems (the term is derived from Hermes and Aphrodite, a Greek god and goddess). Although some hermaphrodites fertilize themselves, most must mate with a member of the same species. In this case, each animal serves as both male and female, donating and receiving sperm, as we saw for earthworms. Every individual is a potential mate, and each hermaphroditic mating can result in twice as many offspring as from a male-female mating, where only one partner's eggs are fertilized.

A Figure 46.4 Sex reversal in a sequential hermaphrodite.
A male Caribbean bluehead wrasse and two smaller females feed on a sea urchin. All wrasses of this species are born female, but the oldest largest fish complete their lives as males.

Another remarkable reproductive pattern is sequential hermaphroditism, in which an individual reverses its sex during its lifetime. In some species, the sequential hermaphrodite is female first, while in other species it is male first. In various species of reef fishes called wrasses, sex reversal is associated with age and size. For example, the Caribbean bluehead wrasse is a female-first species in which only the largest (usually the oldest) individuals change from female to male (Figure 46.4). These fish live in harems consisting of a single male and several females. If the male dies or is removed in an experiment, the largest female in the harem becomes the new male. Within a week, the transformed individual is producing sperm instead of eggs. In this species, the male defends the harem against intruders, and thus larger size may give a greater reproductive advantage to males than it does to females. In contrast, there are male-first animals that change from male to female when size increases. In such cases, greater size may increase the reproductive success of females more than it does males. For example, the production of huge numbers of gametes is an important asset for sedentary animals, such as oysters, that release their gametes into the surrounding water. Larger females tend to produce more eggs than smaller ones, and species of oysters that are sequential hermaphrodites are generally male first.

The diverse reproductive cycles and patterns we observe in the animal kingdom are adaptations that have evolved by natural selection. We will see many other examples as we survey the various mechanisms of sexual reproduction.

Concept Check 46.1

- What is the most important difference between the outcomes of asexual and sexual reproduction?
- How is the term *sequential hermaphroditism* misleading?

For suggested answers, see Appendix A.

Fertilization depends on mechanisms that help sperm meet eggs of the same species

The mechanisms of **fertilisation**, the union of sperm and egg, play an important part in sexual reproduction. Some species have **external fertilization**: Eggs are released by the female into a wet environment, where [hey are fertilized by the male (**Figure 46.5**). Other species have **internal fertilization**: Sperm are deposited in or near the female reproductive tract, and fertilization occurs within the tract. (The cellular and molecular details of fertilization are discussed in Chapter 47.)

A moist habitat is almost always required for external fertilization, both to prevent gametes from drying out and to allow the sperm to swim to the eggs. Many aquatic invertebrates simply shed their eggs and sperm into the surroundings, and fertilization occurs without the parents actually making physical contact. However, timing is crucial to ensure that mature sperm encounter ripe eggs.

For species that use external fertilization, environmental cues such as temperature or day length may cause a whole copulation to release gametes at once, or chemical signals from one individual releasing gametes may trigger gamete release in others. Alternatively, individuals may exhibit specific mating behaviors leading to the fertilization of the eggs of one female by one male. Such "courtship" behavior has two important benefits: It allows mate selection and, by triggering the release of both sperm and eggs, increases the probability of successful fertilization.

Internal fertilization is an adaptation to terrestrial life that enables sperm to reach an egg when the environment is dry. It requires cooperative behavior that leads to copulation. In some cases, uncharacteristic sexual behavior is eliminated by natural selection in a direct manner; for example, female spiders may eat males that fail to give or respond to specific signals during mating. Internal fertilization requires sophisticated reproductive systems, including copulatory organs that deliver sperm and receptacles for its storage and transport to ripe eggs.

However fertilization occurs, the mating animals may make use of **pheromones**, chemical signals released by one organism that influence the physiology and/or behavior of other individuals of the same species. Pheromones are small, volatile or water-soluble molecules that disperse into the environment and, like hormones, are active in minute amounts. Many pheromones function as mate attractants. The mate attractants of some female insects can be detected by males as much as a mile away. (We will return to mating behavior and pheromones in Chapter 51.)

A Figure 46.5 External fertilization. Many amphibians shed gametes into the environment, where fertilization occurs. In most species, behavioral adaptations ensure that a male is present when the female releases eggs. Here, a female frog, clasped by a male (on top), has released a mass of eggs. The male released sperm (not visible) at the same time, and external fertilization has already occurred in the water.

Ensuring the Survival of Offspring

All species produce more offspring than can survive to reproduce. Species with external fertilization usually produce enormous numbers of zygotes, but the proportion that survive and develop further is often quite small. Internal fertilization usually produces fewer zygotes, but this may be offset by greater protection of the embryos and parental care of the young. Major types of protection include tough eggshells, development of the embryo within the reproductive tract of the mother, and parental care of the eggs and offspring.

The embryos of many species of terrestrial animals develop in eggs that can withstand harsh environments. Birds, reptiles, and monotremes have amniote eggs with calcium and protein shells that resist water loss and physical damage. (By contrast, the eggs of fishes and amphibians have only a gelatinous coat.)

Rather than secreting a protective shell around the egg, many animals retain the embryo, which develops within the female reproductive tract. Marsupial mammals, such as kangaroos and opossums, retain their embryos for only a short period in the uterus; the embryos then crawl out and complete fetal development attached to a mammary gland in the mother's pouch. However, the embryos of eutherian (placental) mammals, such as humans, develop entirely within the uterus, nourished by the mother's blood supply through a special organ, the placenta (discussed in Chapter 34 and later in this chapter).

When a kangaroo crawls out of its mother's pouch for the first time, or when a human is born, it is not yet capable of independent existence. We are familiar with adult birds feeding their young and mammals nursing their offspring, but parental care is much more widespread than we might suspect, and it takes a variety of unusual forms. In one species of tropical frog, for instance, the male carries the tadpoles in his stomach until

A Figure 46.6 Parental care in an invertebrate. Compared with many other insects, giant water bugs of the genus *Belostoma* produce relatively few offspring, but parental protection enhances survival. Fertilization is internal, but the female then glues her fertilized eggs to the back of the male (shown here). Whereas the males of most insect species provide no parental care for their offspring, the male giant water bug carries them for days, frequently fanning water over them. This treatment helps keep the eggs moist, aerated, and free of parasites.

they metamorphose and hop out as young frogs. There are also many cases of parental care among invertebrates (Figure 46.6).

Gamete Production and Delivery

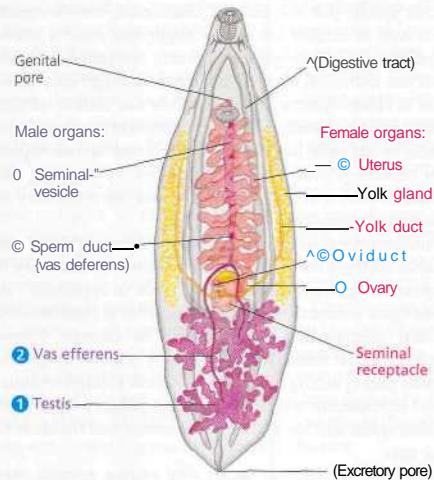

To reproduce sexually, animals must have systems that produce gametes and make them available to the gametes of the opposite sex. These reproductive systems are varied. The least complex systems do not even contain distinct gonads, the organs that produce gametes in most animals. Among the simplest systems are those of polychaete worms (phylum Annelida). Most polychaetes have separate sexes but do not have distinct gonads; rather, the eggs and sperm develop from undifferentiated cells lining the coelom. As the gametes mature, they are released from the body wall and fill the coelom. Depending on the species, mature gametes may be shed through the excretory openings, or the swelling mass of eggs may split the body open, killing the parent and spilling the eggs into the environment.

The most complex reproductive systems contain many sets of accessory tubes and glands that carry, nourish, and protect the gametes and the developing embryos. Many animals whose body plans are otherwise relatively simple possess

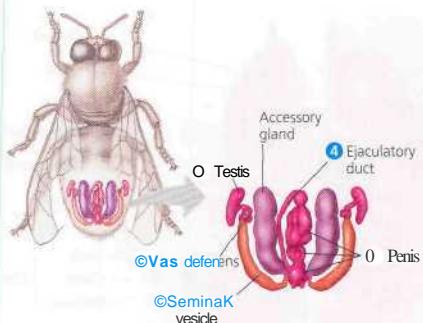

highly complex reproductive systems. The reproductive systems of parasitic flatworms, for example, are among the most complex in the animal kingdom (Figure 46.7). These worms are hermaphrodites.

Most insects have separate sexes with complex reproductive systems (Figure 46.8). In the male, sperm develop in a pair of testes and are conveyed along a coiled duct to two seminal vesicles, where they are stored. During mating, sperm are ejaculated into the female reproductive system. In the female, eggs develop in a pair of ovaries and are conveyed through ducts to the vagina, where fertilization occurs. In many species, the female reproductive system includes a spermatheca, a sac in which sperm may be stored for a year or more.

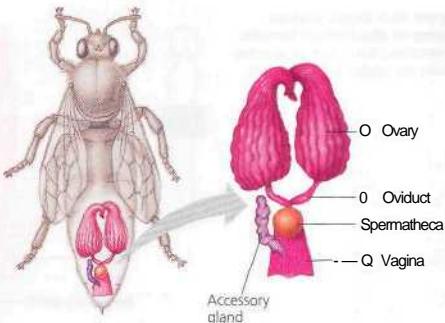

The basic plans of all vertebrate reproductive systems are quite similar, but there are some important variations. In many nonmammalian vertebrates, the digestive, excretory and reproductive systems have a common opening to the outside, the cloaca, which was probably present in the ancestors of all vertebrates. By contrast, most mammals lack a cloaca and have a separate opening for the digestive tract, and most female mammals have separate openings for the excretory and reproductive systems as well. The uterus of most vertebrates is

A Figure 46.7 Reproductive anatomy of a parasitic flatworm. Most flatworms (phylum Platyhelminthes) are hermaphroditic. Both male and female reproductive systems open to the outside via the genital pore. Sperm, made in the testes, travel as shown by the numbered sequence to the seminal vesicle, which stores them. During copulation, sperm are ejaculated into the female system (usually of another flatworm) and then move through the uterus to the seminal receptacle. Eggs from the ovary pass into the oviduct, where they are fertilized by sperm from the seminal receptacle and coated with yolk and shell material secreted by the yolk glands. From the oviduct, the fertilized eggs pass into the uterus and then out of the body.

(a) Male honeybee. Sperm form in the testes, pass through the sperm duct (*vas deferens*), and are stored in the seminal vesicle. The male ejaculates sperm along with fluid from the accessory glands. (Males of some species of insects and other arthropods have appendages called claspers that grasp the female during copulation.)

(b) Female honeybee. Eggs develop in the ovaries and then pass through the oviducts and into the vagina. A pair of accessory glands (only one is shown) add protective secretions to the eggs in the vagina. After mating, sperm are stored in the spermatheca, a sac connected to the vagina by a short duct.

A. Figure 46.8 Insect reproductive anatomy. Circled numbers indicate sequences of sperm and egg movement.

partly or completely divided into two chambers. However, in humans and other mammals that produce only a few young at a time, as well as in birds and many snakes, the uterus is a single structure. Male reproductive systems differ mainly in the copulatory organs. Many nonmammalian vertebrates do not have a well-developed penis and simply turn the cloaca inside out to ejaculate.

Concept Check 46.2

1. In what ways does internal fertilization facilitate terrestrial life?
2. By what "strategies" do animals with (a) external fertilization and (b) internal fertilization ensure that they will have offspring that survive to adulthood?

for suggested answers, see Appendix A.

Concept 46.3

Reproductive organs produce and transport gametes: focus on humans

Female Reproductive Anatomy

The female's external reproductive structures are the clitoris and two sets of labia, which surround the clitoris and vaginal opening. The internal organs are a pair of gonads and a system of ducts and chambers that carry gametes and house the embryo and fetus (Figure 46.9, on the next page).

Ovaries

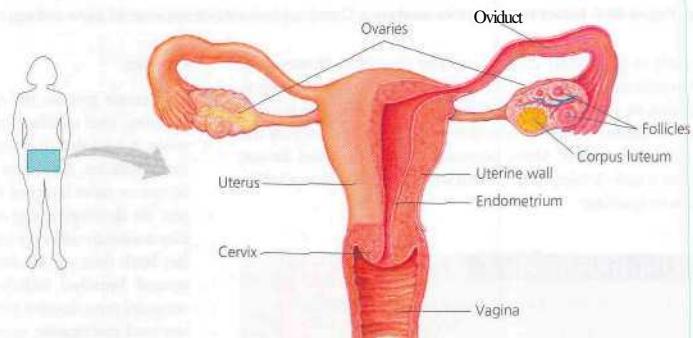

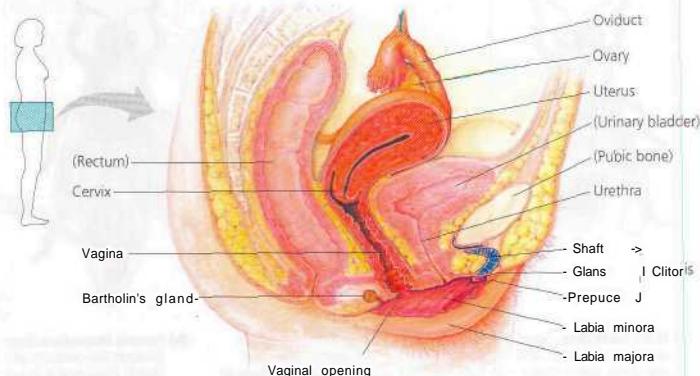

The female gonads, the ovaries, lie in the abdominal cavity, flanking, and attached by a mesentery to, the uterus. Each ovary is enclosed in a tough protective capsule and contains many follicles. A **follicle** consists of one egg cell surrounded by one or more layers of follicle cells, which nourish and protect the developing egg cell. Most or all of the 400,000 follicles a woman will ever have are thought to be formed before her birth (but see the last paragraph in Figure 46.11). Only several hundred follicles will release egg cells during a woman's reproductive years. Starting at puberty and continuing until menopause, usually one follicle matures and releases its egg cell during each menstrual cycle. The cells of the follicle also produce the primary female sex hormones, the **estrogens**. The egg cell is expelled from the follicle in the process of ovulation. The remaining follicular tissue then grows within the ovary to form a solid mass called the **corpus luteum** ("yellow body"). The corpus luteum secretes additional estrogens and **progesterone**, a hormone that helps maintain the uterine lining during pregnancy. If the egg cell is not fertilized, the corpus luteum disintegrates, and a new follicle matures during the next cycle.

Oviducts and Uterus

The female reproductive system is not completely closed, and the egg cell is released into the abdominal cavity near the opening of the **oviduct**, or fallopian tube. The oviduct has a funnel-like opening, and cilia on the epithelium lining the duct help collect the egg cell by drawing fluid from the body cavity into the duct. The cilia also convey the egg cell down the duct to the uterus, also known as the womb. The uterus is a thick, muscular organ that can expand during pregnancy to accommodate

• **Figure 46.9 Reproductive anatomy of the human female.**

For orientation, some nonreproductive structures are labeled in parentheses.

a 4-kg fetus. The inner lining of the uterus, the endometrium, is richly supplied with blood vessels. The neck of the uterus is the cervix, which opens into the vagina.

Vagina and Vulva

The vagina is a thin-walled chamber that is the repository for sperm during copulation and that serves as the birth canal through which a baby is born. It opens to the outside at the vulva, the collective term for the external female genitalia.

At birth, and usually until sexual intercourse or vigorous physical activity ruptures it, a thin piece of tissue called the hymen partly covers the vaginal opening in humans. The vaginal opening and the separate urethral opening are located within a recess called the vestibule, bordered by a pair of slender skin folds, the labia minora. A pair of thick, fatty ridges, the labia majora, encloses and protects the labia minora and vestibule. Located at the front edge of the vestibule, the clitoris consists of a short shaft supporting a rounded

glans, or head, covered by a small hood of skin, the prepuce. During sexual arousal, the clitoris, vagina, and labia minora all engorge with blood and enlarge. The clitoris consists largely of erectile tissue. Richly supplied with nerve endings, it is one of the most sensitive points of sexual stimulation. During sexual arousal, Bartholin's glands, located near the vaginal opening, secrete mucus into the vestibule, keeping it lubricated and facilitating intercourse.

Mammary Glands

Mammary glands are present in both sexes but normally function only in women. They are not part of the reproductive system but are important to mammalian reproduction. Within the glands, small sacs of epithelial tissue secrete milk, which drains into a series of ducts opening at the nipple. Fatty (adipose) tissue forms the main mass of the mammary gland of a nonlactating mammal. The low level of estrogen in males prevents the development of both the secretory apparatus and

the fat deposits, so male breasts remain small, and the nipples are not connected to the ducts.

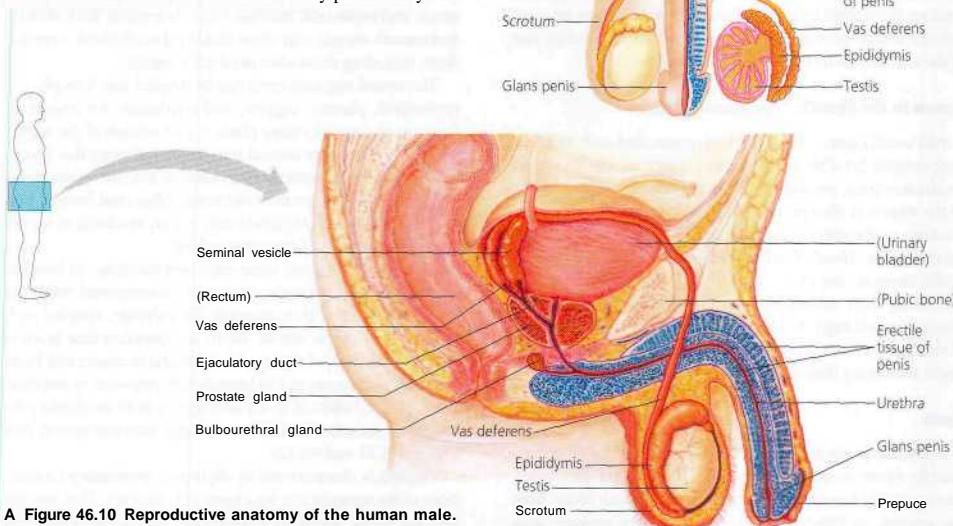

Male Reproductive Anatomy

In most mammalian species, including humans, the male's external reproductive organs are the scrotum and penis. The internal reproductive organs consist of gonads that produce gametes (sperm cells) and hormones, accessory glands that secrete products essential to sperm movement, and ducts that carry the sperm and glandular secretions (**Figure 46.10**).

Testes

The male gonads, or **testes** (singular, testis), consist of many highly coiled tubes surrounded by several layers of connective tissue. These tubes are the **seminiferous tubules**, where sperm form. The **Leydig cells** that are scattered between the seminiferous tubules produce testosterone and other androgens.

Production of normal sperm cannot occur at the body temperatures of most mammals, and the testes of humans and many other mammals are held outside the abdominal cavity in the **scrotum**, which is a fold of the body wall. The temperature in a scrotum is about 2°C below that in the abdominal cavity. The testes develop high in the abdominal cavity and descend into the scrotum just before birth. In many rodents, the testes are drawn back into the abdominal cavity between breeding seasons, interrupting sperm maturation. Some mammals whose body temperature is low enough to allow sperm maturation, such as monotremes, whales, and elephants, retain the testes within the abdominal cavity permanently.

Ducts

From the seminiferous tubules of a testis, the sperm pass into the coiled tubules of the **epididymis**. It takes about 20 days for sperm to pass through the 6-m-long tubules of each epididymis of a human male. During this passage, the sperm become motile and gain the ability to fertilize an egg. During **ejaculation**, the sperm are propelled from the epididymis through the muscular **vas deferens**. These two ducts (one from each epididymis) run from the scrotum around and behind the

urinary bladder, where each joins a duct from the seminal vesicle, forming a short ejaculatory duct. The ejaculatory ducts open into the urethra, the tube that drains both the excretory system and the reproductive system. The urethra runs through the penis and opens to the outside at the tip of the penis.

Glands

Three sets of accessory glands—the seminal vesicles, prostate gland, and bulbourethral glands—add secretions to the semen, the fluid that is ejaculated. A pair of seminal vesicles contributes about 60% of the total volume of semen. The fluid from the seminal vesicles is thick, yellowish, and alkaline. It contains mucus, the sugar fructose (which provides most of the energy used by the sperm), a coagulating enzyme, ascorbic acid, and prostaglandins, local regulators discussed in Chapter 45.

The prostate gland is the largest of the semen-secreting glands. It secretes its products directly into the urethra through several small ducts. Prostatic fluid is thin and milky; it contains anticoagulant enzymes and citrate (a sperm nutrient). The prostate gland is the source of some of the most common medical problems of men over age 40. Benign (noncancerous) enlargement of the prostate occurs in more than half of all men in this age-group and in virtually all men over 70. Prostate cancer is one of the most common cancers in men. It is treated surgically or with drugs that inhibit gonadotropins, resulting in reduced prostate activity and size.

The bulbourethral glands are a pair of small glands along the urethra below the prostate. Before ejaculation, they secrete a clear mucus that neutralizes any acidic urine remaining in the urethra. Bulbourethral fluid also carries some sperm released before ejaculation, which is one reason for the high failure rate of the withdrawal method of birth control.

Semen in the Female Reproductive Tract

A man usually ejaculates 2–5 mL of semen, and each milliliter may contain 50–130 million sperm. Once in the female reproductive tract, prostaglandins in the semen cause thinning of the mucus at the opening of the uterus and stimulate contractions of the uterine muscles, which help move the semen up the uterus. The alkalinity of the semen helps neutralize the acidic environment of the vagina, protecting the sperm and increasing their motility. When first ejaculated, the semen coagulates, making it easier for uterine contractions to move it along; then anticoagulants liquefy the semen, and the sperm begin swimming through the female tract.

Penis

The human penis is composed of three cylinders of spongy erectile tissue derived from modified veins and capillaries. During sexual arousal, the erectile tissue fills with blood from the arteries. As this tissue fills, the increasing pressure seals off the veins that drain the penis, causing it to engorge with

blood. The resulting erection is essential to insertion of the penis into the vagina. Rodents, raccoons, walruses, whales, and several other mammals also possess a **baculum**, a bone that is contained in, and helps stiffen, the penis. Temporary impotence, a reversible inability to achieve an erection, can result from alcohol consumption, certain drugs, and emotional problems. Several drugs and penile implant devices are available for men with nonreversible impotence due to nervous system or circulatory problems. The oral drug Viagra promotes the action of the local regulator nitric oxide (NO), enhancing relaxation of smooth muscles in the blood vessels of the penis. This allows blood to enter the erectile tissue and sustain an erection.

The main shaft of the penis is covered by relatively thick skin. The head, or glans penis, has a much thinner covering and is consequently more sensitive to stimulation. The human glans is covered by a fold of skin called the foreskin, or prepuce, which may be removed by circumcision. Circumcision, which arose from religious traditions, has no verified basis in health or hygiene.

Human Sexual Response

As mentioned earlier, many animals have elaborate mating behavior. The arousal of sexual interest in humans is even more complex, involving a variety of psychological as well as physical factors. Nevertheless, human sexual response is characterized by a common physiological pattern.

Two types of physiological reactions predominate in both sexes: vasocongestion, the filling of a tissue with blood, caused by increased blood flow through the arteries of that tissue, and myotonia, increased muscle tension. Both skeletal and smooth muscle may show sustained or rhythmic contractions, including those associated with orgasm.

The sexual response cycle can be divided into four phases: excitement, plateau, orgasm, and resolution. An important function of the excitement phase is preparation of the vagina and penis for coitus (sexual intercourse). During this phase, vasocongestion is particularly evident in erection of the penis and clitoris; enlargement of the testes, labia, and breasts; and vaginal lubrication. Myotonia may occur, resulting in nipple erection or tension of the arms and legs.

In the plateau phase, these responses continue. In females, the outer third of the vagina becomes vasocongested, while the inner two-thirds slightly expands. This change, coupled with the elevation of the uterus, forms a depression that receives sperm at the back of the vagina. Breathing increases and heart rate rises, sometimes to 150 beats per minute—not in response to the physical effort of sexual activity, but as an involuntary response to stimulation of the autonomic nervous system (see Figures 48.21 and 48.22).

Orgasm is characterized by rhythmic, involuntary contractions of the reproductive structures in both sexes. Male orgasm has two stages. Emission is the contraction of the glands and ducts of the reproductive tract, which forces semen into the

urethra. Expulsion, or ejaculation, occurs when the urethra contracts and the semen is expelled. During female orgasm, the uterus and outer vagina contract, but the inner two-thirds of the vagina do not. Orgasm is the shortest phase of the sexual response cycle, usually lasting only a few seconds. In both sexes, contractions occur at about 0.8-second intervals and may involve the anal sphincter and several abdominal muscles.

The resolution phase completes the cycle and reverses the responses of the earlier stages. Vasocongested organs return to their normal size and color, and muscles relax. Most of the changes of resolution are completed in 5 minutes. Loss of penile and clitoral erection, however, may take longer. An initial loss of erection is rapid in both sexes, but a return of the organs to their nonaroused size may take as long as an hour.

Concept Check 46.3

- Arrange the following male ducts in the correct sequence for the travel of sperm: epididymis, seminiferous tubule, urethra, vas deferens.
- How do human male accessory glands support both sperm motility and fertilization?
- In human sexual response, what organs undergo vasocongestion?

for suggested answers, see Appendix A.

46.4 (Concept)

In humans and other mammals, a complex interplay of hormones regulates gametogenesis

How exactly are gametes produced in the mammalian body? The process, gametogenesis, is based on meiosis, but details differ in females and males. Oogenesis, the development of mature ova (egg cells), is described in **Figure 46.11**, on the next page. Spermatogenesis, the production of mature sperm cells, is a continuous and prolific process in the adult male. Each ejaculation of a human male contains 100 to 650 million sperm cells, and males can ejaculate daily with little loss of fertilizing capacity. Spermatogenesis occurs in the seminiferous tubules of the testes. **Figure 46.12** describes the process in some detail.

Oogenesis differs from spermatogenesis in three major ways. First, during the meiotic divisions of oogenesis, cytokinesis is unequal, with almost all the cytoplasm monopolized by a single daughter cell, the secondary oocyte. This large cell can go on to become the ovum; the other products of meiosis, smaller cells called polar bodies, degenerate. By contrast, in spermatogenesis, all four products of meiosis develop into mature sperm (compare Figures 46.11 and 46.12). Second, although the cells from

which sperm develop continue to divide by mitosis throughout the male's life, this is thought not to be the case for oogenesis in the human female (but see the text in Figure 46.11). Third, oogenesis has long "resting" periods, in contrast to spermatogenesis, which produces mature sperm from precursor cells in an uninterrupted sequence.

The Reproductive Cycles of Females

In females, the secretion of hormones and the reproductive events they regulate are cyclic. Whereas males produce sperm continuously, females release only one egg or a few eggs at a specific time during each cycle. Hormonal control of the female cycle is complex, as we shall see later.

