About the Authors

Neil A. Campbell combined the investigative nature of a research scientist with the soul of an experienced and caring teacher. He earned his M.A. in Zoology from UCLA and his Ph.D. in Plant Biology from the University of California, Riverside, where he received the Distinguished Alumnus Award in 2001. Dr. Campbell published numerous research articles on how certain desert and coastal plants thrive in salty soil and how the sensitive plant (*Mimosa*) and other legumes move their leaves. His 30 years of teaching in diverse environments included general biology courses at Cornell University, Pomona College, and San Bernardino Valley College, where he received the college's first Outstanding Professor Award in 1986. Most recently Dr. Campbell was a visiting scholar in the Department of Botany and Plant Sciences at the University of California, Riverside. In addition to his authorship of this book, he coauthored Biology: *Concepts and Connections* and Essential Biology with Jane Reece. Each year, over 600,000 students worldwide use Campbell/Reece biology textbooks.

Jane B. Reece has worked in biology publishing since 1978, when she joined the editorial staff of Benjamin Cummings. Her education includes an A.B. in Biology from Harvard University, an M.S. in Microbiology from Rutgers University and a Ph.D. in Bacteriology from the University of California, Berkeley. At UC Berkeley, and later as a postdoctoral fellow in genetics at Stanford University her research focused on genetic recombination in bacteria. She taught biology at Middlesex County College (New Jersey) and Queensborough Community College (New York). As an editor at Benjamin Cummings, Dr. Reece played major roles in a number of successful textbooks. In addition to being a coauthor with Neil Campbell on *BIOLOGY*, *Biología*; *Concepts and Connections*, and *Essential Biology*, she coauthored *The World of the Cell* Third Edition, with W. M. Becker and M. E. Poenie.

NEIL A. CAMPBELL
died October 21, 2004 after finishing work on this revision.
He is deeply mourned by his many friends and colleagues
at Benjamin Cummings and
throughout the biology community.

Preface

Charles Darwin described evolution as a process of "descent with modification." It is a phrase that also fits the continuing evolution of *BIOLOGY*. This Seventh Edition is our most ambitious revision of the book since its origin—a new textbook "species" with several evolutionary adaptations shaped by the changing environment of biology courses and by the astonishing progress of biological research. But these adaptive modifications are still true to the two complementary teaching values at the core of every edition of *BIOLOGY*. First, we are dedicated to crafting each chapter from a framework of key concepts that will help students keep the details in place. Second, we are committed to engaging students in scientific inquiry through a combination of diverse examples of biologists' research and opportunities for students to practice inquiry themselves.

These dual emphases on concept building and scientific inquiry emerged from our decades of classroom experience. It is obviously gratifying that our approach has had such broad appeal to the thousands of instructors and millions of students who have made *BIOLOGY* the most widely used college science textbook. But with this privilege of sharing biology with so many students comes the responsibility to continue improving the book to serve the biology community even better. As we planned this new edition, we visited dozens of campuses to hear what students and their instructors had to say about their biology courses and textbooks. What we learned from those conversations about new directions in biology courses and the changing needs of students informed the many improvements you'll find in this Seventh Edition of *BIOLOGY*.

We have restructured each chapter to bring its key concepts into even sharper focus

The discovery explosion that makes modern biology so exciting also threatens to suffocate students under an avalanche of information. The past few editions of *BIOLOGY* set the details in a context of key concepts, typically ten to twenty per chapter. In this new edition, we have taken the next evolutionary step of restructuring each chapter to help students focus on fewer, even bigger ideas—typically just five or six key concepts per chapter. A new Overview section at the beginning of each chapter sets an even broader context for the key concepts that follow. And at the end of each of the concept sections, a Concept Check with two or three questions enables students to assess whether they understand that concept before going on to the next. Answers to the Concept Check questions are located in Appendix A, as are the answers to the Self-Quizzes from the Chapter Review at the end of each chapter.

In our ongoing interactions with students and instructors, they have responded enthusiastically to our new organization and pedagogy. Compared to other textbooks, including earlier editions of our own, students have found the new chapter structure and design of *BIOLOGY*, Seventh Edition, to be more inviting, more accessible, and much more efficient to use. But in achieving these goals, we have not compromised the depth and scientific accuracy the biology community has come to expect from us.

54

Ecosystems

a. Figure 54.1 An aquarium, an ecosystem bounded by glass.