Menstrual Versus Estrous Cycles

Two different types of cycles occur in female mammals. Humans and certain other primates have menstrual cycles, whereas other mammals have estrous cycles. In both cases, ovulation occurs at a time in the cycle after the endometrium (lining of the uterus) has started to thicken and develop a rich blood supply, preparing the uterus for the possible implantation of an embryo. One difference between the two types of cycles involves the fate of the uterine lining if pregnancy does not occur. In menstrual cycles, the endometrium is shed from the uterus through the cervix and vagina in a bleeding called menstruation. In estrous cycles, the endometrium is reabsorbed by the uterus, and no extensive bleeding occurs.

Other major distinctions include more pronounced behavioral changes during estrous cycles than during menstrual cycles and stronger effects of season and climate on estrous cycles. Whereas human females may be receptive to sexual activity throughout their menstrual cycle, most mammals will copulate only during the period surrounding ovulation. This period of sexual activity, called **estrus** (from the Latin *oestrus*, frenzy, passion), is the only time the condition of the vagina permits mating. Estrus is sometimes called heat, and indeed the female's body temperature increases slightly. The length and frequency of reproductive cycles vary widely among mammals. The human menstrual cycle averages 28 days (although cycles vary, ranging from about 20 to 40 days). In contrast, the estrous cycle of the rat is only 5 days. Bears and dogs have one cycle per year; elephants have several.

The Human Female Reproductive Cycle: A Closer Look

Let's examine the reproductive cycle of the human female in more detail as a case study of how a complex function is coordinated by hormones. The term menstrual cycle refers specifically to the changes that occur in the uterus; therefore, it is also called the uterine cycle. It is caused by cyclic events that occur in the ovaries—that is, by the ovarian cycle. Thus, the female reproductive cycle is actually one integrated cycle involving two organs, the uterus and the ovaries.

Figure 46.11

Exploring Human Oogenesis

Oogenesis begins in the female embryo with differentiation of primordial germ cells into oogonia, ovary-specific stem cells. An oogonium multiplies by mitosis and begins meiosis, but the process stops at prophase I. The cells at this stage, called primary oocytes, remain quiescent within small follicles (cavities lined with protective cells) until puberty; when hormones reactivate them. Beginning at puberty, follicle-stimulating hormone (FSH) periodically stimulates a follicle to grow and induces its primary oocyte to complete meiosis I and start meiosis II. Meiosis then stops again. Arrested at metaphase II, the secondary oocyte is released at ovulation, when its follicle breaks open. Usually only one oocyte matures and is released each month. Meiosis does not continue until a sperm penetrates the oocyte; only then is oogenesis actually completed, producing an ovum. (In other animal species, the sperm may enter the oocyte at the same stage, earlier, or later.)

The meiotic divisions in oogenesis involve unequal cytokinesis, with the smaller cells becoming polar bodies (the first polar body may or may not divide again). After meiosis is completed, the haploid nuclei of the sperm and the now mature ovum fuse; this event is fertilization.

The ruptured follicle left behind after ovulation develops into the corpus luteum. If the released oocyte is not fertilized, however, the corpus luteum degenerates.

For many years, scientists have believed that women, like most female mammals, are born with all the primary oocytes they will ever have—that no new ones develop after birth. In March of 2004, however, researchers reported that multiplying oogonia exist in the ovaries of adult mice and can develop into oocytes. The researchers are now looking for similar cells in human ovaries. It is possible that the marked decline in fertility that occurs as women age results from the gradual depletion of oogonia rather than solely from the degeneration of aging oocytes.

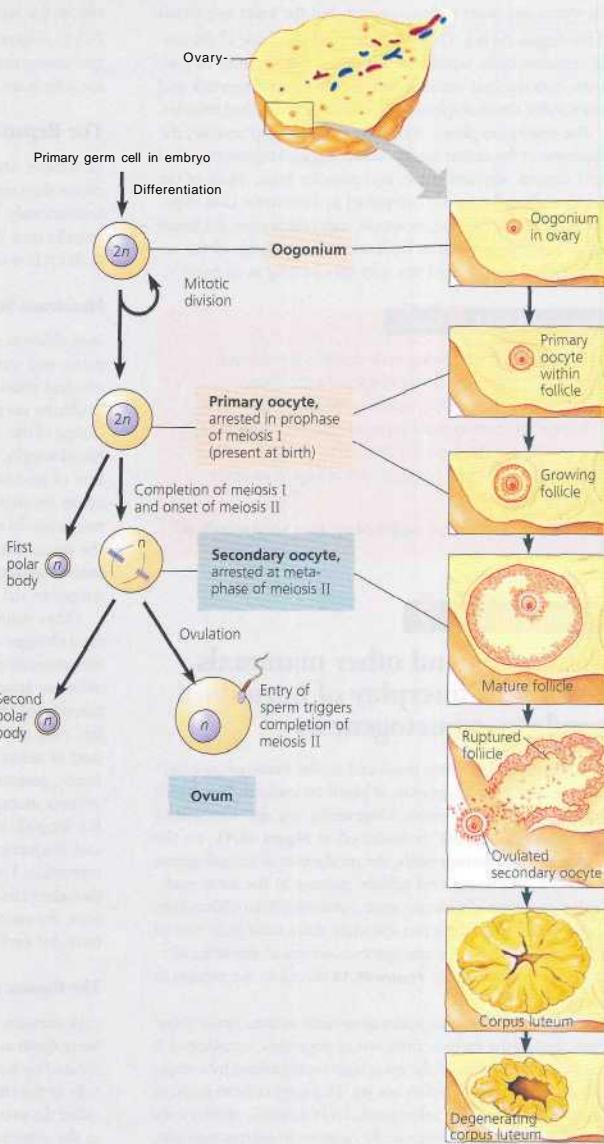

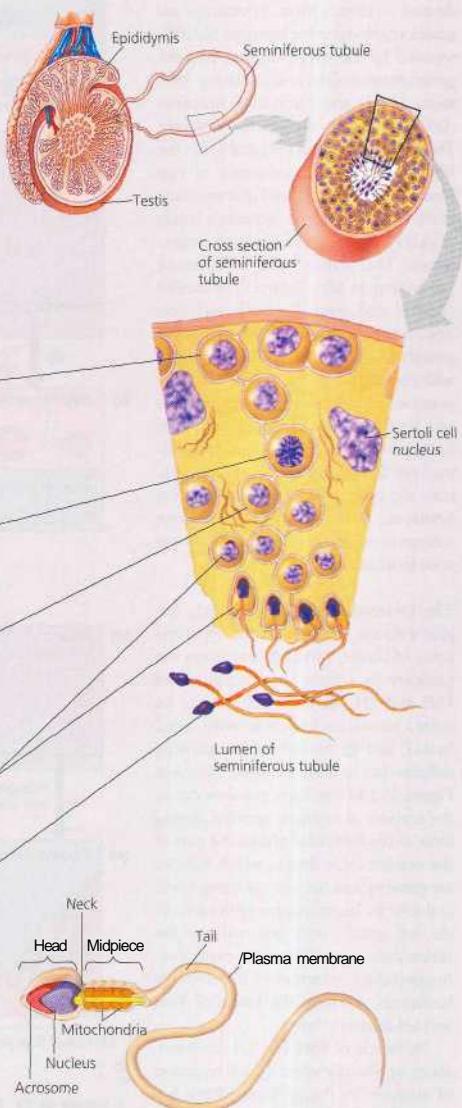

Figure 46.12
Exploring Human Spermatogenesis

These drawings correlate the meiotic stages in sperm development (left) with the microscopic structure of seminiferous tubules. Primordial germ cells of the embryonic testis differentiate into spermatogonia, the stem cells that give rise to sperm. As spermatogonia differentiate into spermatocytes and then into spermatids, meiosis reduces the chromosome number from diploid ($2n = 46$ in humans) to haploid ($n = 23$). The developing cells are pushed from a location near the outer wall of the seminiferous tubule toward the lumen (central opening) and then to the epididymis, where they become motile.

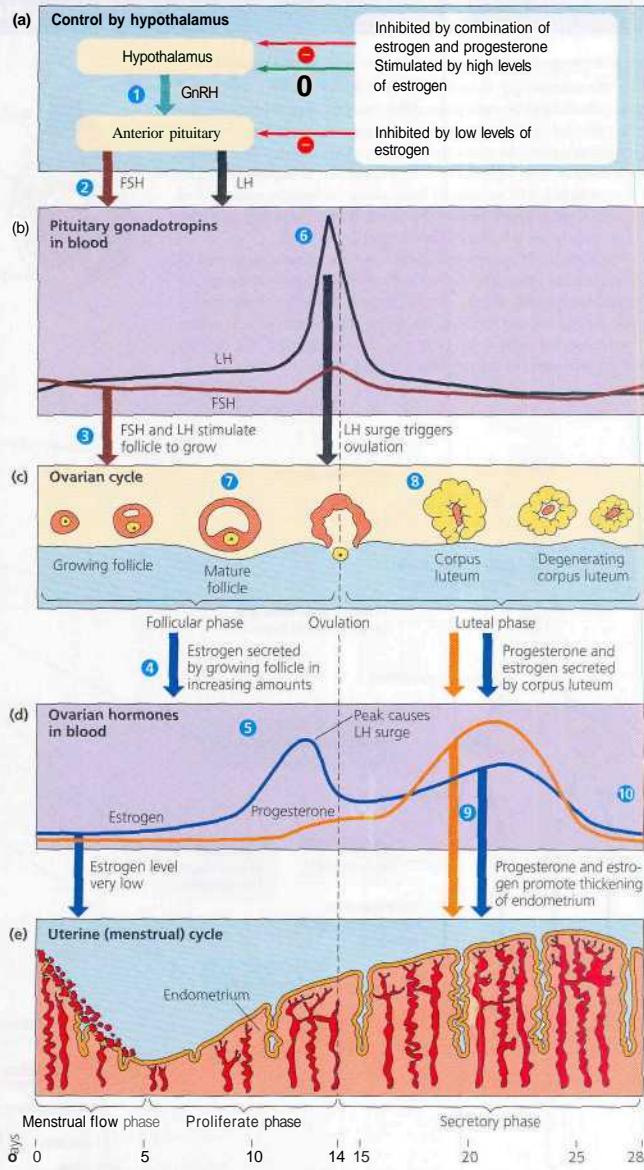

The structure of a sperm cell fits its function. In humans, as in most species, a head containing the haploid nucleus is tipped with a special body, the acrosome, which contains enzymes that help the sperm penetrate the egg. Behind the head, the sperm cell contains large numbers of mitochondria (or a single large one, in some species) that provide ATP for movement of the tail, which is a flagellum.

The hormones at the top levels of control of this dual cycle are the same brain hormones that control the male reproductive system. These hormones are gonadotropin-releasing hormone (GnRH), secreted by the hypothalamus, and the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH), secreted by the anterior pituitary. The concentrations of FSH and LH in the blood control the production of two kinds of steroid hormones that are made in the ovaries: estrogen (actually a family of closely related hormones) and progesterone. The ovarian cycle of hormone production in turn controls the uterine cycle of endometrial growth and loss. The outcome is that ovarian follicle growth and ovulation are synchronized with preparation of the uterine lining for possible implantation of an embryo. As you read the following discussion, refer to **Figure 46.13** as a guide to understanding how the five kinds of hormones regulate the system. You will learn that the hormones participate in an elaborate scheme involving both positive and negative feedback.

The Ovarian Cycle. 0 The cycle begins with the release from the hypothalamus of GnRH, which 0 stimulates the pituitary to secrete small amounts of FSH and LH. 0 The FSH (true to its name) stimulates follicle growth, aided by LH, and 0 the cells of the growing follicles start to make estrogen. Notice in Figure 46.13d that there is a slow rise in the amount of estrogen secreted during most of the **follicular phase**, the part of the ovarian cycle during which follicles are growing and oocytes maturing. (Several follicles begin to grow with each cycle, but usually only one matures; the others disintegrate.) The low levels of estrogen inhibit secretion of the pituitary hormones, keeping the levels of FSH and LH relatively low.

The levels of FSH and LH, however, shoot up sharply when 0 the secretion of estrogen by the growing follicle begins to rise steeply. Whereas a low level of estrogen inhibits the secretion of

A Figure 46.13 The reproductive cycle of the human female. This figure shows (c) the ovarian cycle and (e) the uterine (menstrual) cycle are regulated by changing hormone levels in the blood, depicted in parts (a), (b), and (d). The time scale at the bottom of the figure applies to parts (b)(e).

pituitary gonadotropins, a high concentration has the opposite effect: H stimulates the secretion of gonadotropins by acting on the hypothalamus to increase its output of GnRH. © You can see this response in Figure 46.13b as steep increases in FSH and LH levels that occur soon after the increase in the concentration of estrogen, indicated in Figure 46.13d. The effect is greater for LH because the high concentration of estrogen also increases the sensitivity of "LH-releasing cells in the pituitary to GnRH. By now, the follicles can respond more strongly to LH because more of their cells have receptors for this hormone. The increase in LH concentration caused by increased estrogen secretion from the growing follicle is an example of positive feedback. The LH induces final maturation of the follicle. Q The maturing follicle develops an internal fluid-filled cavity and grows very large, forming a bulge near the surface of the ovary. The follicular phase ends, about a day after the LH surge, with **ovulation**: The follicle and adjacent wall of the ovary rupture, releasing the secondary oocyte.

© Following ovulation, during the **luteal phase** of the ovarian cycle, LH stimulates the transformation of the follicular tissue left behind in the ovary to form the corpus luteum, a glandular structure (see Figure 46.13c). (LH is named for this "fertilizing" function.) Under continued stimulation by LH during this phase of the ovarian cycle, the corpus luteum secretes progesterone and estrogen (see Figure 46.13d). As the levels of progesterone and estrogen rise, the combination of these hormones exerts negative feedback on the hypothalamus and pituitary, inhibiting the secretion of LH and FSH. Near the end of the **luteal phase**, the corpus luteum disintegrates, causing concentrations of estrogen and progesterone to decline sharply. The dropping levels of ovarian hormones liberate the hypothalamus and pituitary from the inhibitory effects of these hormones. The pituitary can then begin to secrete enough FSH to stimulate the growth of new follicles in the ovary, initiating the next ovarian cycle.

True Utterine (Menstrual) Cycle. The hormones secreted by the ovaries—estrogen and progesterone—have a major effect on the uterus. Estrogen secreted in increasing amounts by growing follicles signals the endometrium to thicken. In this way the follicular phase of the ovarian cycle is coordinated with the **proliferative phase** of the uterine cycle (see Figure 46.13e). Before ovulation, the uterus is already being prepared for a possible embryo. After **ovulation**, @ estrogen and progesterone secreted by the corpus luteum stimulate continued development and maintenance of the endometrium, including **enlargement** of arteries and growth of endometrial glands. These glands secrete a nutrient fluid that can sustain an early embryo even before it actually implants in the uterine lining. Thus, the luteal phase of the ovarian cycle is coordinated with what is called the **secretory phase** of the uterine cycle.

d) The rapid drop in the level of ovarian hormones when the corpus luteum disintegrates causes spasms of the arteries in the

uterine lining that deprive it of blood. The upper two-thirds of the endometrium disintegrates, resulting in menstruation—the **menstrual flow phase** of the uterine cycle—and the beginning of a new cycle. By convention, the first day of menstruation is designated day 1 of the uterine (and ovarian) cycle. Menstrual bleeding usually persists for a few days. During menstruation, a fresh batch of ovarian follicles are just beginning to grow.

Cycle after cycle, the maturation and release of egg cells from the ovary are integrated with changes in the uterus, the organ that must accommodate an embryo if the egg cell is fertilized. If an embryo has not implanted in the endometrium by the end of the secretory phase of the uterine cycle, a new menstrual flow commences, marking day 1 of the next cycle. Later in the chapter, you will learn about override mechanisms that prevent disintegration of the endometrium in pregnancy.

In addition to the roles of estrogen in coordinating the female reproductive cycle, this hormone family is responsible for the secondary sex characteristics of the female. Estrogen induces deposition of fat in the breasts and hips, increases water retention, affects calcium metabolism, stimulates breast development, and influences female sexual behavior.

Menopause. After about 450 cycles, human females undergo **menopause**, the cessation of ovulation and menstruation. Menopause usually occurs between the ages of 46 and 54. Apparently, during these years the ovaries lose their responsiveness to gonadotropins from the pituitary (FSH and LH), and menopause results from a decline in estrogen production by the ovary. Menopause is an unusual phenomenon; in most species, females as well as males retain their reproductive capacity throughout life. Is there an evolutionary explanation for menopause? Why might natural selection have favored females who had stopped reproducing? One intriguing hypothesis proposes that during early human evolution, undergoing menopause after having some children actually increased a woman's fitness; losing the ability to reproduce allowed her to provide better care for her children and grandchildren, thereby increasing the survival of individuals bearing her genes.

Hormonal Control of the Male Reproductive System

In the male, the principal sex hormones are the androgens, of which testosterone is the most important. Androgens are steroid hormones produced mainly by the Leydig cells of the testes, interstitial cells located near the seminiferous tubules.

Testosterone and other androgens are directly responsible for the primary and secondary sex characteristics of the male. Primary sex characteristics are associated with the reproductive system: development of the vasa deferentia and other ducts, development of external reproductive structures, and sperm production. Secondary sex characteristics are features not directly related to the reproductive system, including

deepening of the voice, distribution of facial and pubic hair, and muscle growth (androgens stimulate protein synthesis). Androgens are also potent determinants of behavior in mammals and other vertebrates. In addition to specific sexual behaviors and sex drive, androgens increase general aggressiveness and are responsible for vocal behavior such as singing in birds and calling by frogs. Hormones from the anterior pituitary and hypothalamus control androgen secretion and sperm production by the testes. As you study **Figure 46.14**, keep in mind that each hormone acts only on cells that have specific receptors for it (see Chapter 45).

Concept Check 46.4

- FSH and LH get their names from events of the female reproductive cycle, but they also function in males. How are their functions in females and males similar?
- How does an estrous cycle differ from a menstrual cycle, and in what types of animals are the two types of cycles found?
- Why do we regard the ovarian cycle and the uterine (menstrual) cycle as parts of a single cycle?
- What specific hormonal changes trigger ovulation?

For suggested answers, see Appendix A.

Concept 46.5

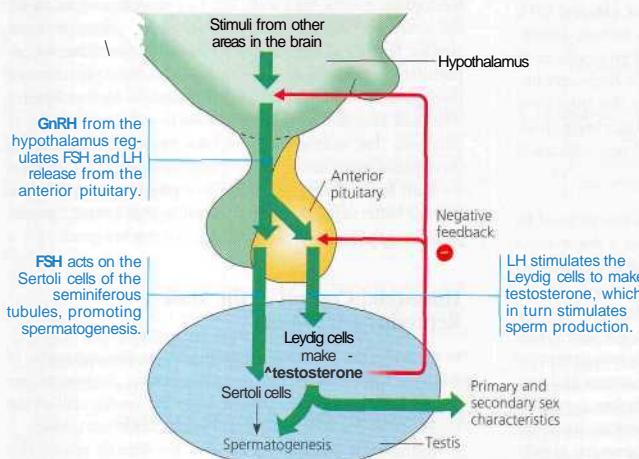

In humans and other placental mammals, an embryo grows into a newborn in the mother's uterus

In humans and other placental (eutherian) mammals, pregnancy, or gestation, is the condition of carrying one or more embryos in the uterus. Human pregnancy averages 266 days (38 weeks) from fertilization of the egg, or 40 weeks from the start of the last menstrual cycle. Duration of pregnancy in other species correlates with body size and the maturity of the young at birth. Many rodents have gestation periods of about 21 days, whereas those of dogs are closer to 60 days. In cows, gestation averages 270 days (almost the same as humans) and in elephants, more than 600 days.

Conception, Embryonic Development, and Birth

Fertilization of an egg by a sperm—also called conception in humans—occurs in the oviduct (**Figure 46.15**). About 24 hours later, the resulting zygote begins dividing, a process called cleavage. Cleavage continues, with the embryo becoming a ball of cells by the time it reaches the uterus 3 to 4 days after fertilization. By about 1 week after fertilization, cleavage has produced an embryonic stage called the blastocyst, a sphere of cells containing a cavity. In a process that takes several more days for completion, the blastocyst implants into the endometrium.

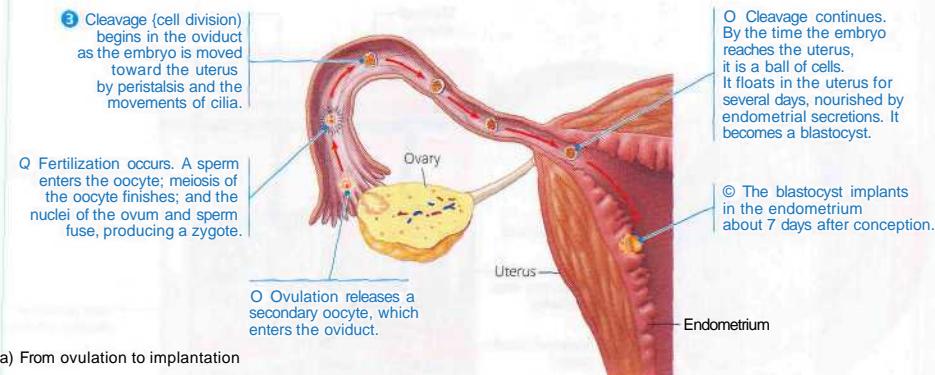

The embryo secretes hormones that signal its presence and control the mother's reproductive system. One embryonic hormone, human chorionic gonadotropin (HCG), acts like pituitary LH to maintain secretion of progesterone and estrogens by the corpus luteum through the first few months of pregnancy. In the absence of this hormonal override, the decline in maternal LH due to inhibition of the pituitary would result in menstruation and loss of the embryo. Levels of HCG in the maternal blood are so high that some is excreted in the urine, where it can be detected in pregnancy tests.

A Figure 46.14 Hormonal control of the testes. Gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the anterior pituitary to secrete two gonadotropin hormones with different effects on the testes, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). FSH acts on Sertoli cells, which nourish developing sperm (see Figure 46.12). LH acts on Leydig cells, which produce androgens, chiefly testosterone. Negative feedback by testosterone on the hypothalamus and anterior pituitary is the main mechanism by which blood levels of LH, FSH, and GnRH are regulated.

First Trimester

Human gestation can be divided for convenience into three trimesters of about three months each. The first trimester is the time of most radical change for both

(a) From ovulation to implantation

(b) Implantation of blastocyst

A Figure 46.15 Formation of the zygote and early postfertilization events. You will learn more about fertilization and cleavage in Chapter 47.

the mother and the embryo. Let's take up our story where we left off, at implantation. The endometrium responds to implantation by growing over the blastocyst. Differentiation of the embryo's body structures now begins. (You will learn much more about embryonic development in Chapter 47.)

During its first 2 to 4 weeks of development, the embryo obtains nutrients directly from the endometrium. Meanwhile, the outer layer of the blastocyst, called the trophoblast, grows out and mingles with the endometrium, eventually helping to form the placenta. This disk-shaped organ, containing both embryonic and maternal blood vessels, grows to about the size of a dinner plate and can weigh close to 1 kg. Diffusion of material between maternal and embryonic circulations provides nutrients, exchanges respiratory gases, and disposes of metabolic wastes for the embryo. Blood from the embryo travels to the placenta through arteries of the umbilical cord and returns via the umbilical vein (**Figure 46.16**, on the next page).

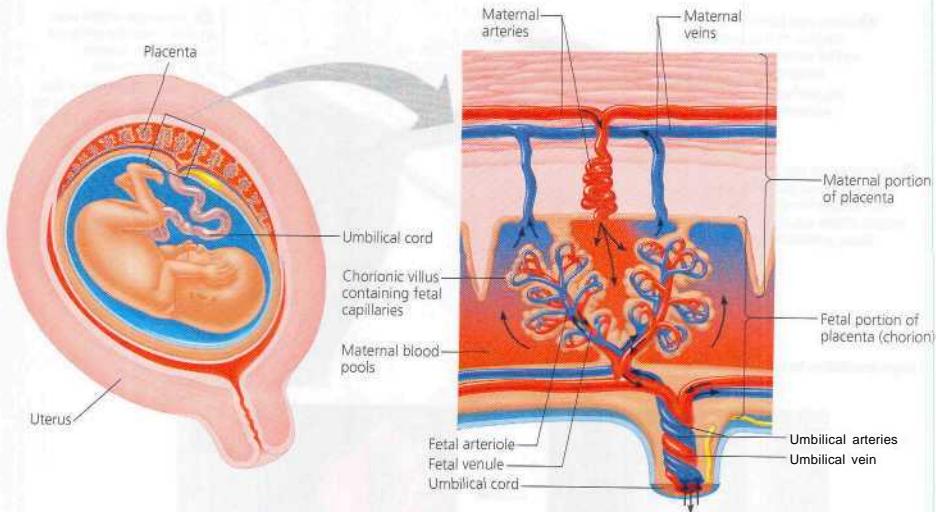

The first trimester is the main period of organogenesis, the development of the body organs (**Figure 46.17**). The heart begins beating by the fourth week and can be detected with a stethoscope by the end of the first trimester. By the end of the eighth week, all the major structures of the adult are present in rudimentary form. (It is during organogenesis that the embryo

is most sensitive to such threats as radiation and drugs that can cause birth defects.) At 8 weeks, the embryo is called a fetus. Although well differentiated, the fetus is only 5 cm long by the end of the first trimester.

Meanwhile, the mother is also undergoing rapid changes. High levels of progesterone initiate changes in her reproductive system. These include increased mucus in the cervix that forms a protective plug, growth of the maternal part of the placenta, enlargement of the uterus, and (by negative feedback on the hypothalamus and pituitary) cessation of ovulation and menstrual cycling. The breasts also enlarge rapidly and are often quite tender.

Second Trimester

During the second trimester, the fetus grows to about 30 cm and is very active. The mother may feel movements during the early part of the second trimester, and fetal activity may be visible through the abdominal wall by the middle of this time period. Hormone levels stabilize as HCG declines, the corpus luteum deteriorates, and the placenta completely takes over the production of progesterone, which maintains the pregnancy. During the second trimester, the uterus grows enough for the pregnancy to become obvious.

A Figure 46.16 Placental circulation.

From the fourth week of development until birth, the placenta, a combination of maternal and embryonic tissues, transports nutrients, respiratory gases, and wastes between the embryo or fetus and the mother. Maternal blood enters the placenta in arteries, flows

through blood pools in the endometrium, and leaves via veins. Embryonic or fetal blood, which remains in vessels, enters the placenta through arteries and passes through capillaries in fingerlike chorionic villi, where oxygen and nutrients are acquired. As indicated in the drawing, the fetal (or embryonic) capillaries and

villi project into the maternal portion of the placenta. Fetal blood leaves the placenta through veins leading back to the fetus. Materials are exchanged by diffusion, active transport, and selective absorption between the fetal capillary bed and the maternal blood pools.

(a) 5 weeks. Limb buds, eyes, the heart, the liver, and rudiments of all other organs have started to develop in the embryo, which is only about 1 cm long.

(b) 14 weeks. Growth and development of the offspring, now called a fetus, continue during the second trimester. This fetus is about 6 cm long.

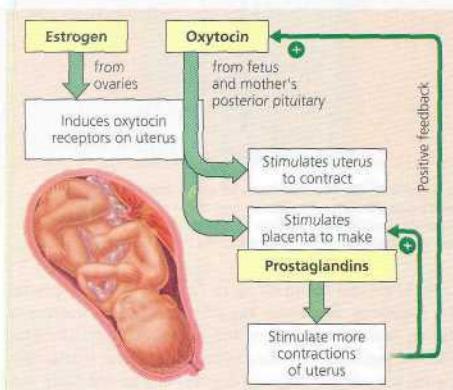

(c) 20 weeks. By the end of the second trimester (at 24 weeks), the fetus grows to about 30 cm in length.