Key Concepts keep the supporting details in context.

The Overview sets the stage for the rest of the chapter.

Figure references in color help students move easily between text and figures.

Key Concepts

- 54.1 Ecosystem ecology emphasizes energy flow and chemical cycling
- 54.2 Physical and chemical factors limit primary production in ecosystems
- 54.3 Energy transfer between trophic levels is usually less than 20% efficient
- 54.4 Biological and geochemical processes move nutrients between organic and inorganic parts of the ecosystem
- 54.5 The human population is disrupting chemical cycles throughout the biosphere

Overview

Ecosystems, Energy, and Matter

A ecosystem consists of all the organisms living in a community, such as the aquarium in **Figure 54.1**, or a large area such as a lake or forest. As with populations and communities, the boundaries of ecosystems are usually not distinct; cities and farms are examples of human-dominated ecosystems. Many ecologists regard the entire biosphere as a global ecosystem, a composite of all the local ecosystems on Earth.

Regardless of an ecosystem's size, its dynamics involve two processes that cannot be fully described by population or community processes and phenomena: energy flow and chemical cycling. Energy enters most ecosystems in the form of sunlight. It is then converted to chemical energy by autotrophs,

among which are plants and bacteria. Heterotrophic organisms assimilate these elements in inorganic forms, such as carbon dioxide (CO_2), water (H_2O), and minerals. Some of these are excreted by animals. The elements are returned in inorganic form to the air, soil, and water by the metabolism of plants and animals and by other organisms, such as bacteria and fungi, that break down organic wastes and dead organisms.

Energy energy and matter move through ecosystems via the transfer of substances during photosynthesis and feeding relationships. However, because energy, unlike matter, cannot be recycled, an ecosystem must be powered by a continuous influx of energy from an external source—in most cases, the sun. Energy flows through ecosystems, while matter cycles within them.

Revolves critical to human survival and welfare, ranging from the food we eat to the energy we breathe, are products of ecosystem processes. In this chapter, we will explore the role of energy and matter in ecosystems and consider some of the impacts of human activities on these processes.

Concept 54.1

Ecosystem ecology emphasizes energy flow and chemical cycling

Ecosystem ecologists view consumers as transformers of energy and processors of matter. By grouping the species in a community into trophic levels, showing relationships (see the transformation of energy in terms of chemical elements

Each numbered **< Beep! Head** announces the beginning of a new concept section.

▲ Figure 54.2 Fungi decomposing a dead tree.

consumers in an ecosystem. In a forest, for example, ravens might feed on earthworms that have been feeding on leaf litter and its associated prokaryotes and fungi. But even more important than this channelling of energy from producers to consumers is the role that detritivores play in making available chemical elements available to producers.

Detritivores recycle the organic material in an ecosystem back into it.

Concept Check 54.1

1. Why is the transfer of energy in an ecosystem referred to as energy flow, not energy cycling?
2. How does the second law of thermodynamics explain why an ecosystem's energy supply must be continually replenished?
3. How are detritivores essential to sustaining ecosystems?

For suggested answers, see Appendix A.

Concept 54.2

Physical and chemical factors limit primary production in ecosystems

The amount of light energy converted to chemical energy (organic compounds) by autotrophs during a given time period is called primary production. Primary production is often measured in units of solar energy (calories) per square meter per hour and energy flow.

Ecosystem Energy Budgets

Most primary energy in a terrestrial ecosystem is used to support respiration (about 50–60% of primary production). After respiration, energy is used for growth, which is broken down to general ATP. Consumers acquire energy through secondary and higher-level trophic levels (e.g., a field web, such as in Figure 53.13). Therefore, the sum of primary and secondary production sets the spending limit for the energy budget of the entire ecosystem.

Global Energy Budget

(continued)

Concept Check Questions at the end of each concept section encourage students to assess their mastery of the concept.

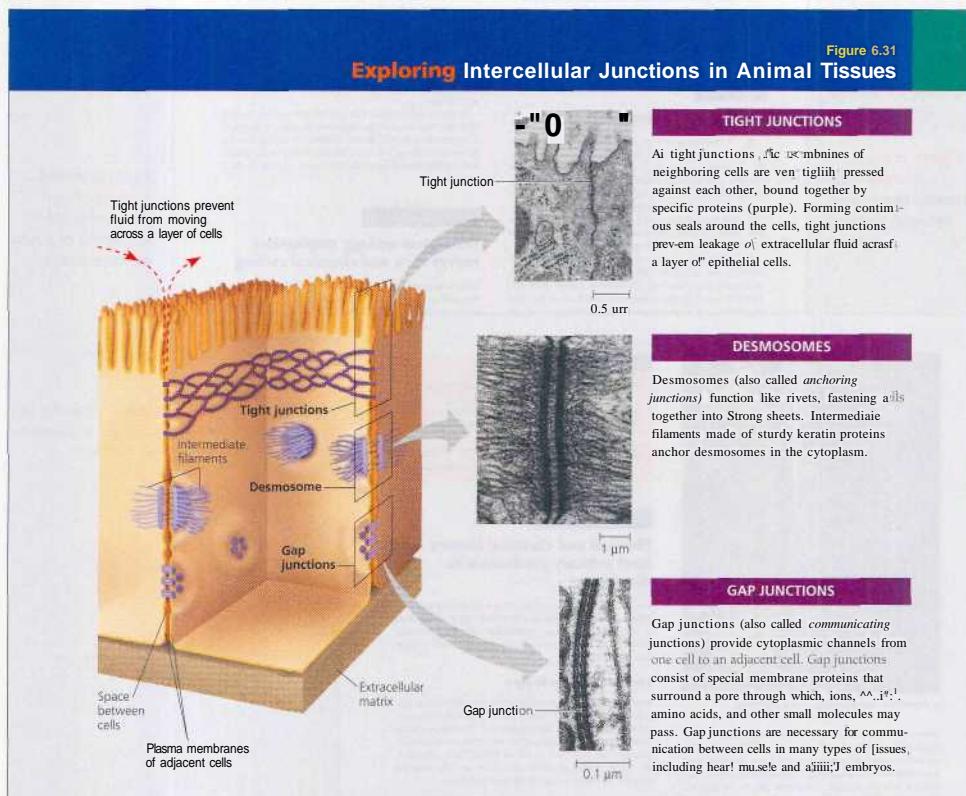

New "Exploring Figures" provide efficient access to many complex topics

Biology is a visual science. Thus we have always authored *BIOLOGY'S* graphics and narrative side by side to coordinate their message. In the Seventh Edition, this text-art integration reaches its next evolutionary level with a new feature called "Exploring Figures." Each of these large figures is a learning unit that brings together a set of related illustrations and the text that describes them. The Exploring Figures enable stu-

dents to access dozens of complex topics much more efficiently, now that the textual and visual components have merged.

The Exploring Figures represent core chapter content, not to be confused with some textbooks' "boxes," which feature content that is peripheral to the flow of a chapter. Modern biology is challenging enough without diverting students' attention from a chapter's conceptual storyline. Thus, each Exploring Figure is referenced in the main text body where it fits into the development of a concept, just as the text points students to all the other supporting figures at the appropriate places in the narrative.

In **Exploring Figures**, art, photos, and text are fully integrated.

Scientific inquiry is more prominent than ever in *BIOLOGY* and its supplements

One objective for many biology instructors is for students to learn to think as scientists. In both the lecture hall and laboratory, colleagues are experimenting with diverse approaches

for involving students in scientific inquiry, in which questions about nature focus strategic investigation and analysis of data. New textbook features and new inquiry-based supplements make this edition of *BIOLOGY* more effective than ever as a partner to instructors who emphasize the process of science.

Modeling Inquiry by Example

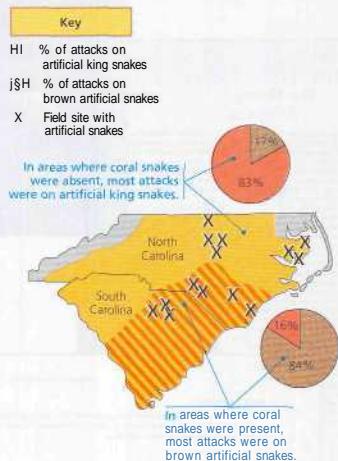

Scientific inquiry has always been one of *BIOLOGISTS* unifying themes. Each edition has traced the history of many research questions and scientific debates to help students appreciate not just "what we know" but "how we know,"¹ and "what we do not yet know." In *BIOLOGY*, Seventh Edition, we have strengthened this theme by making examples of scientific inquiry much more prominent throughout the book.