A Figure 46.17 Human fetal development.

Third Trimester

The final trimester is one of growth of the fetus to about 3–5 kg in weight and 50 cm in length. Fetal activity may decrease as the fetus fills the available space within the embryonic membranes. As the fetus grows and the uterus expands around it, the mother's abdominal organs become compressed and displaced, leading to frequent urination, digestive blockages, and strain in the back muscles. A complex interplay of local regulators (prostaglandins) and hormones (chiefly estrogen and oxytocin) induces and regulates labor, the process by which childbirth occurs. The mechanism that triggers labor is not fully understood, but **Figure 46.18** shows one model. "Estrogen, which reaches its highest level in the mother's blood during the last weeks of pregnancy, induces the formation of oxytocin receptors on the uterus. Oxytocin, produced by the fetus and the mother's posterior pituitary, stimulates powerful contractions by the smooth muscles of the uterus. Oxytocin also stimulates the placenta to secrete prostaglandins, which enhance the contractions. In turn, the physical and emotional stresses associated with the contractions stimulate the release of more oxytocin and prostaglandins, a positive feedback system that underlies the process of labor.

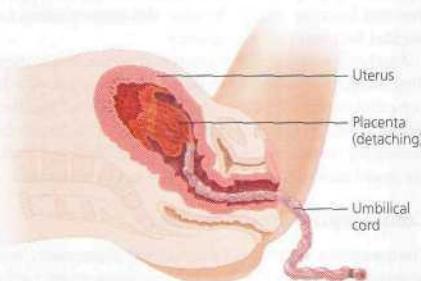

Birth, or parturition, is brought about by a series of strong, rhythmic uterine contractions. The process of labor has three stages (**Figure 46.19**). The first stage is the opening up and thinning of the cervix, ending with complete dilation. The second stage is expulsion, or delivery, of the baby. Continuous strong contractions force the fetus down and out of the uterus and vagina. The umbilical cord is cut and clamped at this time. The final stage of labor is delivery of the placenta, which normally follows the baby.

① Dilation of the cervix

② Expulsion: delivery of the infant

③ Delivery of the placenta

▲ **Figure 46.19 The three stages of labor.**

Lactation is an aspect of postnatal care unique to mammals. After birth, decreasing levels of progesterone free the anterior pituitary from negative feedback and allow prolactin secretion. Prolactin stimulates milk production after a delay of 2 or 3 days. The release of milk from the mammary glands is controlled by oxytocin (see p. 944 and Figure 45.7).

The Mother's Immune Tolerance of the Embryo and Fetus

Pregnancy is an immunological enigma. Half of the embryo's genes are inherited from the father; thus, many of the chemical markers present on the surface of the embryo will be foreign to the mother. Why, then, does the mother not reject the embryo as a foreign body, as she would a tissue or organ graft bearing antigens from another person? Reproductive immunologists are working to solve this puzzle.

A major key to the puzzle may be the tissue called the trophoblast (see Figures 46.15 and 47.18). Originally the outermost layer of the blastocyst, the trophoblast brings about implantation by growing into the endometrium and later develops into the fetal part of the placenta (see Figures 46.15 and 46.16). How might the trophoblast, and later the placenta, protect the embryo from rejection? Some possibilities follow.

During early pregnancy, the trophoblast seems to prevent the mother's immune system from rejecting the blastocyst by releasing signal molecules with immunosuppressive effects. These include HCG, a variety of protein "factors," a prostaglandin, several interleukins, and an interferon. Several lines of research suggest that some combination of these substances interferes with immune rejection by acting on the mother's T lymphocytes, important players in the immune system (see Chapter 43).

A very different hypothesis is that the trophoblast and later the placenta secrete an enzyme that rapidly breaks down local supplies of tryptophan, an amino acid necessary for T cell survival and function. At least in mice, this enzyme seems to be essential for maintaining pregnancy.

Another possibility is the absence of certain histocompatibility antigens on placental cells and the secretion of a hormone that induces synthesis of a "death activator" membrane protein (FasL) on placental cells. Activated T cells have a complementary "death receptor" (Fas), and the binding of FasL to Fas would cause the T cells to self-destruct by apoptosis.

Contraception and Abortion

Contraception, the deliberate prevention of pregnancy, can be achieved in a number of ways. Some contraceptive methods prevent the release of mature eggs (secondary oocytes) and sperm from gonads, others prevent fertilization by keeping sperm and egg apart, and still others prevent implantation of an embryo (**Figure 46.20**). The following brief introduction to the biology of the most often used methods makes no pretense of being a contraception manual. For more complete information, you should consult a physician or health center personnel.

Fertilization can be prevented by abstinence from sexual intercourse or by any of several barriers that keep live sperm from contacting the egg. Temporary abstinence, often called the **rhythm method** of birth control or **natural family planning**, depends on refraining from intercourse when conception is most likely. Because the egg can survive in the oviduct for 24

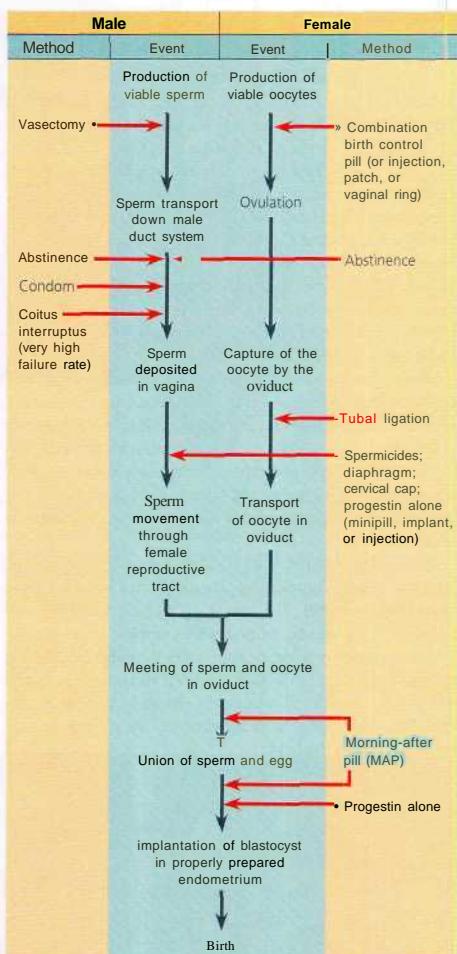

Figure 46.20 Mechanisms of some contraceptive methods. Red arrows indicate where these methods, devices, or products interfere with the flow of events from the production of sperm and egg (secondary oocyte) to the birth of a baby.

to 48 hours and sperm for up to 72 hours, a couple practicing temporary abstinence should not engage in intercourse during several days before and after ovulation. The most effective methods for timing ovulation combine several indicators, including changes in cervical mucus and body temperature during the menstrual cycle. Thus, natural family planning requires that the couple be knowledgeable about

these physiological signs. A pregnancy rate of 10-20% is typically reported for couples practicing natural family planning. (Pregnancy rate is the number of women who become pregnant during a year out of every 100 women using a particular family planning method, expressed as a percentage.) Some couples use the natural family planning method to increase the probability of conception.

As a method of preventing fertilization, coitus intemiptus, or withdrawal (removal of the penis from the vagina before ejaculation), is unreliable. Sperm maybe present in secretions that precede ejaculation, and a lapse in timing or willpower can result in late withdrawal.

The several **barrier methods** of contraception that block the sperm from meeting the egg have pregnancy rates of less than 10%. The **condom**, used by the male, is a thin, latex rubber or natural membrane sheath that fits over the penis to collect the semen. For sexually active individuals, latex condoms are the only contraceptives that offer some protection against sexually transmitted diseases, including AIDS. (This protection is, however, not absolute.) The barrier device most commonly used by females is the **diaphragm**, a dome-shaped rubber cap fitted into the upper portion of the vagina before intercourse. Both of these devices are more effective when used in conjunction with a spermicidal (sperm-killing) foam or jelly. Other barrier devices for women include the cervical cap, which fits tightly around the opening of the cervix and is held in place for a prolonged period by suction, and the vaginal pouch, or "female condom."

Except for complete abstinence from sexual intercourse, the methods that prevent the release of gametes are the most effective means of birth control. Sterilization (discussed later) is almost 100% effective, and chemical contraceptives, most often used in the form of **birth control pills**, have pregnancy rates of less than 1%. The most commonly used birth control pills are a combination of a synthetic estrogen and a synthetic progestin (progesterone-like hormone). This combination acts by negative feedback to stop the release of GnRH by the hypothalamus, and thus of FSH and LH by the pituitary. The prevention of LH release prevents ovulation. As a backup mechanism, the inhibition of FSH secretion by the low dose of estrogen in the pills prevents follicles from developing. A similar combination of hormones is also available as an injection, in a ring inserted into the vagina, and as a patch. Combination birth control pills can be used in high doses as morning-after pills (MAPs). Taken within 3 days of unprotected intercourse, they prevent fertilization or implantation, with an effectiveness of about 75%.

A second type of birth control pill, called the minipill, contains only progestin. It does not effectively block ovulation, and it is not quite as effective a contraceptive as a hormonal combination. The minipill prevents fertilization mainly by causing thickening of a woman's cervical mucus so that it blocks sperm from entering the uterus. The progestin also

causes changes in the endometrium that interfere with implantation if fertilization occurs. Progestin can be administered in time-release, match-sized capsules that are implanted under the skin and last for five years or by injections that last for three months, as well as in tablet (minipill) form.

Are there long-term side effects of hormonal contraceptives? For women taking a combination version, cardiovascular problems are the most serious concern. Birth control pills slightly raise a woman's risk of abnormal blood clotting, high blood pressure, heart attack, and stroke. Smoking while using chemical contraception increases the risk of mortality tenfold or more. Although the pill increases the risk for cardiovascular disease, it eliminates the dangers of pregnancy; women on birth control pills have mortality rates about one-half those of pregnant women. Also, the pill decreases the risk of ovarian and endometrial cancers and benign breast disease.

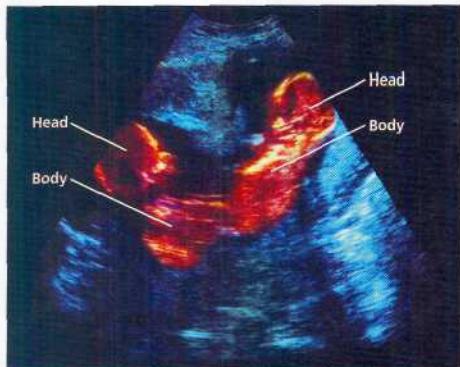

One elusive research goal has been a chemical contraceptive for men. Chemicals that alter testosterone levels have tended to be unsatisfactory because they affect secondary sex characteristics as well as spermatogenesis. Recently, however, researchers have begun to look for drugs that target other kinds of molecules involved in spermatogenesis. One promising drug (actually a sugar) is already approved for another purpose. When administered to mice, it causes nonfunctional sperm to be made, apparently by inhibiting synthesis of certain glycolipids.

Sterilization is the permanent prevention of gamete release. **Tubal ligation** in women usually involves cauterizing or tying off (ligating) a section of the oviducts to prevent eggs from traveling into the uterus. Vasectomy in men is the cutting of each vas deferens to prevent sperm from entering the urethra. Both male and female sterilization procedures are relatively safe and free from harmful effects. Both are also difficult to reverse, so the procedures should be considered permanent.

Abortion is the termination of a pregnancy in progress. Spontaneous abortion, or miscarriage, is very common; it occurs in as many as one-third of all pregnancies, often before the woman is even aware she is pregnant. In addition, each year about 1.5 million women in the United States choose abortions performed by physicians. A drug called mifepristone, or RU486, developed in France, enables a woman to terminate pregnancy nonsurgically within the first 7 weeks. An analog of progesterone, RU486 blocks progesterone receptors in the uterus, thus preventing progesterone from maintaining pregnancy. It is taken with a small amount of prostaglandin to induce uterine contractions.

Modern Reproductive Technology

Recent scientific and technological advances have made it possible to deal with many reproductive problems. For example, it is now possible to diagnose many genetic diseases and other congenital disorders (those present at birth) while the

A Figure 46.21 Ultrasound image. This color-enhanced image shows twins in the uterus. The image was produced on a computer screen when high-frequency sounds from an ultrasound scanner held against the pregnant woman's abdomen bounced off the fetuses.

fetus is in the uterus. Amniocentesis and chorionic villus sampling are invasive techniques in which amniotic fluid or fetal cells are obtained for genetic analysis (see Figure 14.17). Non-invasive procedures usually use ultrasound imaging to detect fetal condition (Figure 46.21). A newer noninvasive technique relies on the fact that a few fetal blood cells leak across the placenta into the mother's bloodstream. A blood sample from the mother yields fetal cells that can be identified with specific antibodies (which bind to proteins on the surface of fetal cells) and then tested for genetic disorders.

Diagnosing genetic diseases in fetuses poses ethical questions. To date, almost all detectable disorders remain untreatable in the uterus, and many cannot be corrected even after birth. Parents may be faced with difficult decisions about whether to terminate a pregnancy or cope with a child who may have profound defects and a short life expectancy. These are complex issues that demand careful, informed thought and competent counseling.

Reproductive technology can help with a number of infertility problems. Hormone therapy will sometimes increase sperm or egg production, and surgery can correct disorders such as blocked oviducts. Many infertile couples turn to fertilization

procedures called assisted reproductive technology (ART). These procedures generally involve surgically removing eggs (secondary oocytes) from a woman's ovaries following hormonal stimulation, fertilizing the eggs, and returning them to the woman's body. Unused eggs, sperm, and embryos from such procedures can be frozen for later pregnancy attempts.

With *in vitro* fertilization (IVF), the most common ART procedure, the oocytes are mixed with sperm in culture dishes and incubated for several days to allow the fertilized eggs to start developing. When they have developed into embryos of at least eight cells each, the embryos are carefully inserted into the woman's uterus and allowed to implant. In ZIFT (zygote intrafallopian transfer), eggs are also fertilized *in vitro*, but zygotes are transferred immediately to the woman's oviducts (fallopian tubes). In GIFT (gamete intrafallopian transfer), the eggs are not fertilized *in vitro*. Instead, the eggs and sperm are placed in the woman's oviducts in the hope that fertilization will occur there. Any of these procedures can use sperm or eggs from donors.

These techniques are now performed in major medical centers throughout the world. Though they cost thousands of dollars per attempt, they have resulted in thousands of children. To date, evidence of abnormalities resulting from the procedures has been scanty.

Once conception and implantation have successfully occurred, a developmental program unfolds that transforms the zygote into 8 baby. The mechanisms of this development in humans and other animals are the subject of Chapter 47.

Concept Check 46.5

1. Describe the state of the embryo just before it implants in the uterine lining.
2. Why does testing for HCG (human chorionic gonadotropin) work as a pregnancy test early in pregnancy but not late in pregnancy? What is the function of HCG in pregnancy?
3. _____ is to males as tubal ligation is to _____.
4. Why is the term *test tube baby* an inaccurate reference to the product of *in vitro* fertilization?

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 46.1

Both asexual and sexual reproduction occur in the animal kingdom

- Asexual reproduction produces offspring whose genes all come from a single parent. Sexual reproduction requires the fusion of male and female gametes to form a diploid zygote (p. 964).

• Mechanisms of Asexual Reproduction (pp. 964–965)

Fission, budding, and fragmentation with regeneration are mechanisms of asexual reproduction in various invertebrates.

- Reproductive Cycles and Patterns** (pp. 965–966) Animals may reproduce exclusively sexually or asexually, or they may alternate between the two. Variations on these two modes are made possible through parthenogenesis, hermaphroditism, and sequential hermaphroditism. Reproductive cycles are controlled by hormones and environmental cues.

Concept 46.2

Fertilization depends on mechanisms that help sperm meet eggs of the same species

- In external fertilization, eggs shed by the female are fertilized by sperm in the external environment. In internal fertilization, egg and sperm unite within the female's body. In either case, fertilization requires critical timing, often mediated by environmental cues, pheromones, and/or courtship behavior. Internal fertilization requires important behavioral interactions between male and female animals, as well as compatible copulatory organs (p. 967).
- Ensuring the Survival of Offspring** (pp. 967–968) Greater protection of embryos and parental care usually follow production of relatively few offspring by internal fertilization.
- Gamete Production and Delivery** (pp. 968–969) Reproductive systems range from the production of gametes by undifferentiated cells in the body cavity to complex assemblages of male and female gonads with accessory tubes and glands that carry and protect gametes and developing embryos.

Concept 46.3

Reproductive organs produce and transport gametes: focus on humans

- Female Reproductive Anatomy** (pp. 969–971) Externally, the human female has a vulva, consisting of the vestibule (with separate openings of the vagina and urethra), the labia minora, the labia majora, and the clitoris. Internally, the vagina is connected to the uterus, which connects to two ovaries. Two ovaries (female gonads) are stocked with **follicles** containing developing egg cells (oocytes). After ovulation, the remnant of the follicle forms a **corpus luteum**, which secretes hormones for a variable duration, depending on whether or not pregnancy occurs. Although separate from the reproductive system, the mammary glands, or breasts, evolved in association with parental care.

Activity Reproductive System of the Human Female

- Male Reproductive Anatomy** (pp. 971–972) External reproductive structures of the human male are the scrotum and penis. The male gonads, or testes, reside in the cool environment of the scrotum. They possess hormone-producing cells and sperm-forming seminiferous tubules that successively lead into the epididymis, vas deferens, ejaculatory duct, and urethra, which exits at the tip of the penis.

Activity Reproductive System of the Human Male
Investigation What Might Obstruct the Male Urethra?

- Human Sexual Response** (pp. 972–973) Both males and females experience the erection of certain body tissues due to vasocongestion and myotonia, culminating in orgasm.

Concept 46.4

In humans and other mammals, a complex interplay of hormones regulates gametogenesis

- Oogenesis is the female form of gametogenesis, the production of gametes, and spermatogenesis is the male form. Sperm develop continuously, whereas the maturation of egg cells is discontinuous and cyclic. Meiosis is central to both processes, but in oogenesis, cytokinesis is unequal, producing only one large ovum. In spermatogenesis, each starting cell becomes four sperm (pp. 973–975).

- The Reproductive Cycles of Females** (pp. 973, 976–977) Female hormones are secreted in a rhythmic fashion reflected in the menstrual or estrous cycle. In both types of cycles, the endometrium thickens in preparation for possible implantation. The menstrual cycle, however, includes endometrial bleeding, and sexual receptivity is not limited to a heat period, as in the estrous cycle. The female reproductive cycle is orchestrated by cyclic secretion of GnRH from the hypothalamus and of FSH and LH from the anterior pituitary. FSH and LH bring about complex changes in the ovary and, via estrogen and progesterone, in the uterus. The developing follicle produces estrogen, and the corpus luteum secretes progesterone and estrogens. Positive and negative feedback regulate the levels of the five hormones that coordinate the cycle.

- Hormonal Control of the Male Reproductive System** (pp. 977–978) Androgens (chiefly testosterone) from the testes cause the development of primary and secondary sex characteristics in the male. Androgen secretion and sperm production are both controlled by hypothalamic and pituitary hormones.

Concept 46.5

In humans and other placental mammals, an embryo grows into a newborn in the mother's uterus

• Conception, Embryonic Development, and Birth

(pp. 978–981) After fertilization of the egg and the completion of meiosis in the oviduct, the zygote undergoes cleavage and develops into a blastocyst before implantation in the endometrium. Human pregnancy can be divided into three trimesters. All major organs have started developing by 8 weeks. Birth, or parturition, results from strong, rhythmic uterine contractions. Positive feedback involving prostaglandins and the hormones estrogen and oxytocin regulates labor.

- The Mother's Immune Tolerance of the Embryo and Fetus** (p. 982) A pregnant woman's acceptance of her "foreign" offspring is still not fully understood but may be due to the suppression of the immune response in her uterus.

- Contraception and Abortion** (pp. 982–983) Contraceptive methods may prevent the release of mature gametes from the gonads, fertilization, or implantation of the embryo.
- Modern Reproductive Technology** (pp. 983–984) In addition to helping detect problems before birth, modern technology can help infertile couples by *in vitro* fertilization.

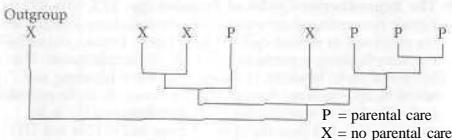

TESTING YOUR KNOWLEDGE

Evolution Connection

In animals, hermaphroditism is often found in species that are fixed to a surface. Mobile species are less often hermaphroditic. Why?

Scientific Inquiry

Imagine studying evolution of parental care in a certain animal group. You map the distribution of care behavior on a phylogenetic tree as shown below (see Chapter 25). What is the simplest interpretation of how this behavior evolved? If the outgroup exhibited parental care, how would your interpretation change?

Investigation *What Might Obstruct the Male Urethra?*

Science, Technology, and Society

Techniques for sorting sperm, combined with *in vitro* fertilization, make it possible to choose a baby's sex. What potential problems can you foresee if this procedure becomes widely available?

Animal Development

A Figure 47.1 A human embryo about six to eight weeks after conception.

Key Concepts

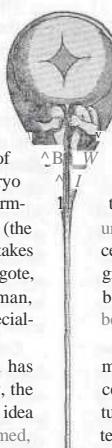

- 47.1 After fertilization, embryonic development proceeds through cleavage, gastrulation, and organogenesis
- 47.2 Morphogenesis in animals involves specific changes in cell shape, position, and adhesion
- 47.3 The developmental fate of cells depends on their history and on inductive signals

Overview

A Body-Building Plan for Animals

single cell about the size of the period at the end of this sentence. **Figure 47.1** shows a human embryo about six to eight weeks after conception. The brain is forming in the head (upper left), and the developing heart (the red spot in the center) has already begun to pulsate. It takes a total of only about nine months for a single-celled zygote, or fertilized egg, to be transfigured into a newborn human, milt of trillions of differentiated cells organized into specialized tissues and organs.

The question of how a zygote becomes an animal has been asked for centuries. As recently as the 18th century, the prevailing theory was a notion called *preformation*: the idea that the egg or sperm contains an embryo—a preformed, miniature infant, or "homunculus"—that simply becomes larger during development (**Figure 47.2**). **A, Figure 47.2 A** "homunculus" inside the head of a human sperm. This engraving was made in 1694.

form of an animal emerges gradually from a relatively formless egg. As microscopy improved during the 19th century, biologists could see that embryos took shape in a series of progressive steps, and epigenesis displaced preformation as the favored explanation among embryologists. The concept of preformation may have some merit, however: Although an embryo's form emerges gradually as it develops, aspects of the developmental plan are already in place in the eggs of many species.

An organism's development is determined by the genome of the zygote and also by differences that arise between early embryonic cells. These differences set the stage for the expression of different genes in different cells. In some species, early embryonic cells become different because of the uneven distribution of maternal substances called cytoplasmic determinants. These substances affect development of the cells that inherit them during early mitotic divisions of the zygote (see Figure 21.11a). In other species, the initial differences between cells are due primarily to their location in embryonic regions with different characteristics. In most species, a combination of these two mechanisms establishes differences between early embryonic cells.

As cell division continues and the embryo develops, mechanisms that selectively control gene expression lead to cell differentiation, the specialization of cells in their structure and function. The timely communication of instructions, telling cells precisely what to do and when to do it, occurs by cell signaling among different embryonic cells. Along with cell division and differentiation, development involves morphogenesis, the process by which an animal takes shape and the differentiated cells end up in the appropriate locations.

By combining molecular genetics with classical approaches to embryology, developmental biologists are now beginning to answer many questions about how a fertilized egg cell gives rise to a particular animal. In this chapter, we concentrate mainly on organisms, such as the sea urchin, frog and chick, that have been the subject of classical embryological studies. Although developmental events in these animals are easy to observe in the laboratory, they are more difficult to study genetically than the organisms described in Chapter 21. However, molecular techniques are now available for studying the molecular mechanisms of developmental events in these and other species.

In addition to these model organisms, development of our own species has always been of great interest to us and will be covered in this chapter as well. Because ethical concerns preclude experimentation on human embryos, knowledge about human development has been based partly on what we can extrapolate from other mammals, such as the mouse, and partly on observation of very early human development following *in vitro* fertilization.

We will begin with a description of the basic stages of embryonic development common to most animals. Then we will look at the cellular and molecular mechanisms that result in generation of the body form. Finally, we will consider the process by which embryonic cells travel down the appropriate pathways of differentiation so that they can play their necessary roles in a functional multicellular animal.

Concept 47.1

After fertilization, embryonic development proceeds through cleavage, gastrulation, and organogenesis

Important events regulating development occur during fertilization and each of three successive stages that begin to build the animal's body. During the first stage, called cleavage, cell division creates a hollow ball of cells, the blastula, from the zygote. The second stage, gastrulation, produces a three-layered embryo, the gastrula. The third stage, organogenesis, generates rudimentary organs from which adult structures grow.

In our discussion, we will focus on a few species that have been used as model organisms to investigate each of these processes. As researchers study development in more and more species, they are finding some variations but also many similarities in the processes. For each stage of development, we first consider the species for which the most is known and then compare what is known about the same process in other species. We begin by looking at the fertilization of an egg cell by a sperm.

Fertilization

The sperm and egg (gametes), which unite during fertilization, are both highly specialized cell types produced by a complex series of developmental events in the testes and ovaries of the parents (see Figures 46.11 and 46.12). The main function of fertilization is to combine haploid sets of chromosomes from two individuals into a single diploid cell, the zygote. Another key function is activation of the egg: Contact of the sperm with the egg's surface initiates metabolic reactions within the egg that trigger the onset of embryonic development.

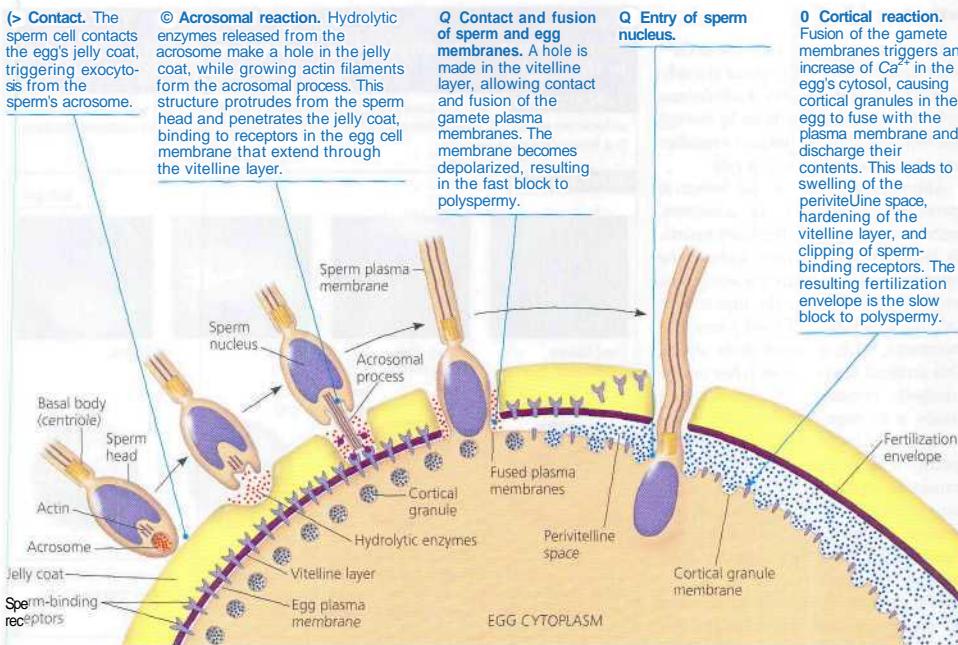

Fertilization has been studied most extensively in sea urchins. Their gametes can simply be combined in seawater in the laboratory, and subsequent events are easily observed. Although sea urchins (phylum Echinodermata) are not vertebrates or even chordates, they share with those two groups the characteristic of being deuterostomes (see Figure 32.9). Despite differences in details, fertilization and early development in sea urchins provide good general models for similar events in vertebrates.

The Acrosomal Reaction

The eggs of sea urchins are fertilized externally after the animals release their gametes into the surrounding seawater. The jelly coat that surrounds the egg provides a source of soluble molecules that attract the sperm, which swim toward the egg. When the head of a sperm cell comes into contact with the jelly coat, molecules present in the egg's coat trigger the acrosomal reaction (Figure 47.3).

This process begins when a specialized vesicle at the tip of the sperm, called the acrosome, discharges hydrolytic enzymes. These enzymes digest the jelly coat, enabling an elongating sperm structure called the *acrosomal process* to penetrate the jelly coat. A protein on the tip of the acrosomal process then adheres to molecules of a specific receptor protein on the egg's surface. These receptors extend from the plasma membrane of the egg cell through the *vitelline layer*, a meshwork of extracellular matrix molecules lying under the jelly coat. In sea urchins and many other animals, this "lock-and-key" recognition of molecules ensures that eggs will be fertilized only by sperm of the same species. Such species specificity is especially important when fertilization occurs externally in water, where gametes of other species are likely to be present.

Contact of the tip of the acrosome with the egg membrane leads to the fusion of sperm and egg plasma membranes and the entry of the sperm nucleus into the cytoplasm of the egg. Either contact or fusion of the membranes causes ion channels to open in the egg cell's plasma membrane, allowing sodium ions to flow into the egg cell and change the membrane potential (see Chapter 7). This change in membrane potential, called depolarization, is common among animal species. Occurring within about 1–3 seconds after a sperm binds to an egg,

A Figure 47.3 The acrosomal and cortical reactions during sea urchin fertilization. The events following contact of a single sperm and egg ensure that the nucleus of only one sperm enters the cytoplasm of the egg.

Depolarization prevents additional sperm cells from fusing with the egg's plasma membrane. Without this fast block to polyspermy, multiple sperm could fertilize the egg, resulting in an aberrant number of chromosomes in the zygote.

The Cortical Reaction

The membrane depolarization lasts for only a minute or so, thus functioning only as a short-term block to polyspermy; however, fusion of egg and sperm plasma membranes also triggers a series of changes in the egg that cause a longer-lasting block. Sperm binding appears to activate a signal transduction pathway involving two second messengers, IP₃ and DAG, that cause calcium (Ca^{2+}) to be released from the egg's endoplasmic reticulum (ER) into the cytosol (see Figure 11.12). The Ca^{2+} release from the ER begins at the site of sperm entry and then propagates in a wave across the fertilized egg (Figure 47.4, on the next page).

Within seconds, the high concentration of Ca^{2+} brings about the cortical reaction, fusion with the egg's plasma

membrane of numerous vesicles lying in the egg's cortex, the area just beneath the membrane. These cortical granules, formed during oogenesis, now release their contents into the perivitelline space, the space between the plasma membrane and the vitelline layer (see Figure 47.3, step 5). Enzymes released from the cortical granules degrade proteins holding the vitelline layer to the plasma membrane, while mucopolysaccharides produce an osmotic gradient, drawing water into the perivitelline space and swelling it. The swelling pushes the vitelline layer away from the plasma membrane, and other enzymes harden it. Different enzymes clip off and release the external portions of the remaining receptor proteins from the vitelline layer. These changes transform the vitelline layer into the fertilization envelope, which resists the entry of additional sperm. The fertilization envelope and other changes in the egg's surface function together as a longer-term slow block to polyspermy. Although studied in greatest detail in sea urchins, the cortical reaction is known to occur in vertebrates such as fishes and mammals.

Activation of the Egg

Another outcome of the sharp rise in Ca^{2+} concentration in the egg's cytosol is a substantial increase in the rates of cellular respiration and protein synthesis by the egg cell. With these rapid changes in metabolism, the egg is said to be activated.

Although the binding and fusion of sperm are triggers for egg activation, sperm cells do not contribute any materials required for activation. Indeed, the unfertilized eggs of many species can be artificially activated by the injection of Ca^{2+} or by a variety of mildly injurious treatments, such as temperature shock. This artificial activation switches on the metabolic responses of the egg and causes it to begin developing by parthenogenesis (without fertilization by a sperm). It is even possible to artificially activate an egg that has had its own nucleus removed. This finding shows that proteins and mRNAs present in the cytoplasm of the unfertilized egg are sufficient for egg activation.

While the metabolism of the activated sea urchin egg increases, the sperm nucleus within the egg starts to swell. After about 20 minutes, the sperm nucleus merges with the egg nucleus, creating the diploid nucleus of the zygote. DNA synthesis begins, and the first cell division occurs after about 90 minutes in the case of sea urchins and some frogs. The events and timeline of fertilization in sea urchins are summarized in Figure 47.5.

Fertilization in other species shares many features with the process in sea urchins. However, the timing differs with the species, and the stage of meiosis the egg has reached at fertilization also varies among species. At the time of release from the female, sea urchin eggs have completed meiosis. In other species, the eggs are arrested at a specific stage of meiosis; upon fertilization, meiosis is quickly completed along with many of the events already described. Human eggs, for example, are arrested at metaphase of meiosis II (see Figure 46.11) until they are fertilized in the female reproductive tract.

Fertilization in Mammals

In contrast to the external fertilization of sea urchins and most other marine invertebrates, fertilization in terrestrial animals, including mammals, is generally internal. Secretions in the mammalian female reproductive tract alter certain molecules on the surface of sperm cells and also increase sperm motility.

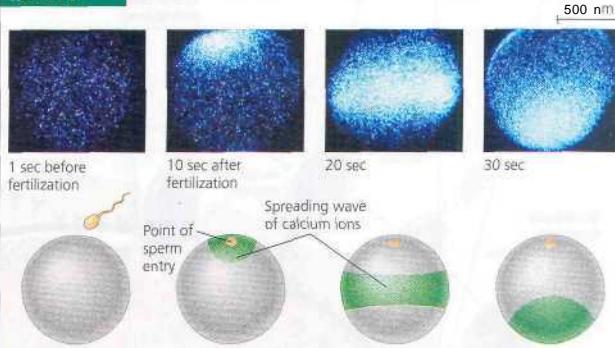

Figure 47.4

Inquiry What is the effect of sperm binding on Ca^{2+} distribution in the egg?

EXPERIMENT

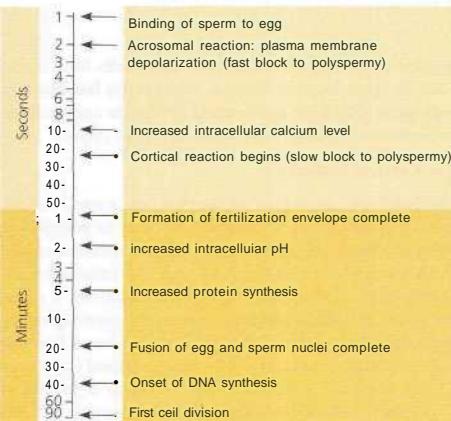

A fluorescent dye that glows when it binds free Ca^{2+} was injected into unfertilized sea urchin eggs. After sea urchin sperm were added, researchers observed the eggs in a fluorescence microscope.

RESULTS

CONCLUSION

The release of Ca^{2+} from the endoplasmic reticulum into the cytosol at the site of sperm entry triggers the release of more and more Ca^{2+} in a wave that spreads to the other side of the cell. The entire process takes about 30 seconds.

A Figure 47.5 Timeline for the fertilization of sea urchin eggs. The process begins when a sperm cell contacts the jelly coat of an egg (top of chart). Notice that the scale is logarithmic.

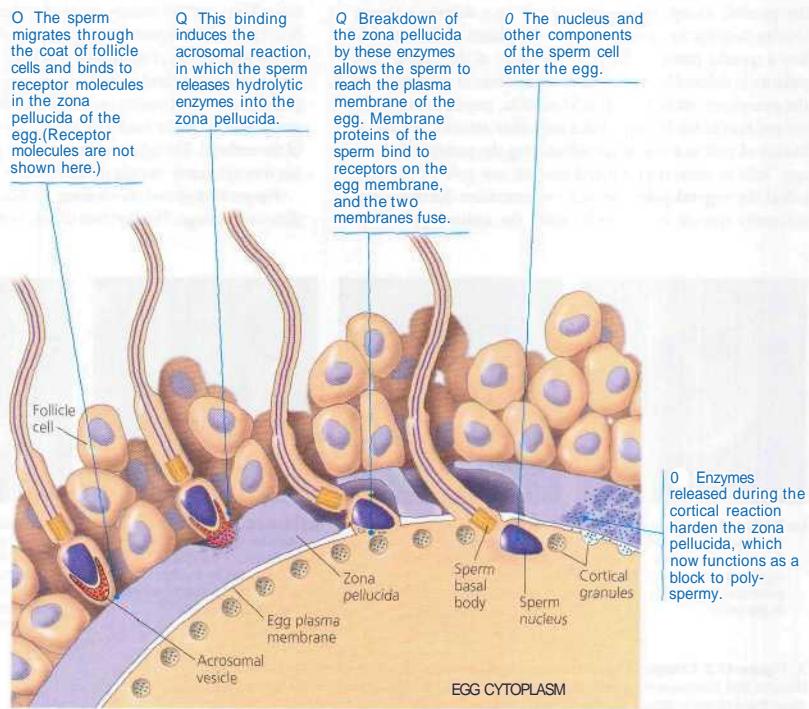

In humans, this enhancement of sperm junction requires about 6 hours of exposure to the female reproductive tract.

The mammalian egg is cloaked by follicle cells released along with the egg during ovulation. A sperm cell must migrate through this layer of follicle cells before it reaches the **zona pellucida**, the extracellular matrix of the egg. One component of the zona pellucida functions as a sperm receptor, binding to a complementary molecule on the surface of the sperm head. Binding of the sperm head to receptor molecules induces an acrosomal reaction similar to that of sea urchin sperm (**Figure 47.6**). Hydrolytic enzymes spilled from the acrosome enable the sperm cell to penetrate the zona pellucida and reach the plasma membrane of the egg. The acrosomal reaction also exposes a **protein** in the sperm membrane that binds with the egg's plasma membrane.

As in sea urchin fertilization, the binding of a sperm cell to the egg triggers changes within the egg leading to a cortical reaction, the release of enzymes from cortical granules to the outside of the cell via exocytosis. The released enzymes catalyze alterations of the zona pellucida, which then functions

as the slow block to polyspermy. (There is no known fast block to polyspermy in mammals.)

After the egg and sperm membranes fuse, the whole sperm, tail and all, is taken into the egg, which lacks a centrosome. A centrosome forms around the centriole that acted as the basal body of the sperm's flagellum. This centrosome, which now includes a second centriole, duplicates to form two centrosomes in the zygote. These will generate the mitotic spindle for the first cell division. The haploid nuclei of mammalian sperm and egg do not fuse immediately as in sea urchin fertilization. Instead, the envelopes of both nuclei disperse, and the two sets of chromosomes (one set from each gamete) share a common spindle apparatus during the first mitotic division of the zygote. Thus, only after this first division, as diploid nuclei form in the two daughter cells, do the chromosomes from the two parents come together in a common nucleus. Fertilization is much slower in mammals than in the sea urchin; the first cell division occurs 12–36 hours after sperm binding in mammals, compared with about 90 minutes in sea urchins.

• Figure 47.6
Early events of fertilization in mammals. As in sea urchins, events that occur during fertilization ensure that only one sperm enters the cytoplasm of the egg.

Cleavage

Once fertilization is completed, a succession of rapid cell divisions ensues. During this period, called cleavage, the cells undergo the S (DNA synthesis) and M (mitosis) phases of the cell cycle, but often virtually skip the G₁ and G₂ phases, so little or no protein synthesis occurs (see Figure 12.5). The embryo does not enlarge during this period of development. Cleavage simply partitions the cytoplasm of one large cell, the zygote, into many smaller cells called blastomeres, each with its own nucleus (**Figure 47.7**).

The first five to seven divisions form a cluster of cells known as the morula (Latin for “mulberry” in reference to the lobed surface of the embryo at this stage). A fluid-filled cavity called the blastocoel begins to form within the morula and is fully formed in the blastula, which is a hollow ball of cells. During cleavage, different regions of cytoplasm present in the original undivided egg cell end up in separate blastomeres. Because the regions may contain different cytoplasmic determinants, in many species this partitioning sets the stage for subsequent developmental events.

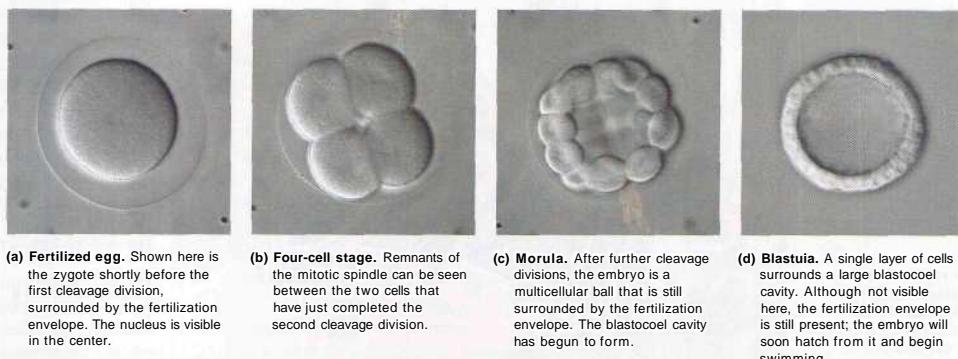

The eggs and zygotes of sea urchins and other animals, with the possible exception of mammals, have a definite polarity. During cleavage in such organisms, the planes of division follow a specific pattern relative to the poles of the zygote. The polarity is defined by the uneven distribution of substances in the cytoplasm, including specific mRNAs, proteins, and yolk (stored nutrients). In many frogs and other animals, the distribution of yolk is a key factor influencing the pattern of cleavage. Yolk is most concentrated toward one pole of the egg, called the vegetal pole; the yolk concentration decreases significantly toward the opposite pole, the animal pole. The

animal pole is also the site where the polar bodies of oogenesis are budded from the cell (see Figure 46.11).

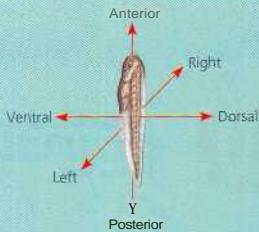

The three body axes shown in **Figure 47.8a** are established early in development. This process has been well studied in particular frog species where different regions of the egg and early embryo can be distinguished by color and followed easily. The animal and vegetal hemispheres of the zygote, named for their respective poles, differ in color. The animal hemisphere is a deep gray because dark-colored melanin granules are embedded in the outer layer (cortex) of the cell in this region. The lack of melanin granules in the vegetal hemisphere allows the yellow color of the yolk to be visible.

Following fusion of the egg and the sperm, rearrangement of the amphibian egg cytoplasm establishes one of the body axes (**Figure 47.8b**). The plasma membrane and associated cortex rotate with respect to the inner cytoplasm. The animal pole cortex moves toward the point of sperm entry, and the vegetal hemisphere cortex across from the point of sperm entry moves toward the animal hemisphere. Molecules in the vegetal cortex are now able to interact with inner cytoplasmic molecules in the animal hemisphere, leading to the formation of cytoplasmic determinants that will later initiate development of dorsal structures. Thus, *cortical rotation* establishes the dorsal-ventral (back-belly) axis of the zygote. In some species, this event also exposes a light gray region of cytoplasm, the gray crescent, that is covered by the pigmented animal cortex near the equator of the egg prior to rotation. Located on the side opposite sperm entry, the gray crescent can be used as a marker for the future dorsal side of the embryo. The lighter pigment of the gray crescent can persist through many rounds of cell division.

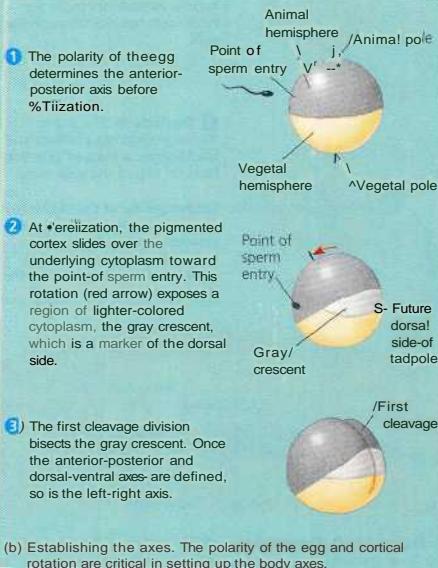

Figure 47.9 shows the cleavage planes during the initial cell divisions in frogs. The first two divisions in frogs are meridional

A Figure 47.7 Cleavage in an echinoderm embryo. Cleavage is a series of mitotic cell divisions that transform the zygote into a sphere of cells called blastomeres. These light micrographs show the embryonic stages of a sand dollar, which are virtually identical to those of a sea urchin.

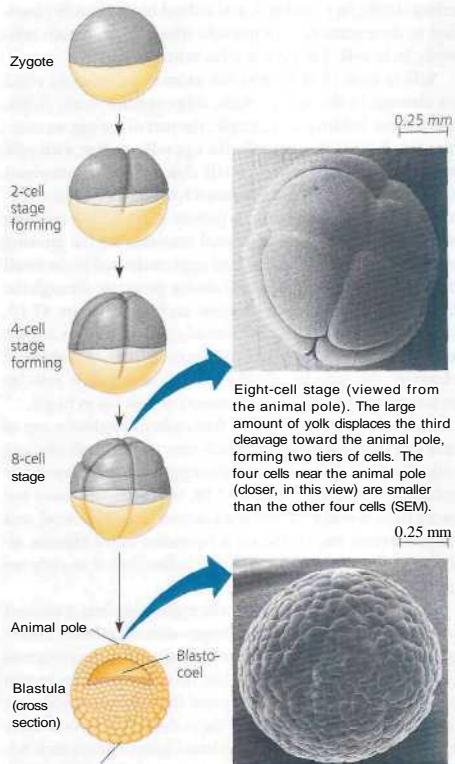

(a) Body axes. The three axes of the fully developed embryo, the tadpole-, are shown above.

4 Figure 47.8 The body axes and their establishment in an amphibian. All three axes are established before the zygote begins cleavage.

(vertical), resulting in four blastomeres of equal size, each extending from the animal pole to the vegetal pole. The third division is equatorial (horizontal), producing an eight-celled embryo. However, the highly uneven distribution of yolk in the frog zygote displaces the mitotic apparatus and eventual cytokinesis toward the animal end of the dividing cells in equatorial divisions. Thus, the four blastomeres in the animal hemisphere are smaller than those in the vegetal hemisphere at the eight-cell stage. The displacing effect of the yolk persists in subsequent divisions. Continued divisions produce a morula and then a

A Figure 47.9 Cleavage in a frog embryo. The cleavage planes in the first and second divisions extend from the animal to the vegetal pole, but the third cleavage is perpendicular to the polar axis.

blastula. In frogs, because of unequal cell division, the blastocoel is located in the animal hemisphere (see Figure 47.9).

Although the eggs of sea urchins and some other animals have less yolk than frog eggs, they still have an animal-vegetal axis, owing to uneven distribution of other substances. Without the restraint imposed by yolk, however, the blastomeres formed during cleavage are more likely to be of similar size, particularly during the first few divisions (see Figure 47.7). Nonetheless, the general cleavage pattern seen in frogs is also seen in sea urchins and other

echinoderms, in chordates, and indeed in all animals classified as deuterostomes. In animals whose eggs contain relatively little yolk, the blastocoel is centrally located.

Yolk is most plentiful and has its most pronounced effect on cleavage in the eggs of birds, other reptiles, many fishes, and insects. In birds, for example, the part of the egg we commonly call the yolk is actually the egg cell, swollen with yolk nutrients. There is a very small disk of actual cytoplasm located at the animal pole (**Figure 47.10**, step O). This enormous cell is surrounded by a protein-rich solution (the egg white) that will provide additional nutrients for the growing embryo. Cleavage of the fertilized egg is restricted to the small disk of yolk-free cytoplasm and cannot penetrate through the dense yolk; thus, the yolk remains uncleaved (Figure 47.10, step O). This incomplete division of a yolk-rich egg is known as meroblastic cleavage. It contrasts with holoblastic cleavage, the complete division of eggs having little yolk (as in sea urchins) or a moderate amount of yolk (as in frogs).

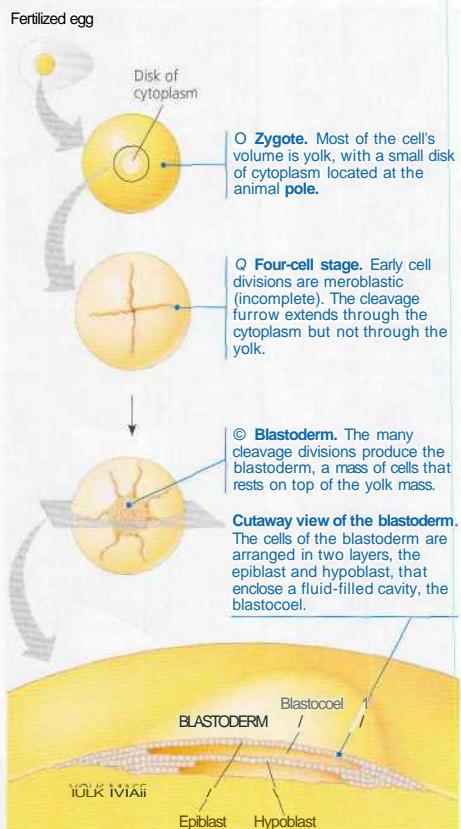

Early cleavage divisions in a bird embryo produce a cap of cells called the blastoderm, which rests on the undivided egg yolk. The blastomeres then sort into upper and lower layers, the *epiblast* and *hypoblast* (Figure 47.10, step ©). The cavity between these two layers is the avian version of the blastocoel, and this embryonic stage is the avian equivalent of the blastula, although its form is different from the hollow ball of an early sea urchin or frog embryo.

In insects such as *Drosophila*, the zygote's nucleus is situated *within* a mass of yolk. Cleavage begins with the nucleus undergoing mitotic divisions that are not accompanied by cytokinesis (see Figure 21.12). These mitotic divisions produce several hundred nuclei, which at first spread throughout the yolk and later migrate to the outer edge of the embryo. After several more rounds of mitosis, a plasma membrane forms around each nucleus, and the embryo, now the equivalent of a blastula, consists of a single layer of about 6,000 cells surrounding a mass of yolk.

Gastrulation

The morphogenetic process called gastrulation is a dramatic rearrangement of the cells of the blastula to form a three-layered embryo with a primitive gut. Although gastrulation differs in detail from one animal group to another, the process is driven by the same general mechanisms in all species: changes in cell motility, changes in cell shape, and changes in cellular adhesion to other cells and to molecules of the extracellular matrix. The result of gastrulation is that some of the cells at or near the surface of the blastula move to an interior location, and three cell layers are established. The three-layered embryo is called the gastrula (plural, *gastrulae*). The positioning of the cell layers in the gastrula allows cells to interact with each other in new ways.

The three layers produced by gastrulation are embryonic tissues collectively termed the embryonic germ layers. The

A Figure 47.10 Cleavage in a chick embryo. The view in the top three drawings is from above, looking toward the animal pole. The bottom drawing is a cutaway view of the embryo with just a portion of the yolk mass showing. The blastoderm that forms during cleavage is the avian equivalent of the blastula in frogs (see Figure 47.9).

ectoderm forms the outer layer of the gastrula; the endoderm lines the embryonic digestive tract; and the mesoderm partly fills the space between the ectoderm and the endoderm. Eventually, these three cell layers develop into all the tissues and organs of the adult animal. Here we examine the events that occur during gastrulation in the sea urchin, frog, and chick.

Figure 47.11 outlines gastrulation in a sea urchin embryo. The sea urchin blastula consists of a single layer of cells enclosing the centrally located blastocoel. Gastrulation begins at the vegetal pole, where individual cells detach from the blastula wall and enter the blastocoel as migratory cells called *mesenchyme*

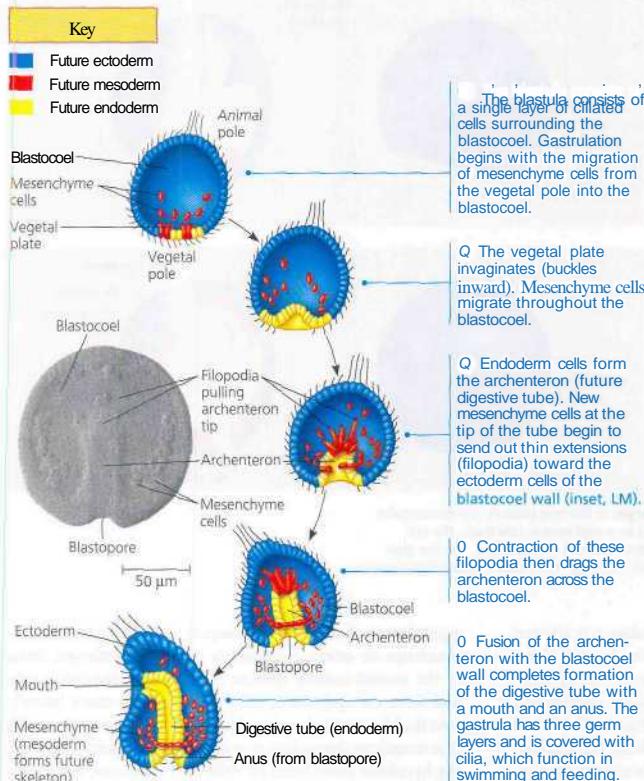

cells. The remaining cells near the vegetal pole flatten slightly and form a *vegetal plate* that buckles inward, a process called invagination. The buckled vegetal plate then undergoes extensive rearrangement of its cells, transforming the shallow invagination into a deeper, narrower, blind-ended tube called the archenteron, or primitive gut. The open end of the archenteron, which will become the anus, is called the blastopore. A second opening forms when the other end of the archenteron touches the inside of the ectoderm and the two layers fuse, forming the mouth end of what is now a rudimentary digestive tube.

Gastrulation produces a sea urchin embryo with a primitive gut and three germ layers, which are commonly color-coded blue for ectoderm, red for mesoderm, and yellow for endoderm

(see Figure 47.11, step 5). This three-layered body plan is characteristic of most animal phyla and is established very early in development. In the sea urchin, the gastrula eventually develops into a ciliated larva that drifts in ocean surface waters as plankton, feeding on bacteria and unicellular algae. After some time, the larva metamorphoses into the adult form of the sea urchin, which takes up residence on the bottom of the ocean.