The increased emphasis on inquiry begins in Chapter 1, where we have thoroughly revised the introduction to the many ways that scientists explore biological questions. Chapter 1 also introduces a new feature called "Inquiry Figures," which showcase outstanding examples of experiments and field studies in a format that is consistent throughout the book. Complementing the Inquiry Figures are the new "Research Method Figures,"¹ which walk students through the techniques and tools of modern biology. You can find a list of the Inquiry and Research Method Figures on pages xx-xxi. These new features, like the Exploring Figures, are integral to chapter flow rather than being appended as boxed asides.

Figure 1.29
Inquiry Does the presence of poisonous coral snakes affect predation rates on their mimics, king snakes?

EXPERIMENT David Pfennig and his colleagues made artificial snakes to test a prediction of the mimicry hypothesis: that king snakes benefit from mimicking the warning coloration of coral snakes only in regions where poisonous coral snakes are present. The Xs on the map below are field sites where the researchers placed equal numbers of artificial king snakes (experimental group) and brown artificial snakes (control group). The researchers recovered the artificial snakes after four weeks and tabulated predation data based on teeth and claw marks on the snakes (see Figure 1.28).

RESULTS In field sites where coral snakes were present, predators attacked far fewer artificial king snakes than brown artificial snakes. The warning coloration of the "king snakes" afforded no such protection where coral snakes were absent. In fact, at those field sites, the artificial king snakes were more likely to be attacked than the brown artificial snakes, perhaps because the bright pattern is particularly easy to spot against the background.

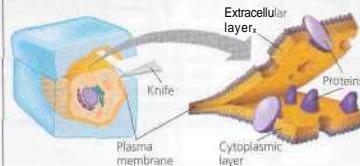

ELIZABETH E. JONES The field experiments support the mimicry hypothesis by not falsifying the key prediction that imitation of coral snakes is only effective where coral snakes are present. The experiments also tested an alternative hypothesis that predators generally avoid all snakes with brightly colored rings, whether or not poisonous snakes with that coloration live in the environment. That alternative hypothesis was falsified by the data showing that the ringed coloration failed to repel predators where coral snakes were absent.

New **Inquiry Figures** and **Research Method Figures** help students learn to think like scientists.

Figure 7.4
Research Method Freeze-Fracture

APPLICATION A cell membrane can be split into its two layers, revealing the ultrastructure of the membrane's interior.

TECHNIQUE A cell is frozen and fractured with a knife. The fracture plane often follows the hydrophilic interior of a membrane, splitting the phospholipid bilayer into two separated layers. The membrane proteins go wholly to one of the layers.

RESULTS These SEMs show membrane proteins (the "bumps") in the two layers, demonstrating that proteins are embedded in the phospholipid bilayer.

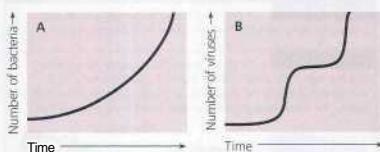

Learning Inquiry by Practice

Modeling scientific inquiry by example has only ephemeral impact unless students have an opportunity to apply what they have learned by asking their own biological questions and conducting their own investigations. On a small scale, *BIOLOGY*, Seventh Edition, encourages students to practice thinking as scientists by responding to "Scientific Inquiry" questions in the Chapter Review at the ends of chapters.

On a much bigger scale, new supplements build on the textbook to provide diverse opportunities for students to practice scientific inquiry. One example is *Biological Inquiry: A Workbook of Investigative Cases*, by Margaret Waterman of Southeast Missouri State University and Ethel Stanley of Beloit College, which is available without cost to students whose instructors request it as a supplement to the textbook. This innovative new workbook offers eight case studies, coordinated with the eight units of chapters in *BIOLOGY*. In each case, a realistic scenario sets up a series of inquiry-based activities. The cases work well either as class-discussion projects or as take-home assignments for students working alone, or better, in small groups.

Another student-centered supplement is *Practicing Biology*, by Jean Heitz, University of Wisconsin, Madison, which

Biological inquiry: A Workbook of Investigative Cases Explore
West Nile virus in the case "The Donor's Dilemma."

Investigation What Causes *Infections in AIDS Patients?*
Investigation Why Do AIDS Rates Differ Across the U.S.?
Investigation What Are the Patterns of Antibiotic Resistance?