In the frog, gastrulation also produces a three-layered embryo with an archenteron. The mechanics of gastrulation are more complicated in a frog, however, because of the large, yolk-laden cells of the vegetal hemisphere and because the wall of the blastula is more than one cell thick in most species. Gastrulation begins on the dorsal side of the blastula, when a group of cells begin to invaginate in a line along the region

where the gray crescent formed in the zygote (see Figure 47.8). This invagination becomes the dorsal side of the blastopore, called the dorsal lip (Figure 47.12,

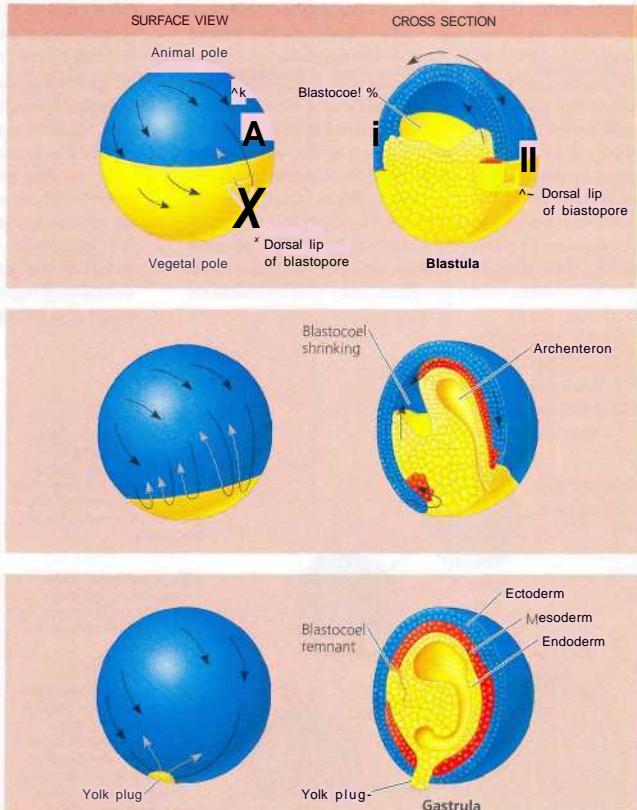

A Figure 47.11 Gastrulation in a sea urchin embryo. The movement of cells during gastrulation forms an embryo with a primitive gut and three germ layers. Some of the mesenchyme (mesoderm) cells that migrate inward (step 0) will eventually secrete calcium carbonate and form a simple internal skeleton. Embryos in steps 0–5 are viewed from the front, those in Q and Q' from the side.

on the next page). The blastopore lip extends as invagination continues to be initiated at each end, until the two ends of the blastopore meet on the ventral side. The blastopore is now a complete circle.

All along the blastopore, future endoderm and mesoderm cells on the surface of the embryo roll under the edge of the lip called involution. Once inside the embryo, these cells move away from the blastopore and become organized into layers of endoderm and mesoderm, with the endoderm on the inside. The blastocoel collapses during this process, displaced by the tube of endoderm. As gastrulation is completed, the circular lip of the blastopore encircles a yolk plug consisting of the outer food-laden cells; these protruding cells will move inward as expansion of the ectoderm causes the blastopore to shrink further. At this point, the cells remaining on the surface make up the ectoderm, surrounding the layers of mesoderm and endoderm. As in the sea urchin, the amphibian anus develops from the blastopore, and the mouth eventually forms at the opposite end of the archenteron after it extends to the ventral side near the animal pole.

Gastrulation in the chick is similar to frog gastrulation in that it involves cells moving from the surface of the embryo to an interior location. In birds, however,

0 Gastrulation begins when a small indented crease, the dorsal lip of the blastopore, appears on one side of the blastula. The crease is formed by cells changing shape and pushing inward from the surface (invagination). Additional cells then roll inward over the dorsal lip (involution) and move into the interior, where they will form endoderm and mesoderm. Meanwhile, cells of the animal pole, the future ectoderm, change shape and begin spreading over the outer surface.

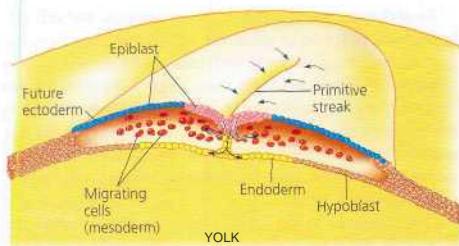

2 The blastopore lip grows on both sides of the embryo, as more cells invaginate. When the sides of the lip meet, the blastopore forms a circle that becomes smaller as ectoderm spreads downward over the surface. Internally, continued involution expands the endoderm and mesoderm, and the archenteron begins to form; as a result, the blastocoel becomes smaller.

3 Late in gastrulation, the endoderm-lined archenteron has completely replaced the blastocoel and the three germ layers are in place. The circular blastopore surrounds a plug of yolk-filled cells.

A Figure 47.12 **Gastrulation in a frog embryo.** In the frog blastula, the blastocoel is displaced toward the animal pole and is surrounded by a wall several cells thick. The cell movements that begin gastrulation occur on the dorsal side of the blastula, where the gray crescent was located in the zygote (see Figure 47.8B). Although still visible as gastrulation begins, the gray crescent is not shown here.

the inward movement of cells during gastrulation is affected by the large mass of yolk pressing against the bottom of the embryo. Recall that cleavage in the chick results in a blastoderm consisting of upper and lower layers—the epiblast and hypoblast—lying atop the yolk mass (see Figure 47.10). All the cells that will form the embryo come from the epiblast. During gastrulation, some epiblast cells move toward the midline of the blastoderm, then detach and move inward toward the yolk (**Figure 47.13**). The pileup of cells moving inward at the blastoderm's midline produces a thickening called the **primitive streak**, which runs along what will become the bird's anterior-posterior axis. The primitive streak is functionally

equivalent to the lip of the blastopore in the frog, but the two structures are oriented differently in the two embryos. Some of the inward-moving epiblast cells displace hypoplast cells and form the endoderm; other epiblast cells move laterally into the blastocoel, forming the mesoderm. The epiblast cells that remain on the surface give rise to the ectoderm. Although the hypoblast contributes no cells to the embryo, it seems to help direct the formation of the primitive streak before the onset of gastrulation and is required for normal development. The hypoblast cells later segregate from the endoderm and eventually form portions of a sac surrounding the yolk and a stalk connecting the yolk mass to the embryo.

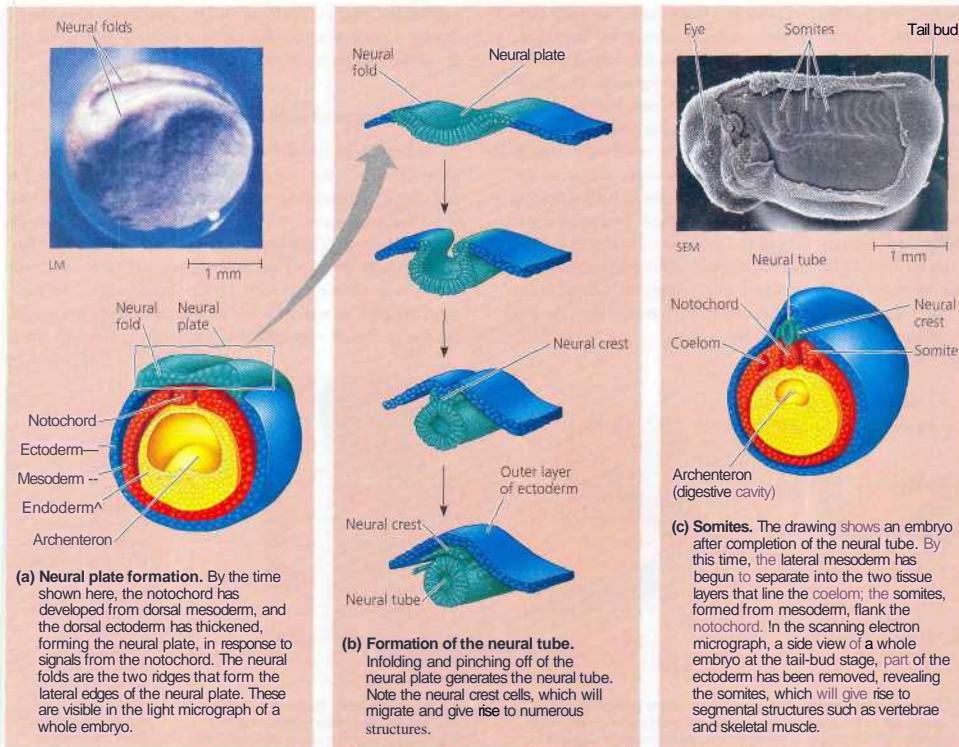

A Figure 47.13 Gastrulation in a chick embryo. During gastrulation, some cells of the epiblast migrate (arrow) into the interior of the embryo through the primitive streak, shown here in transverse section. Some of these cells move downward to form endoderm, while others migrate laterally to form mesoderm. The cells left behind on the surface of the embryo at the end of gastrulation will become ectoderm.

Despite variations in how the three germ layers form in different species, once they are in place, gastrulation is complete. Now is the time when the embryo's organs begin to form.

Organogenesis

Various regions of the three embryonic germ layers develop into the rudiments of organs during the process of organogenesis. While gastrulation involves mass cell movements, organogenesis involves more localized morphogenetic changes in tissue and cell shape. The first evidence of organ building is the appearance of fold, splits, and dense clustering (condensation) of cells. The organs that begin to take shape first in the embryos of frogs and other chordates are the neural tube and the notochord, the skeletal rod characteristic of all chordate embryos.

Figure 47.14 shows some events during early organogenesis in a frog. The notochord is formed from dorsal mesoderm

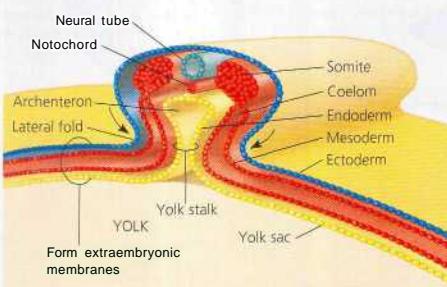

A Figure 47.14 Early organogenesis in a frog embryo.

that condenses just above the arcbenteron (**Figure 47.14a**). Signals sent from the notochord to the ectoderm above it cause that region of ectoderm to become the neural plate. The neural plate soon curves inward, rolling itself into the neural tube which runs along the anterior-posterior axis of the embryo (**Figure 47.14b**). The neural tube will become the central nervous system—the brain in the head and the spinal cord down the rest of the body. The signaling by the mesodermally derived notochord to the ectoderm is a good example of a process seen often during organogenesis: one germ layer signaling another to determine the fate of the second.

Unique to vertebrate embryos, a band of cells called the neural crest develops along the border where the neural tube pinches off from the ectoderm. Cells of the neural crest subsequently migrate to various parts of the embryo, forming peripheral nerves, teeth, skull bones, and so many other different cell types that some have proposed considering neural crest cells as a "fourth germ layer."

Other condensations occur in strips of mesoderm lateral to the notochord, which separate into blocks called somites (**Figure 47.14c**). The somites are arranged serially on both sides along the length of the notochord. Pairs of the somites dissociate into individual mesenchymal (wandering) cells, which migrate to new locations. The notochord functions as a core around which these mesodermal cells gather and form the vertebrae. Part of the notochord between the vertebrae persist as the inner portions of the vertebral disks in adults. (These are the disks that can "slip," causing back pain.) Somite cells also form the muscles associated with the axial skeleton. This serial origin of the axial skeleton and muscles reinforces the idea that chordates are basically segmented animals, although the segmentation becomes less obvious later in development. Lateral to the somites, the mesoderm splits into two layers that form the lining of the body cavity, or coelom.

(a) Early organogenesis. The archenteron forms when lateral folds pinch the embryo away from the yolk. The embryo remains open to the yolk, attached by the yolk stalk, about midway along its length, as shown in this cross section. The notochord, neural tube, and somites subsequently form much as they do in the frog.

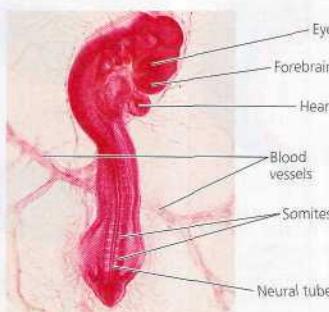

As organogenesis progresses, morphogenesis and cell differentiation continue to refine the organs that arise from the three embryonic germ layers, with many of the internal organs being derived from two of the three layers. Embryonic development of the frog leads to a larval stage, the tadpole, which hatches from the jelly coat that originally protected the egg and developing embryo. Later, metamorphosis will transform the frog from the aquatic, herbivorous tadpole to the terrestrial, carnivorous adult.

Organogenesis in the chick is quite similar to that in the frog. After the three germ layers are formed, the borders of the blastoderm fold downward and come together, pinching the embryo into a three-layered tube joined underneath the middle of the body to the yolk (**Figure 47.15a**). Neural tube formation, development of the notochord and somites, and other events in organogenesis occur much as in the frog embryo. The rudiments of the major organs are evident in a 2- to 3-day-old chick embryo (**Figure 47.15b**).

Figure 47.16 lists the embryonic sources of the major organs and tissues in frogs, chicks, and other vertebrates! Review this figure to become familiar with the embryonic origin of the various body structures.

Developmental Adaptations of Amniotes

All vertebrate embryos require an aqueous environment for development. In the case of fishes and amphibians, the egg is laid in the surrounding sea or pond and needs no special water-filled enclosure. The movement of vertebrate animals onto land required evolution of structures that would allow reproduction in dry environments; two effective structures have evolved that exist today: (1) the shelled egg of birds and other reptiles, as well as a few mammals (monotremes), and (2) the uterus of marsupial and eutherian (placental) mammals.

(b) Late organogenesis. Rudiments of most major organs have already formed in this chick embryo, which is about 56 hours old and about 2-3 mm long (LM).

* **Figure 47.15 Organogenesis in a chick embryo.**
 (a) The germ layers lateral to the embryo itself give rise to extraembryonic membranes (discussed later).
 (b) These membranes eventually are supplied by blood vessels extending from the embryo; several major blood vessels are seen here.

mals. Within the shell or uterus, the embryos of these animals are surrounded by fluid within a sac formed by a membrane called the amnion. Reptiles (including birds) and mammals are therefore called **amniotes** (see Chapter 34).

We have already seen that embryonic development of the chick, an amniote, is very similar to that of the frog, a vertebrate that lacks an amnion. However, in the chick, development also includes the formation of **extraembryonic membranes**, membranes located outside the embryo. Notice in Figure 47.15a that only part of each germ layer contributes to the embryo itself. The germ layers located outside the embryo proper develop into the amnion and three other membranes—the yolk sac, the chorion, and the allantois. These four extraembryonic membranes provide a "life-support system" for further embryonic development within the shelled egg or the uterus of an amniote. Each membrane is a sheet of cells derived from two germ layers. **Figure 47.17** reviews the locations and functions of these membranes in birds and other reptiles.

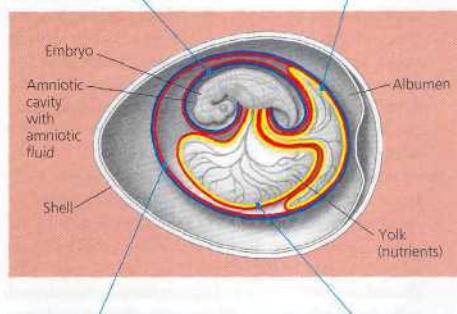

Mammalian extraembryonic membranes will be discussed next, as we describe early development in mammalian embryos. Formation of the placenta, a structure unique to marsupial and eutherian mammals, is an important part of this process.

Mammalian Development

In most mammalian species, fertilization takes place in the oviduct, and the earliest stages of development occur while the embryo completes its journey down the oviduct to the uterus (see Figure 46.15). In contrast to the large, yolky eggs of birds, other reptiles, and monotremes, the eggs of most mammals are quite small, storing little in the way of food reserves. As already mentioned, the mammalian egg cell and zygote have not yet been shown to exhibit obvious polarity with respect to the contents of the cytoplasm, and cleavage of the zygote, which lacks yolk, is holoblastic. However, mammalian gastrulation and early organogenesis follow a pattern similar to that of birds and other reptiles. (Recall from Chapter 34 that mammals descended from reptilian stock during the Mesozoic era.)

Amnion. The amnion protects the embryo in a fluid-filled cavity that prevents dehydration and cushions mechanical shock.

Allantois. The allantois functions as a disposal sac for certain metabolic wastes produced by the embryo. The membrane of the allantois also functions with the chorion as a respiratory organ.

Chorion. The chorion and the membrane of the allantois exchange gases between the embryo and the surrounding air. Oxygen and carbon dioxide diffuse freely across the egg's shell.

Yolk sac. The yolk sac expands over the yolk, a stockpile of nutrients stored in the egg. Blood vessels in the yolk sac membrane transport nutrients from the yolk into the embryo. Other nutrients are stored in the albumen (the "egg white").

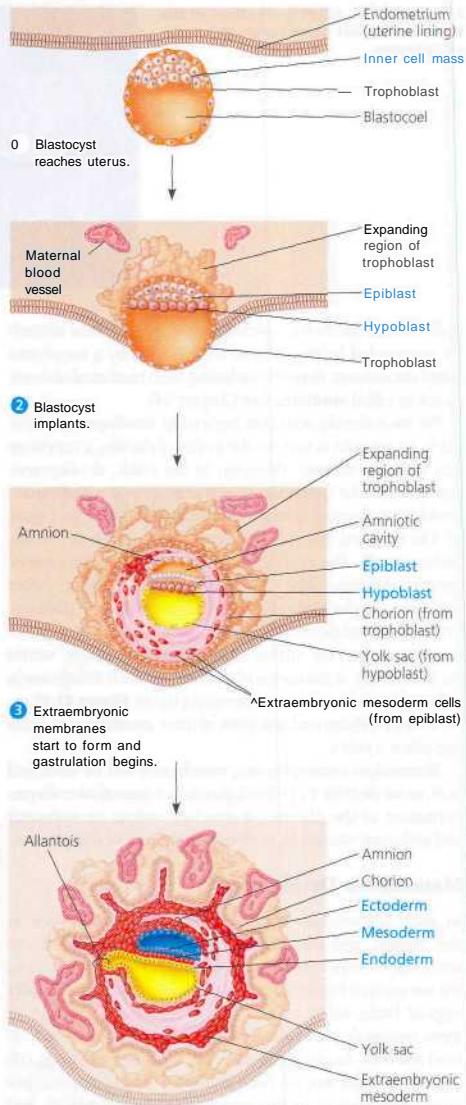

A Figure 47.17 Extraembryonic membranes in birds and other reptiles. There are four extraembryonic membranes: the amnion, the allantois, the chorion, and the yolk sac. Each membrane is a sheet of cells that develops from epithelial sheets of two of the three germ layers external to the embryo proper (see Figure 47.15a).

Early cleavage is relatively slow in mammals. In the case of humans, the first division is complete about 36 hours after fertilization, the second division at about 60 hours, and the third division at about 72 hours. The blastomeres are equal in size. At the eight-cell stage, the blastomeres become tightly adhered to one another, causing the outer surface of the

embryo to appear smooth. **Figure 47.18** depicts development of the human embryo starting about 7 days after fertilization (see key numbers in the figure):

- At the completion of cleavage, the embryo has over 100 cells arranged around a central cavity and has traveled down the oviduct to the uterus. This embryonic stage, the **blastocyst**, is the mammalian version of a blastula. Clustered at one end of the blastocyst cavity is a group of cells called the inner cell mass, which will subsequently develop into the embryo proper and form or contribute to all the extraembryonic membranes.
- The **trophoblast**, the outer epithelium of the blastocyst, initiates implantation by secreting enzymes that break down molecules of the endometrium, the lining of the uterus. This allows the blastocyst to invade the endometrium. As the trophoblast thickens through cell division, it extends fingerlike projections into the surrounding maternal tissue, which is rich in blood vessels. Invasion by the trophoblast leads to erosion of capillaries in the endometrium, causing blood to spill out and bathe trophoblast tissues. Around the time of implantation, the inner cell mass of the blastocyst forms a flat disk with an upper layer of cells, the **epiblast**, and a lower layer, the **hypoblast**, which are homologous to the epiblast and hypoblast of birds (see Figure 47.10, step 3). As in birds, the human embryo develops almost entirely from epiblast cells.
- As implantation is completed, gastrulation begins. Cells move inward from the epiblast through a primitive streak to form mesoderm and endoderm, just as in the chick. At the same time, extraembryonic membranes begin to form. The trophoblast continues to expand into the endometrium. The invading trophoblast, mesodermal cells derived from the epiblast, and adjacent endometrial tissue all contribute to formation of the placenta (see Figure 46.16).
- By the end of gastrulation, the embryonic germ layers have formed. The three-layered embryo is now surrounded by proliferating extraembryonic mesoderm and the four extraembryonic membranes.

The extraembryonic membranes in mammals are homologous to those of birds and other reptiles and develop in a similar way. The **chorion**, which completely surrounds the **embryo** and the other extraembryonic membranes, functions in gas exchange. The **amnion** eventually encloses the embryo in a protective fluid-filled amniotic cavity (The fluid from this cavity is the "water" expelled from the vagina of the mother when the amnion breaks just prior to childbirth.) Below the developing embryo proper, the **yolk sac** encloses another fluid-filled cavity. Although this cavity contains no yolk, the membrane that surrounds it is given the same name as the homologous membrane in birds and other reptiles. The yolk sac membrane

- Gastrulation has produced a three-layered embryo with four extraembryonic membranes.

A Figure 47.18 Four stages in early embryonic development of a human. The epiblast gives rise to the three germ layers, which form the embryo proper. See the text for a description of each stage.

of mammals is a site of early formation of blood cells, which later migrate into the embryo proper. The fourth extraembryonic membrane, the **allantois**, is incorporated into the umbilical cord. Here it forms blood vessels that transport oxygen and nutrients from the placenta to the embryo and rid the embryo of carbon dioxide and nitrogenous wastes. Thus, the extraembryonic membranes of shelled eggs, where embryos are nourished with yolk, were conserved as mammals diverged from reptiles in the course of evolution, but with modifications adapted to development within the reproductive tract of the mother.

The completion of gastrulation is followed by formation of the notochord, neural tube, and somites, the first events in organogenesis. By the end of the first trimester of human development, rudiments of all the major organs have developed from the three germ layers (see Figure 47.16).

Concept Check 47.1

- Predict what would happen if you injected Ca^{2+} into an unfertilized sea urchin egg.
- A frog zygote and frog blastula are nearly the same size. Explain this observation.
- Although gastrulation looks different in sea urchin, frog, and chick embryos, what is its common result in these animals?
- Compare cell movements during gastrulation and organogenesis in animals.

For suggested answers, see Appendix A.

(Concept) 47.2

Morphogenesis in animals involves specific changes in cell shape, position, and adhesion

Now that you have learned about the main events of embryonic development in animals, we will address the cellular and molecular mechanisms by which they occur. Although biologists are far from fully understanding these mechanisms, several key principles have emerged as fundamental to the development of all animals.

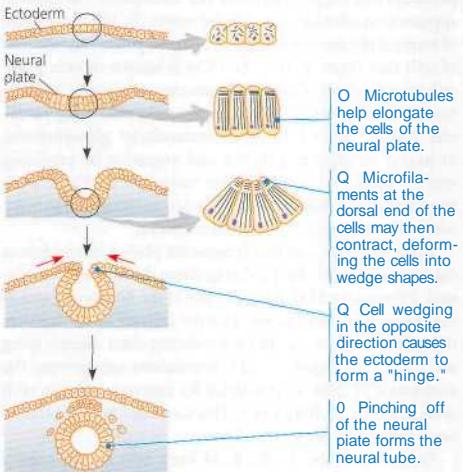

Morphogenesis is a major aspect of development in both animals and plants, but only in animals does it involve the movement of cells. Movement of parts of a cell can bring about changes in cell shape or enable a cell to migrate from one place to another within the embryo. Changes in both cell shape and cell position are involved in cleavage, gastrulation, and organogenesis. Here we consider some of the cellular components that contribute to these events.

The Cytoskeleton, Cell Motility, and Convergent Extension

Changes in the shape of a cell usually involve reorganization of the cytoskeleton (see Table 6.1). Consider, for example, how the cells of the neural plate form the neural tube (Figure 47.19). First, microtubules oriented parallel to the dorsal-ventral axis of the embryo apparently help lengthen the cells in that direction. At the dorsal end of each cell is a parallel array of actin filaments oriented crosswise. These contract, giving the cells a wedge shape that forces the ectoderm layer to bend inward. Similar changes in cell shape occur during other invaginations (inpocketings) and evaginations (out-pocketings) of tissue layers throughout development.

The cytoskeleton also drives cell migration, the active movement of cells from one place to another in developing animals. Cells "crawl" within the embryo by using cytoskeletal fibers to extend and retract cellular protrusions. This type of motility is akin to the amoeboid movement described in Figure 6.27b, but in contrast to the thick pseudopodia of amoeboid cells, the cellular protrusions of migrating embryonic cells are usually flat sheets (lamellipodia) or spikes (filopodia).

During gastrulation in some organisms, imagination is initiated by the wedging of cells on the surface of the blastula, but the movement of cells deeper into the embryo involves the extension of filopodia by cells at the leading edge of the migrating tissue. The cells that first move through the blastopore

A Figure 47.19 Change in cellular shape during morphogenesis. Reorganization of the cytoskeleton is associated with morphogenetic changes in embryonic tissues, as shown here for the formation of the neural tube in vertebrates.

and up along the inside of the blastocoel wall drag others behind them, thus helping direct movement of the entire sheet of cells from the embryo's surface into appropriate locations in the blastocoel. The involuted sheet then forms the endoderm

and mesoderm of the embryo (see figure 47.12). There are also many situations in which cells migrate individually, as when the cells of a somite or the neural crest disperse to various parts of the embryo.

Cell crawling is also involved in convergent extension, a type of morphogenetic movement in which the cells of a tissue layer rearrange themselves so that the sheet becomes narrower (converges) while it becomes longer (extends) (**Figure 47.20**). When many cells wedge between one another, the tissue can extend dramatically. Convergent extension is important in early embryonic development; it occurs, for example, as the archenteron elongates in sea urchin embryos and during involution in the frog gastrula. In the latter case, convergent extension is responsible for the change in shape from the spherical gastrula to the submarine-shaped frog embryo seen in Figure 47.14c.

Roles of the Extracellular Matrix and Cell Adhesion Molecules

Scientists are coming closer to understanding the signaling pathways that trigger and guide cell movement. The process appears to involve the extracellular matrix (ECM), the mixture of secreted glycoproteins lying outside the plasma membranes of cells (see Figure 6.29). The ECM is known to help guide cells in many types of morphogenetic movements. ECM fibers may function as tracks, directing migrating cells along particular routes. Several kinds of extracellular glycoproteins, including fibronectin, promote cell migration by providing specific molecular anchorage for moving cells. The experiment depicted in **Figure 47.21** provides evidence for this function of fibronectin in guiding cell migration.

Evidence also exists that fibronectin plays a similar role at the leading edge of the involuting tissue during frog gastrulation. Fibronectin fibers line the roof of the blastocoel, and as the future mesoderm moves into the interior of the embryo, the cells at the free edge of the involuting sheet migrate along the fibers (see Figure 47.12). Researchers can prevent the attachment of cells to fibronectin by injecting embryos with antibodies against fibronectin. This treatment prevents the inward movement of the mesoderm.

Other substances in the ECM keep cells on the correct paths by *inhibiting* migration in certain directions. Thus, depending on the substances they secrete, nonmigratory cells situated along migration pathways may promote or inhibit movement of other cells.

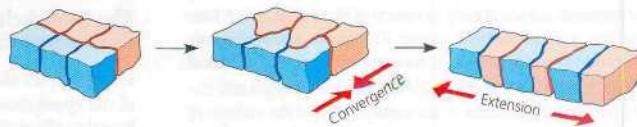

Figure 47.20 **Convergent extension of a sheet of cells.** In this simplified diagram, changes in cell shape and position cause the layer of cells to become narrower and longer. Molecular signals are believed to cause the cells to elongate in a particular direction and to crawl between each other (*convergence*), leading to *extension* of the cell sheet in a perpendicular direction.

Figure 47.21

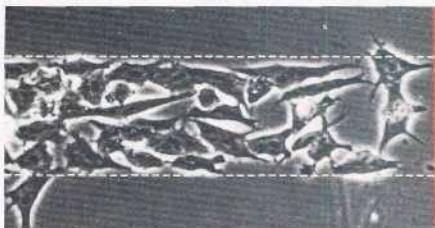

Inquiry Does fibronectin promote cell migration?

EXPERIMENT

Researchers placed a strip of fibronectin on an artificial underlayer. After positioning migratory neural crest cells at one end of the strip, the researchers observed the movement of the cells in a light microscope.

RESULTS

In this micrograph, the dashed lines indicate the edges of the fibronectin layer. Note that cells are migrating along the strip, not off of it.

Direction of migration →

50 μm

CONCLUSION

Fibronectin helps promote cell migration, possibly by providing anchorage for the migrating cells.

As migrating cells move along specific paths through the embryo, receptor proteins on their surfaces pick up directional cues from the immediate environment. Such signals from the FCM environment can direct the orientation of cytoskeletal elements in a way that propels the cell in the proper direction.

Also contributing to cell migration and stable tissue structure are glycoproteins called cell adhesion molecules (CAMs), which are located on the surfaces of cells and bind to CAMs on other cells. CAMs vary in amount, chemical identity or both from one type of cell to another, and these differences help regulate morphogenetic movements and tissue building.

One important class of cell-to-cell adhesion molecule is the cadherins, which require calcium ions for proper function.

There are many different cadherins, and the gene for each cadherin is expressed in specific locations at specific times during embryonic development. Researchers have vividly demonstrated the importance of one particular cadherin in the formation of the frog blastula (**Figure 47.22**). Cadherins are also involved in the tight adhesion of cells in the mammalian embryo that first occurs at the eight-cell stage, when cadherin production begins.

As we have seen, cell behavior and molecular mechanisms contribute to the morphogenesis of the embryo. The same basic cellular and genetic processes ensure that the various types of cells end up in the right places in each embryo.

Concept Check 47.2

- During formation of the neural tube, cube-shaped cells change to wedge-shaped cells. Describe the roles of microtubules and microfilaments in this process.
- In the frog embryo, convergent extension is thought to elongate the notochord along the anterior-posterior axis. How does this morphogenetic process work?

For suggested answers, see Appendix A.

Concept⁸ 47.3

The developmental fate of cells depends on their hist017 and on inductive signals

Coupled with the morphogenetic changes that give an animal and its parts their characteristic shapes, development also requires the timely differentiation of many kinds of cells in specific locations. Two general principles integrate our current knowledge of the genetic and cellular mechanisms that underlie differentiation during embryonic development.

First, during *early cleavage divisions*, *embryonic cells must somehow become different from one another*. In many animal species, initial differences between cells result from the uneven distribution of cytoplasmic determinants in the unfertilized egg. By partitioning the heterogeneous cytoplasm of a polarized egg, cleavage parcels out different mRNAs, proteins, and other molecules to blastomeres in a type of asymmetrical cell division (see Figure 21.11a). The resulting differences in the cells' cytoplasmic composition help specify the body axes and influence the expression of genes that affect the developmental fate of the cells. In amniotes, local environmental differences play the major role in establishing early differences between embryonic cells. For example, cells of the inner cell mass are located internally in the early human embryo, whereas trophoblast cells are located on the outside surface of the blastocyst. The different environments of these two groups of cells appear to determine their very different fates.

Second, once *initial cell asymmetries are set up*, subsequent interactions *among the embryonic cells influence their fate*, usually by causing changes in gene expression. This mechanism, termed **induction**, eventually brings about the differentiation of the many specialized cell types making up a new animal. Induction may be mediated by diffusible chemical signals or, if the cells are actually in contact, by cell-surface interactions.

It will help to keep these two principles in mind as we delve into the molecular and cellular mechanisms of differentiation

Figure 47.22

Inquiry > Is cadherin required for development of the blastula?

EXPERIMENT

Researchers injected frog eggs with nucleic acid complementary to the mRNA encoding a cadherin known as EP cadherin. This "antisense" nucleic acid leads to destruction of the mRNA for normal EP cadherin, so no EP cadherin protein is produced. Frog sperm were then added to control (noninjected) eggs and to experimental (injected) eggs. The control and experimental embryos that developed were observed in a light microscope.

RESULTS

As shown in these micrographs, fertilized control eggs developed into normal blastulas, but fertilized experimental eggs did not. In the absence of EP cadherin, the blastocoel did not form properly, and the cells were arranged in a disorganized fashion.

Control embryo

Experimental embryo

Proper blastula formation in the frog requires

EP cadherin.

and pattern formation during embryonic development of the species we're focusing on in this chapter. To ask questions about *how* the fate of an early embryonic cell is determined, we need to know what that fate is. So let's first look at some historic experiments that provided early researchers with information about cell fates.

Fate Mapping

As discussed in Chapter 21, researchers have worked out the developmental history of every cell in *Cae.norhabditis elegans*, beginning with the first cleavage division of the zygote (see Figure 21.15). Although such a complete cell lineage has not yet been determined for any other animal, biologists have been making more general territorial diagrams of embryonic development, called fate maps, for many years.

In classic studies performed in the 1920s, German embryologist W. Vogt charted fate maps for different regions of early amphibian embryos. Vogt's results were among the earliest indications that the lineage of cells making up the three germ layers created by gastrulation is traceable to cells in the blastula, before gastrulation has begun (Figure 47.23a). Later researchers developed more sophisticated techniques that allowed them to mark an individual blastomere during cleavage and then follow the marker as it was distributed to all the mitotic descendants of that cell (Figure 47.23b).

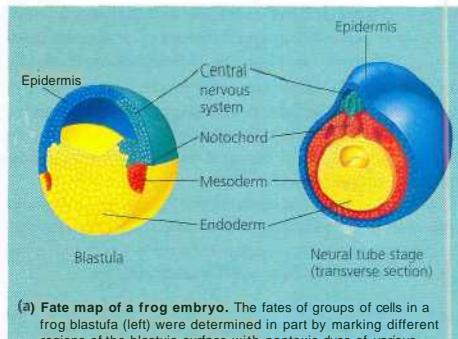

Developmental biologists have combined fate-mapping studies with experimental manipulation of parts of embryos in which they study whether a cell's fate can be changed by moving it elsewhere in the embryo. Two important conclusions have emerged. First, in most animals, specific tissues of the older embryo can be attributed to certain early "founder cells." Second, as development proceeds, a cell's *developmental potential*—the range of structures that it can give rise to—becomes restricted. (For review, see the discussion of cell fate determination in Chapter 21, pp. 418–420.) Starting with the normal embryo's fate map, researchers can examine how the differentiation of cells is altered in experimental situations or in mutant embryos.

Establishing Cellular Asymmetries

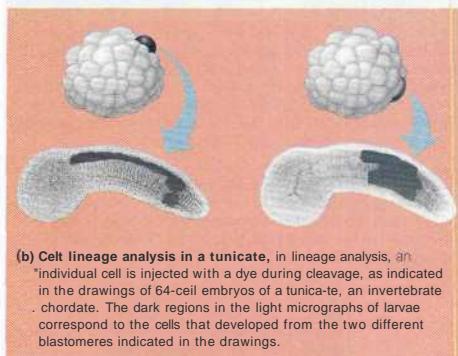

To understand at the molecular level how embryonic cells acquire their fates, it is helpful to think first about how the basic axes of the embryo are established. This can often be traced to a specific event in early development that sets up a particular cellular asymmetry, thus beginning to lay out the body plan.

The Axes of the Basic Body Plan

As you have learned, a bilaterally symmetrical animal has an anterior-posterior axis, a dorsal-ventral axis, and left and right sides (see Figure 47.8a). Establishing this basic body plan is a

(a) Fate map of a frog embryo. The fates of groups of cells in a frog blastula (left) were determined in part by marking different regions of the blastula surface with nontoxic dyes of various colors. The embryos were sectioned at later stages of development, such as the neural tube stage shown on the right, and the locations of the dyed cells determined.

(b) Cell lineage analysis in a tunicate. In lineage analysis, an individual cell is injected with a dye during cleavage, as indicated in the drawings of 64-cell embryos of a tunicate, an invertebrate chordate. The dark regions in the light micrographs of larvae correspond to the cells that developed from the two different blastomeres indicated in the drawings.

A Figure 47.23 Fate mapping for two chordates.

first step in morphogenesis and is a prerequisite for the development of tissues and organs.

In nonamniotic vertebrates, basic instructions for establishing the body axes are set down early, during oogenesis or fertilization. For example, in many frogs, the locations of melanin and yolk in the unfertilized egg define the animal and vegetal hemispheres, respectively. The animal-vegetal axis indirectly determines the anterior-posterior body axis. Fertilization then triggers cortical rotation, which establishes the dorsal-ventral axis and at the same time leads to the appearance of the gray crescent, whose position marks the dorsal side (see Figure 47.8b). Once any two axes are established, the third (in this case, the left-right) axis is specified by default. (Of course, specific molecular mechanisms must then carry out the pattern associated with that axis.)

In amniotes, the body axes are not fully established until later. In chicks, gravity apparently involved in establishing

the anterior-posterior axis as the egg travels down the oviduct in the hen before being laid. Later, pH differences between the two sides of the blastoderm cells establish the dorsal-ventral axis (see Figure 47.10). If the pH is artificially reversed above and below the blastoderm, the part facing the egg white will turn into the belly (ventral side) and the side facing the yolk will turn into the back (dorsal side), opposite to their normal fates. In mammals, no polarity is obvious until after cleavage, although recent research suggests that the orientation of the egg and sperm nuclei before their fusion may play a role in determining the axes.

Restriction of Cellular Potency

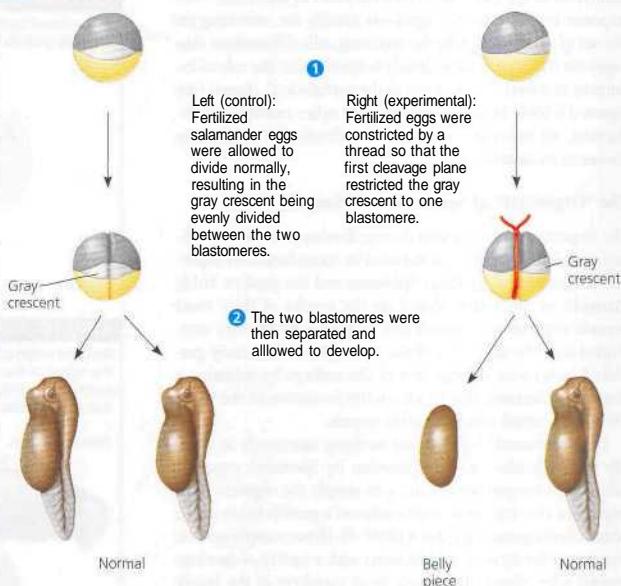

In many species that have cytoplasmic determinants, only the zygote is **totipotent**—that is, capable of developing into all the cell types found in the adult. In these organisms, the first cleavage is asymmetrical, with the two blastomeres receiving different cytoplasmic determinants. However, even in species that have cytoplasmic determinants, the first cleavage may occur along an axis that produces two identical blastomeres, which will have equal developmental potential. This is what happens in amphibians, for instance, as demonstrated in 1938 in an experiment by German zoologist Hans Spemann (Figure 47.24). Thus, the fates of embryonic cells can be affected not only by the distribution of cytoplasmic determinants but also by how their distribution is affected by the zygotes characteristic pattern of cleavage.

In contrast to many other animals, the cells of mammalian embryos remain totipotent until the 16-cell stage, when they become arranged into the precursors of the trophoblast and inner cell mass of the blastocyst. At this time, their different locations determine their fates. The early blastomeres of mammals seem to receive equivalent amounts of cytoplasmic components from the egg. Indeed, up to the 8-cell stage, the blastomeres of a mammalian embryo all look alike, and each can form a complete embryo if isolated.

Regardless of how similar or different early embryonic cells are in a particular species, the progressive restriction of potency is a general feature of development in all animals. In some species, the cells of the early gastrula retain the

Figure 47.24
Inquiry How does distribution of the gray crescent at the first cleavage affect the potency of the two daughter cells?

EXPERIMENT

capacity to give rise to more than one kind of cell, though they have lost their totipotency. If left alone, the dorsal ectoderm of an early amphibian gastrula will develop into a neural plate above the notochord. If the dorsal ectoderm is experimentally replaced with ectoderm from some other location in the same gastrula, the transplanted tissue will form a neural plate. If the same experiment is performed on a late-stage gastrula, however, the transplanted ectoderm will not respond to its new location and will not form a neural plate. In general, the tissue-specific fates of cells in a late gastrula are fixed. Even when they are manipulated experimentally, these cells usually give rise to the same types of cell as in the normal embryo, indicating that their fate is already sealed.

Cell Fate Determination and Pattern Formation by Inductive Signals

Once embryonic cell division creates cells that differ from each other, the cells begin to influence each other's fates by induction. At the molecular level, the effect of induction—the response to an inductive signal—is usually the switching on of a set of genes that make the receiving cells differentiate into a specific tissue. You have already learned about the role of induction in vulval development in the nematode *C. elegans* (see Figure 21.16b). Here we examine two other examples of induction, an essential process in the development of many tissues in most animals.

The "Organizer" of Spemann and Mangold

The importance of induction during development of amphibians was dramatically demonstrated in transplantation experiments performed by Hans Spemann and his student Hilde Mangold in the 1920s. Based on the results of their most famous experiment, summarized in Figure 47.25, they concluded that the dorsal lip of the blastopore in the early gastrula functions as an organizer of the embryo by initiating a chain of inductions that results in the formation of the notochord, the neural tube, and other organs.

Developmental biologists are working intensively to identify the molecular basis of induction by *Spemann's organizer* (also called the *gastrula organizer*, or simply the *organizer*). An important clue has come from studies of a growth factor called bone morphogenetic protein 4 (BMP-4). (Bone morphogenetic proteins, a family of related proteins with a variety of developmental roles, derive their name from members of the family that are important in bone formation.) Amphibian BMP-4 is active exclusively in cells on the ventral side of the gastrula, inducing these cells to travel down the pathway toward formation of ventral structures. One major function of the cells of the organizer seems to be to inactivate BMP-4 on the dorsal side of the embryo by producing proteins that bind to BMP-4, rendering it unable to signal. This, in turn, allows formation of dorsal structures such as the notochord and neural tube. Proteins related to BMP-4 and its inhibitors are also found in other animals, including invertebrates such as the fruit fly. The ubiquity of these molecules suggests that they evolved long ago and may participate in the development of many different organisms.

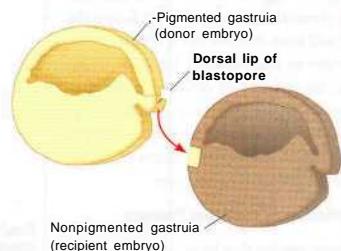

The induction that causes dorsal ectoderm to develop into the neural tube is only one of many cell-cell interactions that transform the three germ layers into organ systems. Many inductions seem to involve a sequence of inductive steps that progressively determine the fate of cells. For example, in the late gastrula of the frog, ectoderm cells destined to become the lenses of the eyes receive inductive signals from the ectodermal cells that will become the neural plate. Additional inductive signals probably come from endodermal cells and mesodermal cells. Finally, inductive signals from the optic cup, an outgrowth

Figure 47.25

In Vitro Can the dorsal lip of the blastopore induce cells in another part of the amphibian embryo to change their developmental fate?

EXPERIMENT

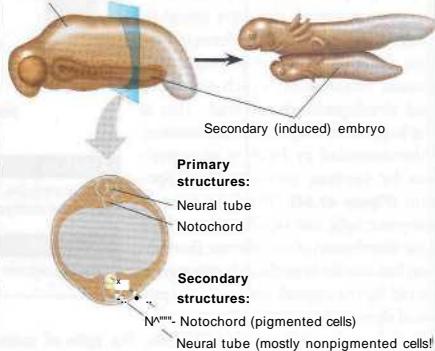

Spemann and Mangold transplanted a piece of the dorsal lip of a pigmented newt gastrula to the ventral side of the early gastrula of a nonpigmented newt.

RESULTS

During subsequent development, the recipient embryo formed a second notochord and neural tube in the region of the transplant, and eventually most of a second embryo. Examination of the interior of the double embryo revealed that the secondary structures were formed in part from host tissue.

Primary embryo

CONCLUSION

The transplanted dorsal lip was able to induce cells in a different region of the recipient to form structures different from their normal fate. In effect, the dorsal lip "organized" the later development of an entire embryo.

of the developing brain, complete the determination of the lens-forming cells.

Formation of the Vertebrate Limb

The action of the gastrula organizer is a classic example of induction, and we can see that the organizer induces cells to

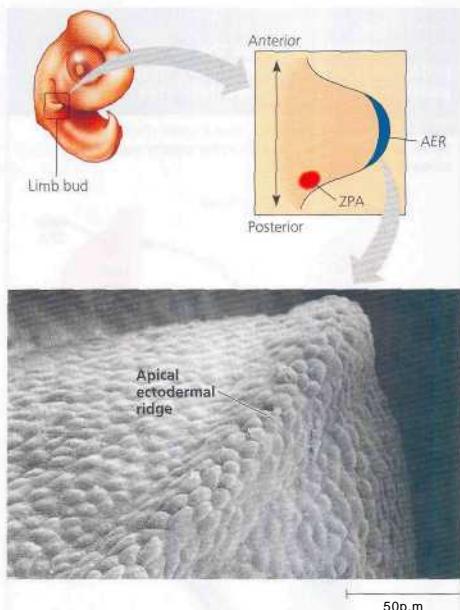

take on their fates in appropriate locations relative to each other. Thus, inductive signals play a major role in pattern formation—the development of an animal's spatial organization, the arrangement of organs and tissues in their characteristic places in three-dimensional space. The molecular cues that control pattern formation, called positional information, tell a cell where it is with respect to the animal's body axes and help to determine how the cell and its descendants respond to future molecular signals.

In Chapter 21, we discussed pattern formation in the development of the body segments of *Drosophila*. For understanding pattern formation in vertebrates, a classic model system has been limb development in the chick. The wings and legs of chicks, like all vertebrate limbs, begin as bumps of tissue called limb buds (Figure 47.26a). Each component of a chick limb, such as a specific bone or muscle, develops with a precise location and orientation relative to three axes: the proximal-distal axis (the "shoulder-to-fingertip" axis), the anterior-posterior axis (the "thumb-to-little finger" axis), and the dorsal-ventral axis (the "knuckle-to-palm" axis). The embryonic cells within a limb bud respond to positional information indicating location along these three axes (Figure 47.26b).

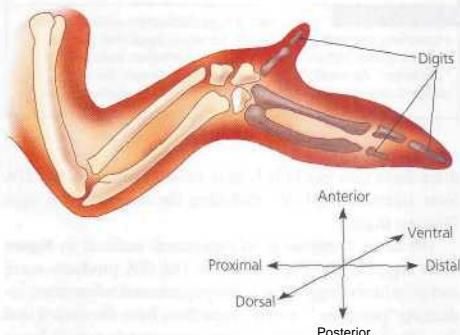

A limb bud consists of a core of mesodermal tissue covered by a layer of ectoderm. Two critical organizer regions in the limb bud have profound effects on the limb's development. These two organizer regions are present in all vertebrate limb buds, including those that will develop into forelimbs (such as wings or arms) and those destined to become hind limbs. The cells of these regions secrete proteins that provide key positional information to the other cells of the bud.

One limb-bud organizer region is the apical ectodermal ridge (AER), a thickened area of ectoderm at the tip of the bud (see Figure 47.26a). The AER is required for the outgrowth of the limb along the proximal-distal axis and for patterning along this axis. The cells of the AER produce several secreted protein signals, belonging to the fibroblast growth factor (FGF) family, that promote limb-bud outgrowth. If the AER is surgically removed and beads soaked with FGF are put in its place, a nearly normal limb will develop. The AER and other ectoderm of the limb bud also appear to guide pattern formation along the limb's dorsal-ventral axis. In experiments where the ectoderm of a limb bud, including the AER, is detached from the mesoderm and then replaced with us orientation rotated 180° back-to-front, the limb elements that form have reversed dorsal-ventral orientation. (This is equivalent to reversing the palm and back of your hand.)

The second major limb-bud organizer region is the zone of polarizing activity (ZPA), a block of mesodermal tissue located underneath the ectoderm where the posterior side of the bud is attached to the body (see Figure 47.26a). The ZPA is necessary for proper pattern formation along the anterior-posterior axis of the limb. Cells nearest the ZPA give rise to the posterior structures, such as the most posterior of the chick's

(a) Organizer regions. Vertebrate limbs develop from protrusions called limb buds, each consisting of mesoderm cells covered by a layer of ectoderm. Two regions, termed the apical ectodermal ridge (AER, shown in this SEM) and the zone of polarizing activity (ZPA), play key organizer roles in limb pattern formation.

(b) Wing of chick embryo. As the bud develops into a limb, a specific pattern of tissues emerges. In the chick wing, for example, the three digits are always present in the arrangement shown here. Pattern formation requires each embryonic cell to receive some kind of positional information indicating location along the three axes of the limb. The AER and ZPA secrete molecules that help provide this information.

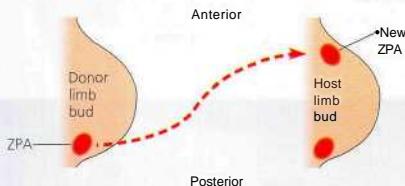

A Figure 47.26 Vertebrate limb development.

Figure 47.27

Inquiry What role does the zone of polarizing activity (ZPA) play in limb pattern formation in vertebrates?

EXPERIMENT

ZPA tissue from a donor chick embryo was transplanted under the ectoderm in the anterior margin of a recipient chick limb bud.

RESULTS

In the grafted host limb bud, extra digits developed from host tissue in a mirror-image arrangement to the normal digits, which also formed (see Figure 47.26b for a diagram of a normal chick wing).

CONCLUSION

The mirror-image duplication observed in this experiment suggests that ZPA cells secrete a signal that diffuses from its source and conveys positional information indicating "posterior." As the distance from the ZPA increases, the signal concentration decreases and hence more anterior digits develop.

three digiti (like our little finger); cells farthest from the ZPA form anterior structures, including the most anterior digit (like our thumb).

The tissue transplantation experiment outlined in **Figure 47.27** supports the hypothesis that the ZPA produces some sort of inductive signal that conveys positional information indicating "posterior." Indeed, researchers have discovered that the cells of the ZPA secrete an important protein growth factor called Sonic hedgehog.* If cells genetically engineered to produce large amounts of Sonic hedgehog are implanted in the anterior region of a normal limb bud, a mirror-image limb

* Sonic hedgehog gets its name from two sources, its similarity to a *Drosophila* protein called Hedgehog, which is involved in segmentation of the fly embryo, and a video game character.

results—just as if a ZPA had been grafted there. Evidence from studying the mouse version of Sonic hedgehog suggests that extra toes in mice—and perhaps also in humans—can result from the production of this protein in the wrong part of the limb bud.

We can conclude from experiments like these that pattern formation requires cells to receive and interpret environmental cues that vary from one location to another. These cues, acting together along three axes, tell cells where they are in the three-dimensional realm of a developing organ. In vertebrate limb development, for instance, we now know that specific proteins serve as some of these cues. In other words, organizer regions such as the AER and the ZPA function as signaling centers. Researchers have recently established that these two regions also interact with each other by way of signaling molecules and signaling pathways to influence each other's developmental fates. Such mutual signaling interactions between mesoderm and ectoderm also occur during formation of the neural tube and during development of many other tissues and organs.

What determines whether a limb bud develops into a forelimb or a hind limb? The cells receiving the signals from the AER and ZPA respond according to their developmental histories. Before the AER or ZPA issues its signals, earlier developmental signals have set up patterns of gene expression distinguishing the future forelimbs from the future hind limbs. These differences cause the limb-bud cells of the forelimb and hind limb to react differently to the same positional cues.

Thus, construction of the fully formed animal involves a sequence of events that include many steps of signaling and differentiation. Initial cell asymmetries allow different types of cells to influence each other to express specific sets of genes. The products of these genes then direct cells to differentiate into specific types. Coordinated with morphogenesis, various pathways of pattern formation occur in all the different parts of the developing embryo. These processes ultimately produce a complex arrangement of multiple tissues and organs, each functioning in the appropriate location to form a single coordinated organism.

Concept Check 47.3

1. Although there are three body axes, only two must be determined during early development. Why?
2. Predict what would happen if you transplanted tissue from the organizer region (above the dorsal lip) of a late-stage frog gastrula to its ventral side.
3. If the ventral cells of an early frog gastrula are experimentally induced to express a protein that inhibits BMP-4, could a second embryo develop? Explain.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 47.1

After fertilization, embryonic development proceeds through cleavage, gastrulation, and organogenesis

- **Fertilization** (pp. 988–991) Fertilization brings together the nuclei of sperm and egg, forming a diploid zygote, and activates the egg to initiate the onset of embryonic development. The acrosomal reaction, which is triggered when the sperm meets the egg, releases hydrolytic enzymes that digest material surrounding the egg. Gamete contact and/or fusion depolarizes the egg cell membrane and sets up a fast block to polyspermy in many animals. Sperm–egg fusion also initiates the cortical reaction, inducing a rise in Ca^{2+} that stimulates cortical granules to release their contents outside the egg. This forms a fertilization envelope that functions as a slow block to polyspermy. In mammalian fertilization, the cortical reaction modifies the zona pellucida as a slow block to polyspermy.

- **Cleavage** (pp. 992–994) Fertilization is followed by cleavage, a period of rapid cell division without growth, which results in the production of a large number of cells called blastomeres. Holoblastic cleavage, or division of the entire egg, occurs in species whose eggs have little or moderate amounts of yolk, such as sea urchins, frogs, and mammals. Meroblastic cleavage, incomplete division of the egg, occurs in species with yolk-rich eggs, such as birds and other reptiles. Cleavage planes usually follow a specific pattern relative to the animal and vegetal poles of the zygote. In many species, cleavage creates a multicellular ball called the blastula, which contains a fluid-filled cavity, the blastocoel.

Activity Sea Urchin Development

- **Gastrulation** (pp. 994–997) Gastrulation transforms the blastula into a gastrula, which has a primitive digestive cavity (the archenteron) and three embryonic germ layers: the ectoderm, mesoderm, and endoderm.

Investigation What Determines Cell Differentiation in the Sea Urchin?