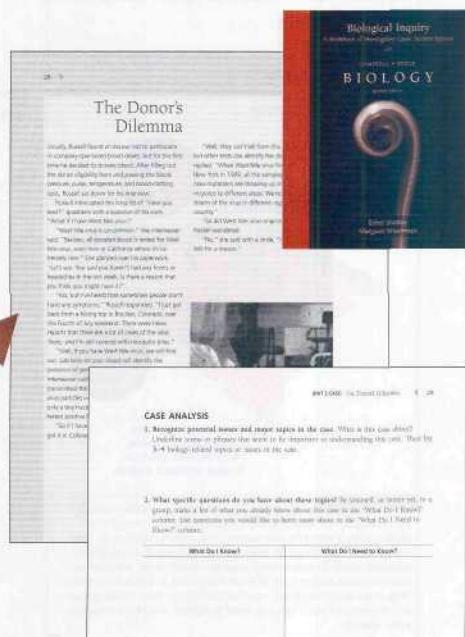

Inquiry Questions, Media Investigations, and the new Biological Inquiry Workbook help students practice scientific inquiry.

is also available without additional cost upon request of instructors using *BIOLOGY*, Seventh Edition. This workbook supports various learning styles with a variety of activities—including modeling, drawing, and concept-mapping—that help students construct an understanding of biological concepts.

Students will find still more opportunities for active learning at Mwww.campbellbiology.com and the CD-ROM that is included with each book. And the excellent Student Study Guide, by Martha Taylor of Cornell University, continues to be a proven learning tool for students.

The Campbell/Reece Interviews: A Continuing Tradition

Scientific inquiry is a social process catalyzed by communication among people who share a curiosity about nature. One of the many joys of authoring *BIOLOGY* has been the privilege to humanize science by interviewing some of the worlds most influential biologists. Eight new interviews that introduce the eight units of the textbook provide students with windows to inquisitive minds that are driving progress in biology and connecting science to society. The interviewees for this edition are listed on page xxiii.

Balancing Inquiry with a Conceptual Foundation

Although this new edition of *BIOLOGY* showcases the process of science more prominently than ever, there are two good reasons to avoid overstating the power of inquiry-based content in any biology textbook.

First, those of us who advocate more inquiry in biology courses mainly have student-centered inquiry in mind, not textbook-centered inquiry. As a mostly passive experience, reading about inquiry in a textbook should be merely an entryway to a variety of active experiences that are promoted by inquiry-based supplements, by investigative labs, and by activities that instructors create to support student-centered inquiry.

Second, the most important way a textbook can support student inquiry is by providing context with clear, accurate explanation of the key biological concepts, just as biologists generally study the scientific literature as background for their own inquiry; students will be much more successful in their personal inquiry if it emerges from a basic understanding of the relevant biology. Thus, *BIOLOGY*, Seventh Edition, is *not* a "reform textbook"¹ of the genre that replaces a careful unfolding of conceptual content with a stream of relatively unconnected research examples, requiring beginning students to put it all together for themselves. We believe that such an unbalanced reaction to the call for inquiry-based reform is likely to leave most students frustrated and ill-equipped to practice active inquiry in their labs, course projects, class discussions, and Socratic lecture environments. In *BIOLOGY*, Seventh Edition, we have carefully integrated the inquiry-based content into the development of each chapter's main ideas so that the research examples reinforce rather than obscure the conceptual framework.

BIOLOGY supports a diversity of courses and serves students throughout their biology education

Even by limiting our scope to a few key concepts per chapter, *BIOLOGY* spans more biological territory than most introductory courses could or should attempt to cover. But given the great diversity of course syllabi, we have opted for a survey broad enough and deep enough to support each instructor's special emphases. Students also seem to appreciate *BIOLOGY*'s breadth and depth; in this era when students sell many of their textbooks back to the bookstore, more than 75% of students who have used *BIOLOGY* have kept it after their introductory course. In fact, we are delighted to receive numerous letters and emails from upper-division students and graduate students, including medical students, expressing their appre-

ciation for the long-term value of *BIOLOGY* as a general resource for their continuing education.