- **Organogenesis** (pp. 997–999) The organs of the animal body develop from specific portions of the three embryonic germ layers. Early events in organogenesis in vertebrates include formation of the notochord by condensation of dorsal mesoderm, development of the neural tube from infolding of the ectodermal neural plate, and formation of the coelom from splitting of lateral mesoderm.

Activity Frog Development

► Developmental Adaptations of Amniotes (pp. 998–999)

The embryos of birds, other reptiles, and mammals develop within a fluid-filled sac that is contained within a shell or the uterus. In these organisms, the three germ layers give rise not only to embryonic tissue but also to the four extraembryonic membranes: the amnion, chorion, yolk sac, and allantois.

- **Mammalian Development** (pp. 999–1001) The eggs of placental mammals are small and store few nutrients. They exhibit holoblastic cleavage and show no obvious polarity. Gastrulation and organogenesis, however, resemble the processes in birds and other reptiles. After fertilization and early cleavage in the oviduct, the blastocyst implants in the uterus. The trophoblast initiates formation of the fetal portion of the placenta, and the embryo

proper develops from a single layer of cells, the epiblast, within the blastocyst. Extraembryonic membranes homologous to those of birds and other reptiles function in intrauterine development.

Concept 47.2

Morphogenesis in animals involves specific changes in cell shape, position, and adhesion

- **The Cytoskeleton, Cell Motility, and Convergent Extension** (pp. 1001–1002) Cytoskeletal rearrangements are responsible for changes in both the shape and position of cells. Both kinds of changes are involved in tissue invaginations, as occurs in gastrulation, for example. In convergent extension, cell movements cause a sheet of cells to become narrower and longer.

- **Roles of the Extracellular Matrix and Cell Adhesion Molecules** (pp. 1002–1003) Fibers of the extracellular matrix provide anchorage for cells and also help guide migrating cells toward their destinations. Fibronectin and other glycoproteins located on cell surfaces are important for cell migration and for holding cells together in tissues.

Concept 47.3

The developmental fate of cells depends on their history and on inductive signals

- **Eate Mapping** (p. 1004) Experimentally derived fate maps of embryos have shown that specific regions of the zygote or blastula develop into specific parts of older embryos.

- **Establishing Cellular Asymmetries** (pp. 1004–1005) In non-amniotic species, unevenly distributed cytoplasmic determinants in the egg cell are important in establishing the body axes and in setting up differences between the blastomeres resulting from cleavage of the zygote. Cells that receive different cytoplasmic determinants undergo different fates. In amniotes, local environmental differences play the major role in establishing initial differences between cells and later the body axes. As embryonic development proceeds, the potency of cells becomes progressively more limited in all species.

- **Cell Fate Determination and Pattern Formation by Inductive Signals** (pp. 1006–1008) Cells in a developing embryo receive and interpret positional information that varies with location. This information is often in the form of signal molecules secreted by cells in special “organizer” regions of the embryo, such as the dorsal lip of the blastopore in the amphibian gastrula and the AER and ZPA of the vertebrate limb bud. The signal molecules influence gene expression in the cells that receive them, leading to differentiation and the development of particular structures.

TESTING YOUR KNOWLEDGE

Evolution Connection

Evolution in insects and vertebrates has involved the repeated duplication of body segments, followed by fusion of some segments and specialization of their structure and function. What parts of vertebrate anatomy reflect the vertebrate segmentation pattern? Can you guess what vertebrate body part is a product of segment fusion and specialization?

Scientific Inquiry

The "snout" of a frog tadpole bears a sucker. A salamander tadpole has a mustache-shaped structure called a balancer in the same area. You perform an experiment in which you transplant ectoderm from the side of a young salamander embryo to the snout of a frog embryo. You find that the tadpole that develops has a balancer. When you transplant ectoderm from the side of a slightly older salamander embryo to the snout of a frog embryo, the frog tadpole ends up with a patch of salamander skin on its snout. Suggest a hypothesis to explain the results of this experiment in terms of the mechanisms of development. How might you test your hypothesis?

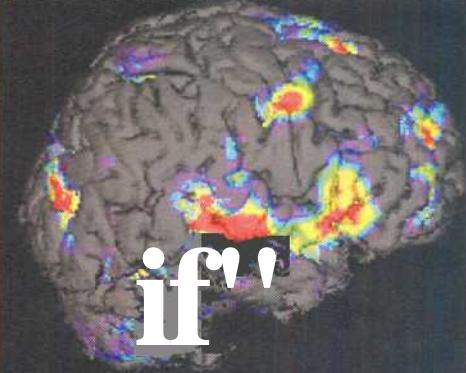

Investigation *What Determines Cell Differentiation in the Sea Urchin?*

Science, Technology, and Society

Many scientists believe that fetal tissue transplants offer great potential for treating Parkinson's disease, epilepsy, diabetes, Alzheimer's disease, and spinal cord injuries. Why might tissues from a fetus be particularly useful for replacing diseased or damaged cells in such conditions? Some people would allow only tissues from miscarriages to be used in fetal transplant research. But most researchers prefer to use tissues from surgically aborted fetuses. Why? What is your position on this controversial issue, and why?

Nervous Systems

A Figure 48.1 A functional magnetic resonance image of brain areas activated during language processing.

Key Concepts

- 4B.1 Nervous systems consist of circuits of neurons and supporting cells
- 4B.2 Ion pumps and ion channels maintain the resting potential of a neuron
- 43.3 Action potentials are the signals conducted by axons
- 48.4 Neurons communicate with other cells at synapses
- 48.5 The vertebrate nervous system is regionally specialized
- 48.6 The cerebral cortex controls voluntary movement and cognitive functions
- 48.7 CNS injuries and diseases are the focus of much research

Overview

Command and Control Center

What happens in your brain when you picture something with your "mind's eye"? Until recently, scientists had little hope of answering that question. The human brain contains an estimated 10^{11} (100 billion) nerve cells, or neurons. Each neuron may communicate with thousands of other neurons in complex information-processing circuits that make the most powerful electronic computers look primitive. An engineer who wants to learn how a computer functions can just open the computer's housing and trace the circuits. But except for rare glimpses (such as during brain surgery), the circuitry of the living human brain has been hidden from view.

That's no longer the case, however, thanks in part to recent technologies that can record brain activity from outside a person's skull. One technique is functional magnetic resonance imaging (**fMRI**). During fMRI, a subject lies with his or her head in the hole of a large, doughnut-shaped magnet that records increased blood flow in brain areas with active neurons. A computer then uses the data to construct a three-dimensional map of the subject's brain activity, like the one shown in **Figure 48.1**. These recordings can be made while the subject is doing various tasks, such as speaking, moving a hand, looking at pictures, or forming a mental image of an object or a person's face.

The results of brain imaging and other research methods, such as those described by Erich Jarvis in the interview on pages 818–819, reveal that groups of neurons function in specialized circuits dedicated to different tasks. These circuits are responsible for the feats of sensing and moving (see Chapter 49) and for the many types of animal behavior (see Chapter 51).

The ability to sense and react originated billions of years ago with prokaryotes that could detect changes in their environment and respond in ways that enhanced their survival and reproductive success—for example, locating food sources by chemotaxis (see Chapter 27). Later modification of this simple process provided multicellular organisms with a mechanism for communication between cells of the body. By the time of the Cambrian explosion more than 500 million years ago (see Chapter 32), systems of neurons that allowed animals to sense and move rapidly had evolved in essentially their present-day forms.

In this chapter, we will discuss the organization of animal nervous systems and the mechanisms by which neurons transmit information. We'll also investigate some of the functions performed by specific parts of the vertebrate

brain. Finally, we'll examine several mental illnesses and neurological disorders that are the subject of intense research today.

Concept 48.1

Nervous systems consist of circuits of neurons and supporting cells

All animals except the sponges have some type of nervous system. What distinguishes the nervous systems of different animal groups is not so much their basic building blocks—the neurons themselves—but how the neurons are organized into circuits.

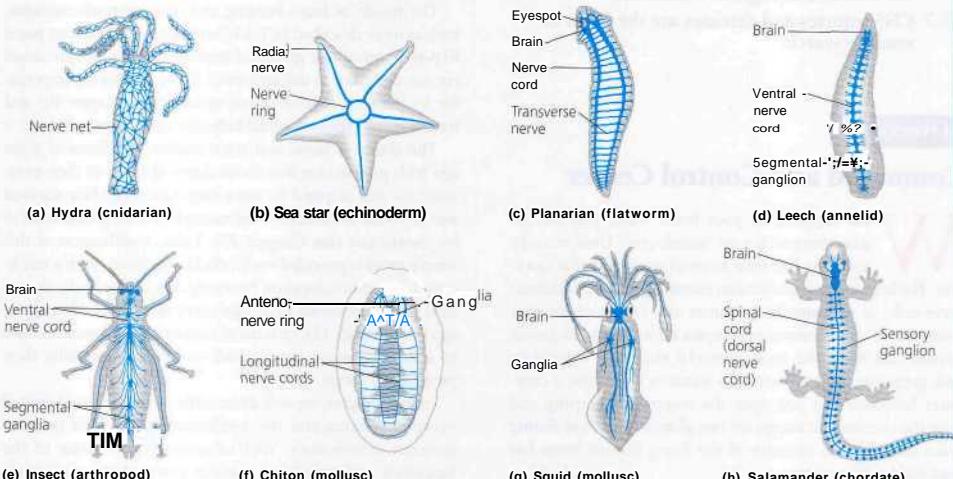

Organization of Nervous Systems

The simplest animals with nervous systems, the cnidarians, have radially symmetrical bodies organized around a gastrovascular cavity (see Figure 33.5). In some cnidarians, such as the hydra shown in **Figure 48.2a**, the neurons controlling the contraction and expansion of the gastrovascular cavity are arranged in diffuse nerve nets. The nervous systems of more complex animals contain nerve nets as well as nerves, which are bundles of fiberlike extensions of neurons. For example, sea stars have a nerve net in each arm, connected by radial nerves to a central nerve ring (**Figure 48.2b**); this organization

is better suited than a diffuse nerve net for controlling more complex movements.

Greater complexity of nervous systems and more complex behavior evolved with cephalization, which included the clustering of neurons in a brain near the anterior (front) end in animals with elongated, bilaterally symmetrical bodies. In flatworms, such as the planarian shown in **Figure 48.2c**, a small brain and longitudinal nerve cords constitute the simplest clearly defined central nervous system (CNS). In more complex invertebrates, such as annelids (**Figure 48.2d**) and arthropods (**Figure 48.2e**), behavior is regulated by more complicated brains and ventral nerve cords containing segmentally arranged clusters of neurons called ganglia (singular *ganglion*). Nerves that connect the CNS with the rest of an animal's body make up the peripheral nervous system (PNS).

Molluscs are good examples of how nervous system organization correlates with an animal's lifestyle. Sessile or slow-moving molluscs such as clams and chitons have little or no cephalization and relatively simple sense organs (**Figure 48.2f**). In contrast, cephalopod molluscs (squids and octopuses) have the most sophisticated nervous systems of any invertebrates, rivaling even those of some vertebrates. The large brain of cephalopods, accompanied by large, image-forming eyes and rapid signaling along nerves, supports the active, predatory life of these animals (**Figure 48.2g**). Researchers have demonstrated that octopuses can learn to discriminate among visual patterns and can perform complex tasks. In vertebrates, the CNS consists of the brain and the spinal cord, which runs along the dorsal (back) side of the body; nerves and ganglia

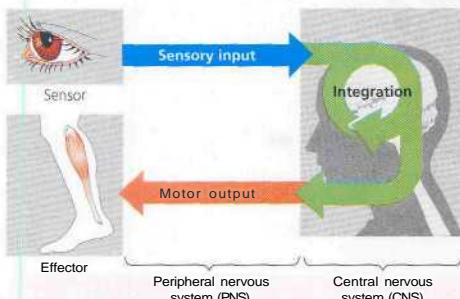

A **Figure 48.2** Organization of some nervous systems.

comprise the PNS (**Figure 48.2h**). We will examine the vertebrate nervous system in more detail later in this chapter.

Information Processing

In general, there are three stages in the processing of information by nervous systems: sensory input, integration, and motor output (**Figure 48.3**). These three stages are handled by

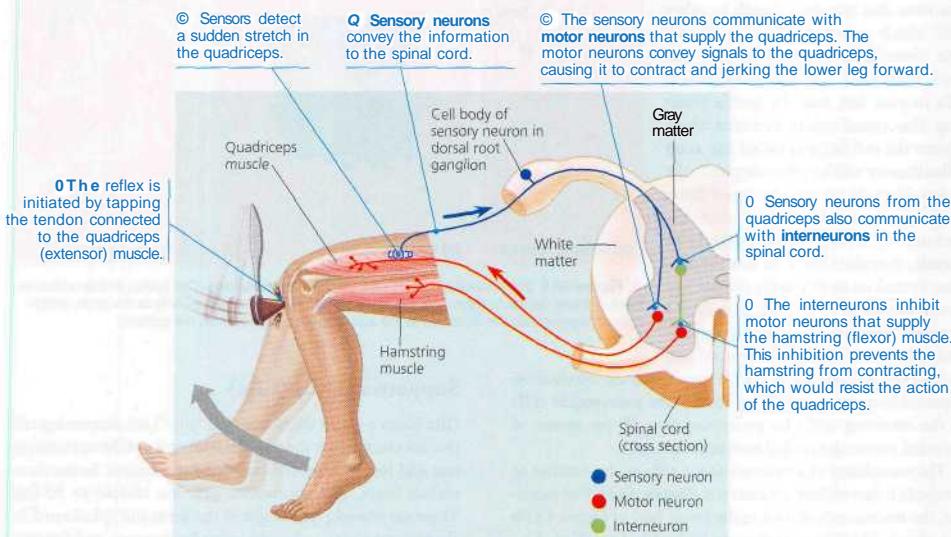

A Figure 48.3 Overview of information processing by nervous systems.

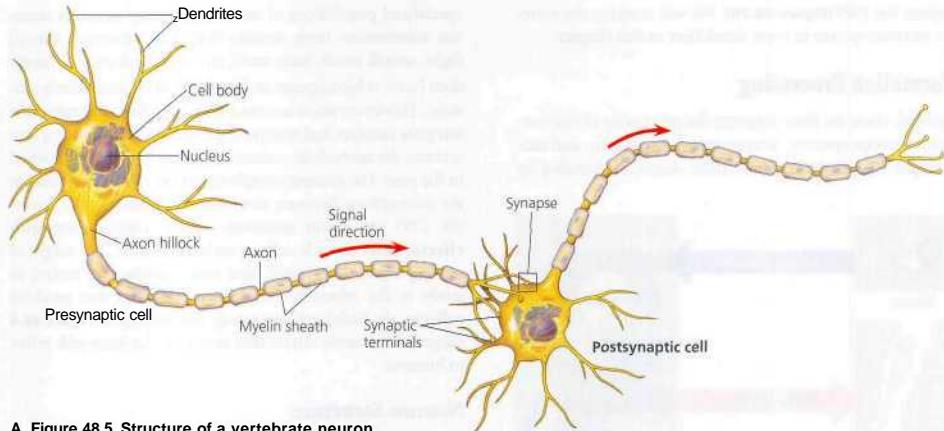

specialized populations of neurons. Sensory neurons transmit information from sensors that detect external stimuli (light, sound, touch, heat, smell, and taste) and internal conditions (such as blood pressure, blood CO₂ level, and muscle tension). This information is sent to the CNS, where interneurons integrate (analyze and interpret) the sensory input, taking into account the immediate context as well as what has happened in the past. The greatest complexity in neural circuits exists in the connections between interneurons. Motor output leaves the CNS via motor neurons, which communicate with effector cells (muscle cells or endocrine cells). The stages of sensory input, integration, and motor output are easiest to study in the relatively simple nerve circuits that produce reflexes, the body's automatic responses to stimuli. **Figure 48.4** diagrams the nerve circuit that underlies the knee-jerk reflex in humans.

Neuron Structure

As you read in Chapter 1, one of the major themes of biology is that form fits function. This theme, which applies at all levels from molecules to organisms, is clearly illustrated at the cellular level by neurons. The ability of neurons to receive and transmit information depends on their elaborate structure. Most of a neuron's organelles, including its nucleus,

k Figure 48.4 The knee-jerk reflex. Many neurons are involved in the reflex, but for simplicity, only one neuron of each type is shown.

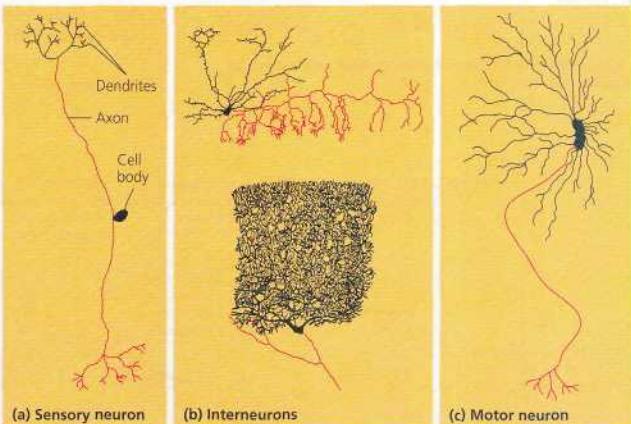

A Figure 48.5 Structure of a vertebrate neuron.

are located in the **cell body** (Figure 48.5). Arising from the cell body are two types of extensions: numerous **dendrites** (from the Greek *dendron*, tree) are highly branched extensions that receive signals from other neurons. The **axon** is typically a much longer extension that transmits signals to other cells, which may be neurons or effector cells. Some axons, such as the ones that reach from your spinal cord to muscle cells in your feet, may be over a meter long. The conical region of an axon where it joins the cell body is called the **axon hillock**; as we will see, this is typically the region where the signals that travel down the axon are generated. Many axons are enclosed by a layer called the **myelin sheath**, described later in this section. Near its end, an axon usually divides into several branches, each of which ends in a

synaptic terminal. The site of communication between a synaptic terminal and another cell is called a **synapse**. At most synapses, information is passed from the transmitting neuron (the **presynaptic cell**) to the receiving cell (the **postsynaptic cell**) by means of chemical messengers called **neurotransmitters**.

The complexity of a neuron's shape reflects the number of synapses it has with other neurons (Figure 48.6). For example, the interneuron shown in the lower part of Figure 48.6 has about 100,000 synapses on its highly branched dendrites, whereas neurons with simpler dendrites have far fewer synapses.

A Figure 48.6 Structural diversity of vertebrate neurons. Cell bodies and dendrites are black in these diagrams; axons are red. In (a), the cell body is connected only to the axon, which conveys signals from the dendrites to the axon's terminal branches (at the bottom).

Supporting Cells (Glia)

Glia (from a Greek word meaning "glue") are supporting cells that are essential for the structural integrity of the nervous system and for the normal functioning of neurons. In the mammalian brain, glia outnumber neurons 10-fold to 50-fold. There are several types of glia in the brain and spinal cord, including astrocytes, radial glia, oligodendrocytes, and Schwann cells. As a group, these cells do much more than just hold neurons together.

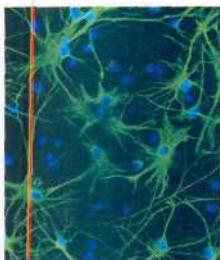

Figure 48.7 Astrocytes. In this section through a mammalian cerebral cortex, astrocytes appear green after being labeled with a fluorescent antibody (LM). The blue dots are cell nuclei, labeled with a different antibody. The term "astrocyte" refers to the star-like shape of the cells.

In the CNS, astrocytes provide structural support for neurons and regulate the extracellular concentrations of ions and neurotransmitters (Figure 48.7). Some astrocytes respond to activity in neighboring neurons by facilitating information transfer at those neurons' synapses. Scientists hypothesize that this facilitation may be part of the cellular mechanism of learning and memory. Astrocytes adjacent to active neurons also cause nearby blood vessels to dilate, which increases blood flow to the area, enabling the neurons to obtain oxygen and glucose more quickly. During development, astrocytes induce the formation of tight junctions (see Figure 6.31) between cells that line the capillaries in the brain and spinal cord. The result is the blood-brain barrier, which restricts the passage of most substances into the CNS, allowing the extracellular chemical environment of the CNS to be tightly controlled.

In an embryo, radial glia form tracks along which newly formed neurons migrate from the neural tube, the structure that gives rise to the CNS (see Figures 47.14 and 47.15). Both radial glia and astrocytes can also act as stem cells, generating neurons and other glia. Researchers view these multipotent precursors as a potential way to replace neurons and glia that are lost to injury or disease, a topic explored in Concept 48.7.

Oligodendrocytes (in the CNS) and Schwann cells (in the PNS) are glia that form the myelin sheaths around the axons of many vertebrate neurons. The structure of a myelinated PNS axon is shown in Figure 48.8. Neurons become myelinated

during development when Schwann cells or oligodendrocytes grow around axons, wrapping them in many layers of membrane, somewhat like a jelly roll. These membranes are mostly lipid, which is a poor conductor of electrical currents. Thus, the myelin sheath provides electrical insulation of the axon, analogous to plastic insulation that covers many electrical wires. In the disease multiple sclerosis, myelin sheaths gradually deteriorate, resulting in a progressive loss of body function due to the disruption of nerve signal transmission.

Concept Check 48.1

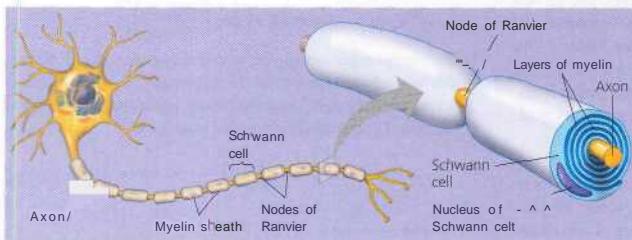

1. a. Arrange the following neurons in the correct sequence for information flow during the knee-jerk reflex: interneuron, sensory neuron, motor neuron.
b. Which of the neuron types is located entirely within the CNS?
2. Would severing a neuron's axon stop the neuron from receiving or from transmitting information? Explain.
3. What would be the most obvious structural abnormality in the nervous system of a mouse lacking oligodendrocytes?

For suggested answers, see Appendix A.

Concept 48.2

Ion pumps and ion channels maintain the resting potential of a neuron

We noted in Chapter 7 that all cells have an electrical potential difference (voltage) across their plasma membrane. This voltage is called the membrane potential. In neurons, the membrane potential is typically between -60 and -80 mV (millivolts) when the cell is not transmitting signals. The minus

A Figure 48.8 Schwann cells and the myelin sheath. In the PNS, glia called Schwann cells wrap themselves around axons, forming layers of myelin. Gaps between adjacent Schwann cells are called nodes of Ranvier. The TEM shows a cross section through a myelinated axon.

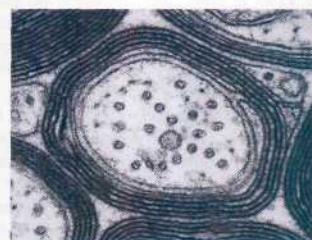

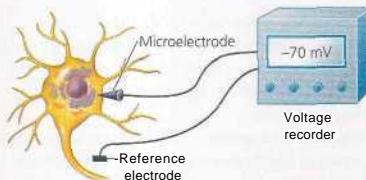

Figure 48.9
Research Method **Intracellular Recording**

APPLICATION

Electrophysiologists use intracellular recording to measure the membrane potential of neurons and other cells.

TECHNIQUE

A microelectrode is made from a glass capillary tube filled with an electrically conductive salt solution. One end of the tube tapers to an extremely fine tip (diameter < 1 μm). While looking through a microscope, the experimenter uses a micropositioner to insert the tip of the microelectrode into a cell. A voltage recorder (usually an oscilloscope or a computer-based system) measures the voltage between the microelectrode tip inside the cell and a reference electrode placed in the solution outside the cell.

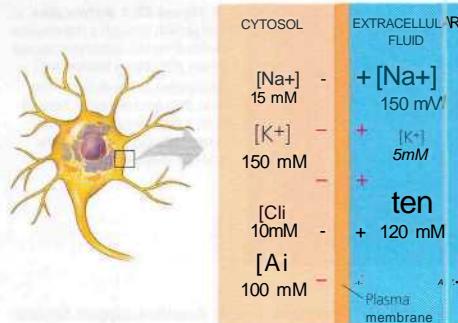

sign indicates that the inside of the cell is negative relative to the outside. **Figure 48.9** explains how electrophysiologists measure a cell's membrane potential.

The Resting Potential

The membrane potential of a neuron that is not transmitting signals is called the resting potential. In all neurons, the resting potential depends on the ionic gradients that exist across the plasma membrane (**Figure 48.10**). In mammals, for example, the extracellular fluid has a sodium ion (Na^+) concentration of 150 millimolar (mM) and a potassium ion (K^+) concentration of 5 mM (1 millimolar = 1 millimole/liter = 10^{-3} mol/L). In the cytosol, the Na^+ concentration is 15 mM and the K^+ concentration is 150 mM. Thus, the Na^+ concentration gradient, expressed as the ratio of outside concentration/inside concentration, is 150/15, or 10. The K^+ concentration gradient is 5/150, or 1/30. (There are also anion gradients, but we will ignore them for the moment.) The Na^+ and K^+ gradients are maintained by the sodium-potassium pump (see Figure 7.16). The fact that the gradients are responsible for the resting potential is shown by a simple experiment: If the pump is disabled by the addition of a specific poison, the gradients gradually disappear, and so does the resting potential.

It is particularly challenging to understand how the resting potential arises from ionic gradients, but it is an essential step in learning how neurons, including our own, work. We start with a model of a mammalian neuron consisting of two chambers separated by an artificial membrane (**Figure 48.11a**). The membrane contains many ion channels (see Chapter 7) that allow only K^+ to diffuse across the membrane. To produce a con-

A Figure 48.10 Ionic gradients across the plasma membrane of a mammalian neuron. The concentrations of Na^+ and Cl^- are higher in the extracellular fluid than in the cytosol. The reverse is true for K^+ . The cytosol also contains a variety of organic anions [A^-], including charged amino acids.

centration gradient for K^+ like that of a mammalian neuron, we add 150 mM potassium chloride (KCl) to the inner chamber and 5 mM KCl to the outer chamber. Like any solute, K^+ tends to diffuse down its concentration gradient, from an area of higher concentration (inner chamber) to an area of lower concentration (outer chamber). But because the channels are selective for K^+ , chloride ions (Cl^-) cannot cross the membrane. As a result, a separation of charge (voltage) develops across the membrane, with an excess of negative charge on the side of the membrane facing the inner chamber. The developing membrane voltage opposes the efflux of K^+ because the excess negative charges attract the positively charged K^+ . Thus, an electrical gradient builds up whose direction is opposite that of the concentration gradient. When the electrical gradient exactly balances the concentration gradient, an equilibrium is established. At equilibrium, there is no net diffusion of K^+ across the membrane.*

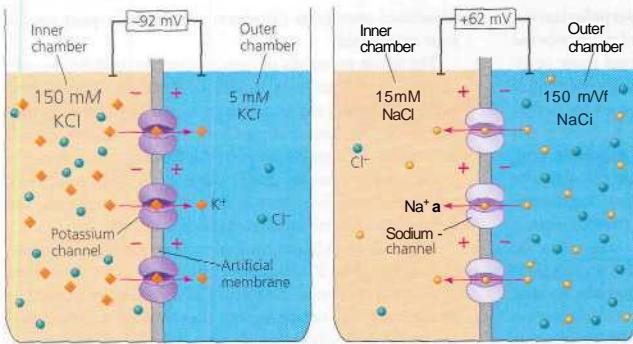

The magnitude of the membrane voltage at equilibrium, called the equilibrium potential (E_{ion}), is given by a formula called the Nernst equation. For an ion with a net charge of +1, such as K^+ , at 37°C, the Nernst equation is

$$E_{\text{K}} = 62 \text{ mV} \left(\log \frac{[\text{ion}]_{\text{outside}}}{[\text{ion}]_{\text{inside}}} \right)$$

The Nernst equation applies to any membrane that is permeable to a single type of ion. In our model, the membrane is permeable only to K^+ , and the Nernst equation can be used to calculate E_{K} , the equilibrium potential for K^+ :

$$E_{\text{K}} = 62 \text{ mV} \log \frac{5 \text{ mM}}{150 \text{ mM}} = -92 \text{ mV} (\text{at } 37^\circ\text{C})$$

* The charge separation needed to generate the resting potential is extremely small: about 10^{-12} mol/cm² of membrane. Thus, the ionic diffusion that leads to the resting potential does not appreciably change the ion concentrations on either side of the membrane.

(a) Membrane selectively permeable to K^+ (b) Membrane selectively permeable to Na^+

-4 Figure 48.11 Modeling a mammalian neuron. Each beaker is divided into two chambers by an artificial membrane. (a) The membrane is selectively permeable to K^+ , and the inner chamber contains a 30-fold higher concentration of K^+ than the outer chamber; at equilibrium, the inside of the membrane is -92 mV relative to the outside; (b) The membrane is selectively permeable to Na^+ , and the inner chamber contains a ten-fold lower concentration of Na^+ than the outer chamber; at equilibrium, the inside of the membrane is +62 mV relative to the outside.

The minus sign indicates that with this K^+ concentration gradient, K^+ is at equilibrium when the inside of the membrane is 92 mV more negative than the outside.

Now imagine that we change OUT model neuron by using a membrane that contains ion channels selective for Na^+ (**Figure 48.11b**). We also replace the contents of the chambers to produce a concentration gradient for Na^+ like that of a "mammalian neuron": 15 mM sodium chloride (NaCl) in the inner chamber and 150 mM NaCl in the outer chamber. Under these conditions, the Nernst equation can be used to calculate E_{Na} , the equilibrium potential for Na^+ :

$$E_{Na} = 62 \text{ mV} \left(\log \frac{150 \text{ mM}}{15 \text{ mM}} \right) - +62 \text{ mV} (\text{at } 37^\circ\text{C})$$

The plus sign indicates that with this Na^+ concentration gradient, Na^+ is at equilibrium when the inside of the membrane is 62 mV more positive than the outside.

How does a real mammalian neuron differ from these model neurons? The plasma membrane of a real neuron at rest has many potassium channels that are open, but it also has a relatively small number of open sodium channels. Consequently the resting potential is around -60 to -80 mV between E_K and E_{Na} . Because neither K^+ nor Na^+ is at equilibrium, there is a net flow of each ion (a current) across the membrane at rest. The resting potential remains steady, which means that the K^+ and Na^+ currents are equal and opposite. The reason the resting potential is closer to E_K than to E_{Na} is that the membrane is more permeable to K^+ than to Na^+ . If something causes the membrane's permeability to Na^+ to increase, the membrane potential will move toward E_{Na} and away from E_K . This is the basis of nearly all electrical signals in the nervous system: The membrane potential can change from its resting value when the membrane's permeability to particular ions changes. Sodium and potassium ions play major roles, but there are also important roles for chloride (Cl^-) and calcium (Ca^{2+}) ions; they follow the same rules (as described by the Nernst equation).

Gated Ion Channels

The resting potential results from the diffusion of K^+ and Na^+ through ion channels that are always open; these channels are said to be *ungated*. Neurons also have gated ion channels, which open or close in response to one of three kinds of stimuli. Stretch-gated ion channels are found in cells that sense stretch (see Figure 48.4) and open when the membrane is mechanically deformed. Ligand-gated ion channels are found at synapses and open or close when a specific chemical, such as a neurotransmitter, binds to the channel. Voltage-gated ion channels are found in axons (and in the dendrites and cell body of some neurons, as well as in some other types of cells) and open or close when the membrane potential changes. As we'll explain in the next section, gated ion channels are responsible for generating the signals of the nervous system.

Concept Check 48.2

- What is the equilibrium potential (E_x) at 37°C for an ion X^+ if $[X^+]_{\text{outside}} = 10 \text{ mM}$ and $[X^+]_{\text{inside}} = 100 \text{ mM}$?
- Suppose a cell's membrane potential shifts from -70 mV to -50 mV. What changes in the cell's permeability to K^+ or Na^+ could cause such a shift?
- Contrast ligand-gated and voltage-gated ion channels in terms of the stimuli that open them.

For suggested answers, see Appendix A.

Concept 48.3

Action potentials are the signals conducted by axons

If a cell has gated ion channels, its membrane potential may change in response to stimuli that open or close those

channels. Some such stimuli trigger a hyperpolarization (**Figure 48.12a**), an increase in the magnitude of the membrane potential (the inside of the membrane becomes more negative). Hyperpolarizations may be caused by the opening of gated K⁺ channels, which increases the membrane's permeability to K⁺ and causes the potential to approach E_K (~−92 mV at 37°C). Other stimuli trigger a depolarization (**Figure 48.12b**), a reduction in the magnitude of the membrane potential (the inside of the membrane becomes less negative). Depolarizations may be due to the opening of gated Na⁺ channels, which increases the membranes permeability to Na⁺ and causes the potential to approach E_{Na} (+62 mV at 37°C). These changes in membrane potential are called graded potentials because the magnitude of the hyperpolarization or depolarization varies with the strength of the stimulus: A larger stimulus causes a larger change in permeability and thus a larger change in the membrane potential.

Production of Action Potentials

In most neurons, depolarizations are graded only up to a certain membrane voltage, called the threshold. A stimulus strong enough to produce a depolarization that reaches the threshold triggers a different type of response, called an action potential (**Figure 48.12c**). An action potential is an all-or-none phenomenon: Once triggered, it has a magnitude that is independent of the strength of the triggering stimulus. Action potentials are the signals that carry information along axons,

sometimes over great distances, such as from your toes to your spinal cord.

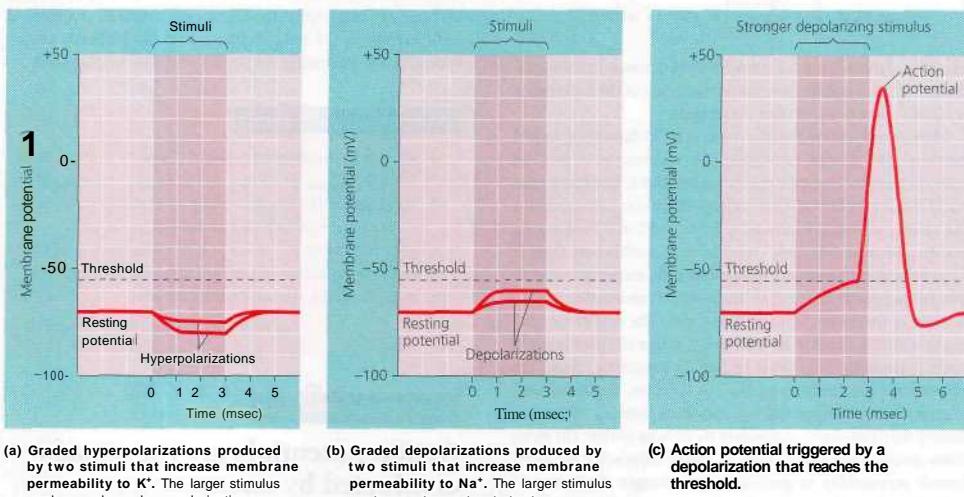

The action potentials of most neurons are very brief—only about 1–2 milliseconds (msec) in duration. Having brief action potentials enables a neuron to produce them at a high frequency. This feature is significant because neurons encode information in their action potential frequency. For example, in the sensory neurons that function in the knee-jerk reflex, action potential frequency is related to the magnitude and suddenness of stretch in the quadriceps muscle.

As **Figure 48.13** illustrates, both voltage-gated Na⁺ channels and voltage-gated K⁺ channels are involved in the production of an action potential. Both types of channels are opened by depolarizing the membrane, but they respond independently and sequentially: Na⁺ channels open before K⁺ channels.

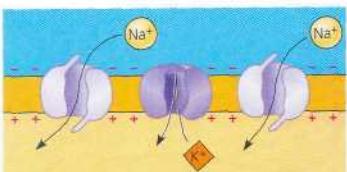

Each voltage-gated Na⁺ channel has two gates, an activation gate and an inactivation gate, and both must be open for Na⁺ to diffuse through the channel. © At the resting potential, the activation gate is closed and the inactivation gate is open on most Na⁺ channels. Depolarization of the membrane rapidly opens the activation gate and slowly closes the inactivation gate.

Each voltage-gated K⁺ channel has just one gate, an activation gate. At the resting potential, the activation gate on most K⁺ channels is closed. Depolarization of the membrane slowly opens the K⁺ channel's activation gate.

How do these channel properties contribute to the production of an action potential? © When a stimulus depolarizes the

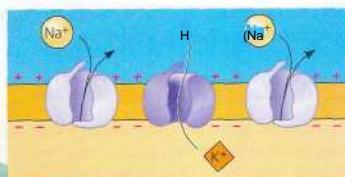

A **Figure 48.12** Graded potentials and an action potential in a neuron.

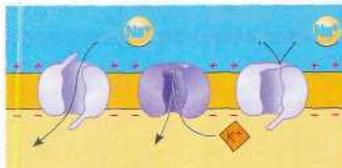

3] Rising phase of the action potential

Depolarization opens the activation gates on most Na^+ channels, while the K^+ channels' activation gates remain closed. Na^+ influx makes the inside of the membrane positive with respect to the outside.

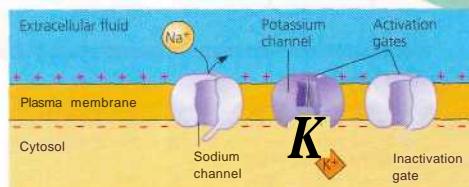

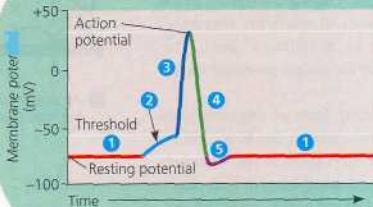

4] Falling phase of the action potential

The inactivation gates on most Na^+ channels close, blocking Na^+ influx. The activation gates on most K^+ channels open, permitting K^+ efflux which again makes the inside of the cell negative.

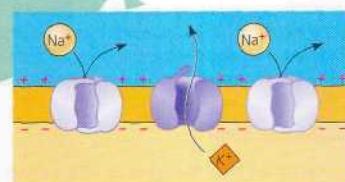

2] Depolarization

A stimulus opens the activation gates on some Na^+ channels. Na^+ influx through those channels depolarizes the membrane. If the depolarization reaches the threshold, it triggers an action potential.

[223 EHB 39] Activation gates on the Na^+ and K^+ channels are closed, and the membrane's resting potential is maintained.

5] EffiSSEG31 Both gates of the Na^+ channels are closed, but the activation gates on some K^+ channels are still open. As these gates close on most K^+ channels, and the inactivation gates open on Na^+ channels, the membrane returns to its resting state.

A Figure 48.13 The role of voltage-gated ion channels in the generation of an action potential. The circled numbers on the graph in the center and the colors of the action potential phases correspond to the five diagrams showing voltage-gated Na^+ and K^+ channels in a neuron's plasma membrane. (Ungated ion channels are not illustrated.)

nembrane, the activation gates on some Na^+ channels open, allowing more Na^+ to diffuse into the cell. The Na^+ influx causes further depolarization, which opens the activation gates on still more Na^+ channels, allowing even more Na^+ to diffuse into the cell, and so on. Once the threshold is crossed, this positive feedback cycle rapidly brings the membrane potential close to E_{Na} during the *rising phase*. However, two events prevent the membrane potential from actually reaching E_{Na} : (a) The inactivation gates on most Na^+ channels close, halting Na^+ influx; and (b) the activation gates on most K^+ channels open, causing a rapid efflux of K^+ . Both events quickly bring the membrane

potential back toward E_K during the *falling phase*. In fact, in the final phase of an action potential, called the *undershoot*, the membrane's permeability to K^+ is higher than at rest, so the membrane potential is closer to E_K than it is at the resting potential. The K^+ channels' activation gates eventually close, and the membrane potential returns to the resting potential.

The Na^+ channels' inactivation gates remain closed during the falling phase and the early part of the undershoot. As a result, if a second depolarizing stimulus occurs during this period, it will be unable to trigger an action potential. The "downtime" following an action potential when a second action

potential cannot be initiated is called the refractory period. This interval sets a limit on the maximum frequency at which action potentials can be generated.

Conduction of Action Potentials

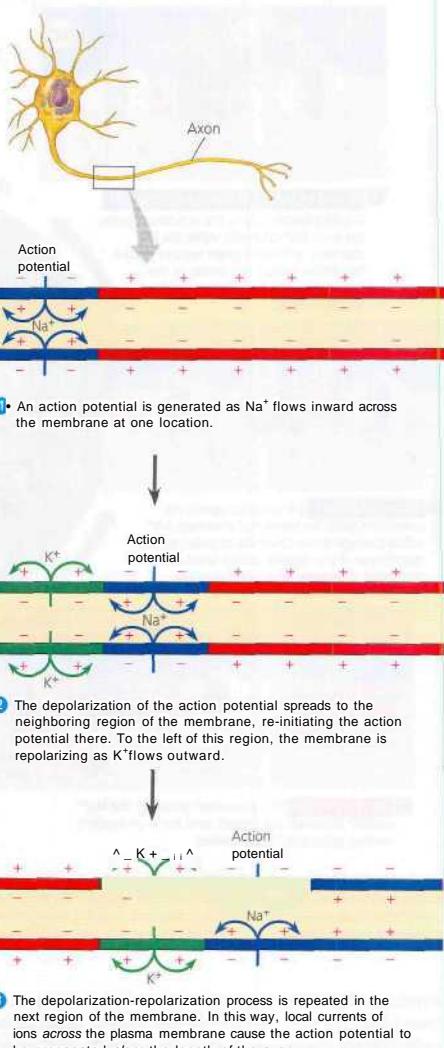

For an action potential to function as a long-distance signal, it must travel without diminishing from the cell body to the synaptic terminals. It does so by regenerating itself along the axon. At the site where an action potential is initiated (usually the axon hillock), Na^+ influx during the rising phase creates an electrical current that depolarizes the neighboring region of the axon membrane (**Figure 48.14**). The depolarization in the neighboring region is large enough to reach the threshold, causing the action potential to be re-initiated there. This process is repeated many times as the action potential travels the length of the axon.

Immediately behind the traveling zone of depolarization due to Na^+ influx is a zone of repolarization due to K^+ efflux. In the repolarized zone, the activation gates of Na^+ channels are still closed. Consequently, the inward current that depolarizes the axon membrane *ahead* of the action potential cannot produce another action potential *behind* it. This prevents action potentials from traveling back toward the cell body. Thus, once an action potential starts, it normally moves in only one direction—toward the synaptic terminals.

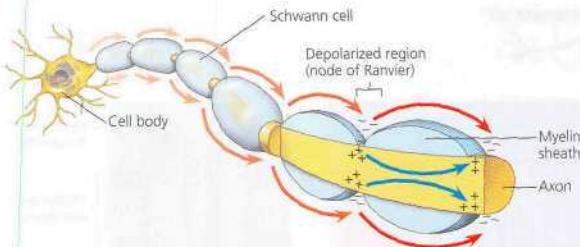

Conduction Speed

Several factors affect the speed at which action potentials are conducted. One factor is the diameter of the axon: The larger (wider) the axon's diameter, the faster the conduction. This is because resistance to the flow of electrical current is inversely proportional to the cross-sectional area of a conductor (such as a wire or an axon). As an analogy, think about how a wide hose offers less resistance to the flow of water than a narrow hose does. Similarly a wide axon provides less resistance to the depolarizing current associated with an action potential than a narrow axon does. Hence, the resulting depolarization can spread farther along the interior of a wide axon, bringing more distant regions of the membrane to the threshold sooner. In invertebrates, conduction speed varies from several centimeters per second in very narrow axons to about 100 m/sec in the giant axons of squids and some arthropods. These giant axons function in behavioral responses requiring great speed, such as the backward tail-flip that enables a lobster or crayfish to escape from a predator.

A different means of increasing the conduction speed of action potentials has evolved in vertebrates. Recall that many vertebrate axons are surrounded by a myelin sheath (see Figure 48.8). Myelin increases the conduction speed of action potentials by insulating the axon membrane. Insulation has

A Figure 48.14 Conduction of an action potential. The three parts of this figure show events that occur in an axon at three successive times as an action potential passes from left to right. At each point along the axon, voltage-gated ion channels go through the sequence of changes described in Figure 48.13. The colors of membrane regions shown here correspond to the action potential phases in Figure 48.13.

► Figure 48.15 Saltatory conduction. In a myelinated axon, the depolarizing current during an action potential at one node of Ranvier spreads along the interior of the axon to the next node (blue arrows), where it re-initiates itself. Thus, the action potential jumps from node to node as it travels along the axon (red arrows).

the same effect as increasing the axon's diameter: It causes the depolarizing current associated with an action potential to spread farther along the interior of the axon, bringing more distant regions of the membrane to the threshold sooner. The great advantage of myelination is its space efficiency. A myelinated axon 20 μm in diameter has about the same conduction speed as a squid giant axon (diameter 1 mm), but more than 2,000 of those myelinated axons could be packed into the space occupied by just one giant axon.

In a myelinated axon, voltage-gated Na^+ and K^+ channels are concentrated at gaps in the myelin sheath called nodes of Ranvier (see Figure 48.8). The extracellular fluid is in contact with the axon membrane only at the nodes. As a result, action potentials are not generated in the regions between the nodes. Rather, the inward current produced during the rising phase of the action potential at a node travels all the way to the next node, where it depolarizes the membrane and generates a new action potential (Figure 48.15). This mechanism is called saltatory conduction (from the Latin *saltare*, to leap) because the action potential appears to jump along the axon from node to node. Saltatory conduction can transmit action potentials at speeds up to 120 m/sec in myelinated axons.

Concept Check 48.3

- How does an action potential differ from a graded potential?
- Suppose a mutation caused the inactivation gates on Na^+ channels to remain closed for a longer time following an action potential. How would that affect the maximum frequency at which action potentials could be generated?
- Arrange the following from lowest to highest conduction speed: (a) myelinated, small-diameter axon; (b) myelinated, large-diameter axon; (c) unmyelinated, small-diameter axon.

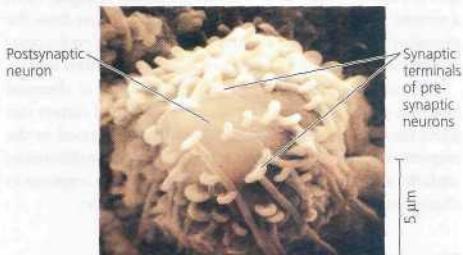

For suggested answers, see Appendix A.

Concept 48.4

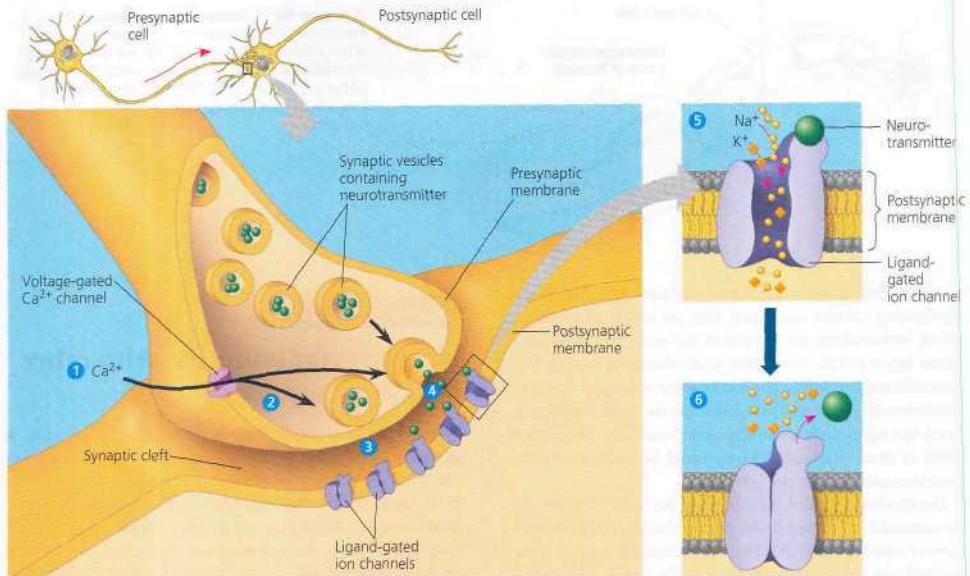

Neurons communicate with other cells at synapses

When an action potential reaches the terminals of an axon, it generally stops there. In most cases, action potentials are not transmitted from neurons to other cells. However, information is transmitted, and this transmission occurs at the synapses. Some synapses, called *electrical synapses*, contain gap junctions (see Figure 6.31), which do allow electrical current to flow directly from cell to cell. In both vertebrates and invertebrates, electrical synapses synchronize the activity of neurons responsible for certain rapid, stereotypical behaviors. For example, electrical synapses associated with the giant axons of lobsters and other crustaceans facilitate the swift execution of their escape responses.

The vast majority of synapses are *chemical synapses*, which involve the release of a chemical neurotransmitter by the presynaptic neuron. The presynaptic neuron synthesizes the neurotransmitter and packages it in synaptic vesicles, which are stored in the neuron's synaptic terminals. Hundreds of synaptic terminals may interact with the cell body and dendrites of a postsynaptic neuron (Figure 48.16). When an action potential

► Figure 48.16 Synaptic terminals on the cell body of a postsynaptic neuron (colorized SEM).

A Figure 48.17 A chemical synapse.

When an action potential depolarizes the plasma membrane of the synaptic terminal, it opens voltage-gated Ca^{2+} channels in the membrane, triggering an influx of Ca^{2+} . The elevated Ca^{2+} concentration in the terminal causes synaptic vesicles to fuse with the

presynaptic membrane. The vesicles release neurotransmitter into the synaptic cleft. The neurotransmitter binds to the receptor portion of ligand-gated ion channels in the postsynaptic membrane, opening the channels. In the synapse illustrated here, both Na^+ and K^+ can diffuse through the channels.

neurotransmitter releases from the receptors, and the channels close. Synaptic transmission ends when the neurotransmitter diffuses out of the synaptic cleft, is taken up by the synaptic terminal or another cell, or is degraded by an enzyme.

reaches a synaptic terminal, it depolarizes the terminal membrane, opening voltage-gated calcium channels in the membrane (**Figure 48.17**). Calcium ions (Ca^{2+}) then diffuse into the terminal, and the rise in Ca^{2+} concentration in the terminal causes some of the synaptic vesicles to fuse with the terminal membrane, releasing the neurotransmitter by exocytosis (see Chapter 7). The neurotransmitter diffuses across the **synaptic cleft**, a narrow gap that separates the presynaptic neuron from the postsynaptic cell. The effect of the neurotransmitter on the postsynaptic cell may be either direct or indirect (described next).

Information transfer is much more modifiable at chemical synapses than at electrical synapses. A variety of factors can affect the amount of neurotransmitter that is released or the responsiveness of the postsynaptic cell. Such modifications underlie an animal's ability to alter its behavior in response to change and form the basis for learning and memory.

Direct Synaptic Transmission

At many chemical synapses, ligand-gated ion channels capable of binding to the neurotransmitter are clustered in the

membrane of the postsynaptic cell, directly opposite the synaptic terminal (see Figure 48.17). Binding of the neurotransmitter to a particular part of the channel, the receptor, opens the channel and allows specific ions to diffuse across the postsynaptic membrane. This mechanism of information transfer is called **direct synaptic transmission**. The result is generally a **postsynaptic potential**, a change in the membrane potential of the postsynaptic cell. At some synapses, for example, the neurotransmitter binds to a **type** of channel through which both Na^+ and K^+ can diffuse. When those channels open, the postsynaptic membrane depolarizes as the membrane potential approaches a value roughly midway between E_K and E_{Na} . Since these depolarizations bring the membrane potential toward the threshold, they are called **excitatory postsynaptic potentials (EPSPs)**. At other synapses, a different neurotransmitter binds to channels that are selective for K^+ only. When those channels open, the postsynaptic membrane hyperpolarizes. Hyperpolarizations produced in this manner are called **inhibitory postsynaptic potentials (IPSPs)** because they move the membrane potential farther from the threshold.

Various mechanisms terminate the effect of neurotransmitters on postsynaptic cells. At many synapses, the neurotransmitter simply diffuses out of the synaptic cleft. At others, the neurotransmitter is taken up by the presynaptic neuron through active transport and repackaged into synaptic vesicles. Glia actively take up the neurotransmitter at some synapses and metabolize it as fuel. The neurotransmitter acetylcholine (discussed shortly) is degraded by an enzyme, acetylcholinesterase, which resides in the synaptic cleft.

Summation of Postsynaptic Potentials

Unlike action potentials, which are all-or-none, postsynaptic potentials are graded; their magnitude varies with a number of factors, including the amount of neurotransmitter released by the presynaptic neuron. Another difference is that postsynaptic potentials usually do not regenerate themselves as they spread along the membrane of a cell; they become smaller with distance from the synapse. Recall that most synapses on a neuron are located on its dendrites or cell body, whereas action potentials are generally initiated at the axon hillock. Therefore, a single EPSP is usually too small to trigger an action potential in a postsynaptic neuron (**Figure 48.18a**).

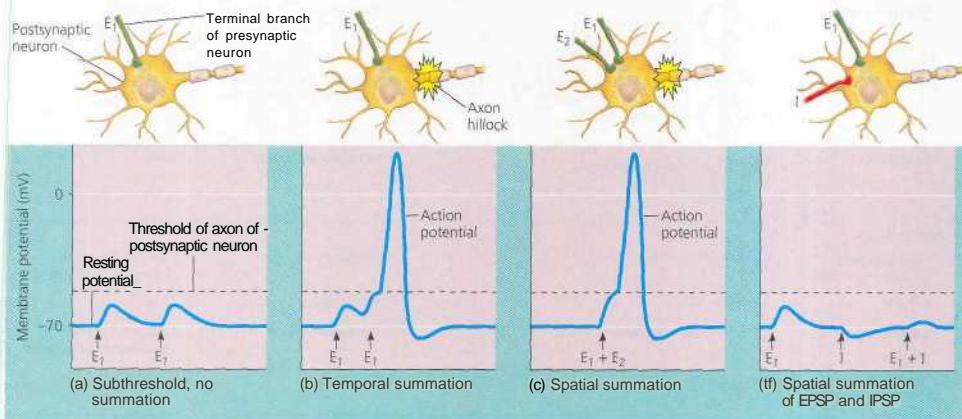

However, if two IPSPs occur in rapid succession at a single synapse, the second EPSP may begin before the postsynaptic neuron's membrane potential has returned to the resting potential after the first EPSP. When that happens, the EPSPs add together, an effect called temporal summation (**Figure 48.18b**). Moreover, EPSPs produced nearly simultaneously by different