Just as we recognize that few courses will cover all 55 chapters of *BIOLOGY*, we also realize that there is no one "correct" sequence of topics for a general biology course. Though a biology textbook's table of contents must be linear, biology itself is more like a web of related concepts without a fixed starting point or a prescribed path. Diverse courses can navigate this network of concepts starting with molecules and cells, with evolution and the diversity of organisms, or with the big-picture ideas of ecology. We have built *BIOLOGY* to be versatile enough to support various syllabi. The eight units of the book are largely self-contained, and most of the chapters within each unit can be assigned in a different sequence. For example, instructors who integrate plant and animal physiology can merge chapters from Unit Six (Plant Form and Function) and Unit Seven (Animal Form and Function). Instructors who begin their course with ecology and continue with this "top-down" approach can assign Unit Eight (Ecology) right after Chapter 1, which introduces the unifying themes that provide students with a panoramic view of biology no matter what the topic order of the course syllabus.

Evolution and *BIOLOGY*'s other themes connect the concepts and integrate the whole hook

The first chapter articulates 11 themes that provide touchstones for students throughout the book and distinguish our approach in *BIOLOGY* from an encyclopedic topical approach. In this Seventh Edition, we have added the theme of "biological systems" to integrate a variety of research initiatives based on high-throughput data collection and readily available computing power. But as in all previous editions, the central theme is evolution, which unifies all of biology by accounting for both the unity and diversity of life. The evolutionary theme is woven into every chapter of *BIOLOGY*. Evolution and the other whole-book themes work with the chapter-level concepts to help students construct a coherent view of life that will serve them long after they have forgotten the details fossilized in any biology textbook.

Neil Campbell and Jane Reece

Acknowledgments

One of the eminent scientists interviewed in this new edition pointed out that much of the fun of doing biology comes from working with a diversity of talented people. The same can be said for making a biology textbook. Fortunately for us, this Seventh Edition of *BIOLOGY* is the product of the talents, dedication, and enthusiasm of a large and varied group of people. The authors wish to express their deepest thanks to the numerous instructors, researchers, students, publishing professionals, and artists who have contributed to this edition.

As authors of both past and present editions of this text, we are mindful of the daunting challenge of keeping up to date in all areas of our rapidly expanding subject. We are particularly grateful to the seven Contributors and Advisers listed on the title page, whose expertise has ensured that the book is current and enlivened with fresh examples. We worked especially closely with developmental biologist Lisa Urry who had major responsibility for updating content and implementing our new format and features for Units 1-3 and Chapter 47. Her rigorous scholarship and attention to detail in the areas of biological chemistry, cell and molecular biology, genetics, and developmental biology were a great boon. We thank her for her commitment and enthusiasm, relentless hard work, punctuality, and good cheer throughout the process. Equally helpful was ecologist Manuel Molles, who brought his scientific and teaching expertise to the revision of Unit 8, enhancing the structure of the unit and its verbal and visual presentation of ecology; he played a major role rewriting the behavioral ecology chapter, which is essentially new. He also helped provide a more ecological perspective to Chapters 40, 42, and 44, in the unit on animal form and function. Science writer Carl Ziramer contributed many improvements and new perspectives to Unit 5, the diversity unit. Evolutionary biologist Christopher Wills helped us tackle the challenge of improving and updating Unit 4, the evolution unit, and Chapter 26. Plant biologist Peter Minorsky helped bring Unit 6 up to date. And neurobiologist Antony Stretton advised us on the revision of Chapters 48 and 49. As in earlier editions, immunologist Mary Jane Niles organized and implemented the significant revision of Chapter 43.

Thanks also to the instructors who suggested revised or new Concept Check and Chapter Review questions. These include (in alphabetical order) Bruce Byers, Jean Heitz, William Hoese, Tom Owens, Mark Lyford, Randy Phillips (special thanks), Mitch Price, Fred Sack, Richard Showman, and Elspeth Walker. It's not easy to write good questions, and we appreciate the time and effort these dedicated educators contributed to enhancing the effectiveness of our book's questions.

Further helping us improve *BIOLOGY*'s scientific accuracy and pedagogy about 240 biologists and teachers, cited on the list that follows these Acknowledgements, provided detailed reviews of one or more chapters for this edition. Special thanks to Lawrence Brewer, Richard Brusca, Anne Clark, Douglas Eernisse, Mark Kirk, Walter Judd, Mike Levine, Diane Marshall, Nick Money, Tom Owens, Kevin Padian, Daniel Papaj, Mitch Price, Bruce Reid, and Alastair Simpson for their guidance.

Thanks also to the numerous other professors and their students, from all over the world, who offered suggestions by writing directly to the authors. In addition, we appreciate the candid and specific feedback we received from the students and faculty who participated in group discussions held at Skyline College, Mills College, and Indiana

University. Last but not least, we thank our coauthors on our nonmajors texts, Eric Simon and Marty Taylor, for providing rigorous feedback on a number of chapters. Of course, we alone bear the responsibility for any errors that remain in the text, but the dedication of our contributors, advisers, reviewers, and correspondents makes us especially confident in the accuracy of this edition.

Many scientists have also helped shape this Seventh Edition by discussing their research fields with us, answering specific questions in their areas of expertise, and, often, sharing their ideas about biology education. Neil Campbell thanks the many University of California, Riverside, colleagues who have influenced this book, including Ring Cardie, Richard Cardullo, Mark Chappell, Darleen DeMason, Norman Ellstrand, Anthony Huang, Bradley Hyman, Tracy Kahn, Elizabeth Lord, Carol Lovatt, Eugene Nothnagel, John Gross, Timothy Paine, David Reznick, Rodolfo Ruibal, Clay Sassaman, William Thomson, John Taimbe, Rick Redack, Mike Adams, and the late John Moore (whose "Science as a Way of Knowing" essays have had such an important influence on the evolution of *BIOLOGY*). Jane Reece thanks members of the Mills College Biology and Chemistry/Physics Departments, especially Elisabeth Wade, as well as Fred Wilt, John Gerhart and Kris Xiyogi from the University of California, Berkeley, for their assistance to contributor Lisa Urry.

Interviews with prominent scientists have been a hallmark of *BIOLOGY* since its inception, and conducting these interviews was again one of the great pleasures of revising the text. To open the eight units of this Seventh Edition, we are proud to include interviews with Lydia Makhubu, Peter Agre, Eric Lander, Kenmetri Kaneshiro, Linda Graham, Natasha Raikhel, Erich Jarvis, and Gene Likens.

The value of *BIOLOGY* as a learning tool is greatly enhanced by the supplementary materials that have been created for instructors and students. We recognize that the dedicated authors of these materials are essentially writing mini (and not so mini) books. We much appreciate the hard work and creativity of the following: Margaret Waterman and Ethel Stanley (authors of the new *Biological Inquiry: A Workbook of Investigative Cases*); Jean Heitz (Practicing Biology, 2nd edition); Joan Sharp (*Instructor's Guide*); Janet Lanza (*New Designs for Bio-Explorations*); Chris Romero (PowerPoint Lectures); Laura Zanello (*Spanish Glossary*); and Judith Morgan and Eloise Brown Carter (*Investigating Biology Lab Manual*, 5th Edition). We thank Bill Barstow for heading up the test bank team, and we wish to acknowledge the test bank contributors: Jean DeSaix, Michael Dim, Conrad Firling, Peter Follette, Mark Hens, Janice Moore, Tom Owens, Marshall Sundberg, Robert Yost, and Ed Zalisko. Thanks also to Bill Wischusen, who compiled our Active Learning Questions and wrote discussion points. Once again, we thank our long-time colleague Marty Taylor for her excellent and student-focused work on the *Student Study Guide*; she has now completed seven editions of this popular student aid. In addition, we are grateful to the many other people—biology instructors, editors, artists, production experts, and narrators—who are listed in the credits for the impressive electronic media that accompany the book.

BIOLOGY, Seventh Edition, results from an unusually strong synergy between a team of scientists and a team of publishing professionals. An all-new design, the comprehensive revision of the illustration

program as well as the text, the addition of major new pedagogical features, and a rich package of supplements, both printed and electronic, combined with a tight schedule to create unprecedented challenges for the publishing team.

The members of the core book team at Benjamin Cummings brought extraordinary talents and extraordinarily hard work to this project. Our leader, Editor-in-Chief Beth Wilbur, is a full colleague in the books creation and a respected advocate for biology education in general and our book in particular in the academic community. Enthusiastic, creative, endlessly supportive of us and the other members of the team, Beth is a wonderful person and a pleasure to work with. Unflappable under pressure, she navigates difficult situations gracefully—a major asset in a project of this complexity.

The incomparable Deborah Gale, Director of Development, managed the entire project on a day-by-day basis. Deborah reproduced the first and second editions of the book, along with the developmental editing of the second edition, and we have been delighted with her return. Amazingly, Deborah is able to combine a totally professional, no-nonsense management style and a willingness to dig into the nitty-gritty with a sense of humor that kept the rest of us happily slaving away at her direction.

Supervising editors Pat Burner and Beth Winickoff had the awesome responsibility of overseeing in detail the work of the contributors, developmental editors, and developmental artists. Together, Pat and Beth carefully read every single chapter and checked every illustration, doing whatever was necessary to make this edition the most effective biology textbook available—and, we think, exceeding the high standards established in previous editions. We are immensely grateful to Pat, the multitalented and tireless Developmental Manager for Biology who has been our colleague for many years, for her incredible dedication, sound editorial judgment, and extraordinary attention to detail. The exceptionally talented Beth Winickoff, new to this Seventh Edition, was the originator of our new process of book development and production. Beth brought fresh perspectives on process, pedagogy, and editorial approach—in addition to her superb hands-on editing of six chapters. We look forward to working again with Pat and Beth on subsequent editions (after they recover from this one, of course!).

The responsibilities of the developmental editors for this edition were especially challenging. Almost all the chapters were heavily revised, requiring intensive editorial involvement from initial planning through production. We were fortunate to have on our team some of college publishing's top developmental editors. In alphabetical order, they were John Burner (Units 5–7), Alice Fugate (Units 4 and 7), Sarah Jensen (Units 2, 3, and 7), Matt Lee (Units 5 and 7), Suzanne Olivier (Units 1 and 2), Ruth Steyn (Units 3 and 7), and Susan Weisberg (Units 7 and 8). In addition to their other tasks, John Burner, Matt Lee, and Ruth Steyn brought their specific content expertise to bear on their chapters' revisions.

The support of our bright, efficient, and good-natured Publishing Assistants, Trinh Bui and Julia Khati, is much appreciated. What would we all have done without them?

We also want to thank someone who doesn't fit neatly into any of our publishing categories: our colleague, former editor, and friend Robin Heyden. Robin brought her imaginative energy and dedication to biology education to the Seventh Edition in several ways. These include early planning for the development of the media for this edition and the conception and developmental management of the new case study workbook by Margaret Waterman and Ethel Stanley. Robin also organized the first Benjamin Cummings Biology Leadership Conference, which brought us a fresh supply of creative teaching ideas from outstanding biology educators.

Once again the book has benefited greatly from the work of Russell Chun, our Senior Producer, Art and Media. Russell established a vibrant new art style for this edition that met the requirements of the content and exceeded our expectations for pedagogical and aesthetic excellence. Under his direction were the developmental artists, who developed all the new figures and redesigned many of the older ones to make them clearer and more appealing. These skilled and creative illustrators were Hilair Chism (Units 1–3 and 7), Blakeley Kim (Unit 8), Kenneth Probst (Units 4 and 5), and Laura Southworth (Units 3 and 7). Carla Simmons (Units 5 and 6) has contributed her artistic and pedagogical talents to every edition of this textbook. Final rendering of the hundreds of new and revised illustrations was carried out by Russell, Phil Guzy Steve McEntee, and the artists of Precision Graphics. Meanwhile, Photo Editor Travis Amos led a team of photo researchers in finding hundreds of new photos for this edition. The photo researchers were Brian Donnelly, Donna Kalal, Ira Kleinberg, Robin Samper, and Maureen Spuhler. The efficient Donna Kalal also coordinated the ordering of photos from a multitude of sources. We are indebted to the entire art and photo team and to the book's talented text and cover designer, Mark Ong, for the most beautiful and visually effective edition ever. In addition to creating the stunning design, Mark was involved in laying out every chapter, and his artistic sensibility reinforced all of our goals for this revision.

The book production team had the crucial responsibility of converting the text manuscript and illustrations to pages ready for the printer. Many thanks to Managing Editor Erin Gregg, who was responsible for overseeing the complex design and production process, including the management of both in-house and freelance employees. At GTS Companies (the compositors), we particularly want to thank Rob Hansen, Brendan Short, Morgan Floyd, and Sherrill Redd, who provided expertise and solutions to complicated production challenges with good humor, and designer Kirsten Sims, who helped us improve the appearance and pedagogical utility of the Exploring Figures. Finally, we thank Manufacturing Manager Pam Augspurger, without whose work you would not be holding a physical copy of the book in your hands.

We are pleased to thank the topnotch publishing professionals who worked on the books printed supplements. Amy Austin, Robin Heyden, Ginnia Simione Jutson, and Joan Keyes developed these supplements, and Vivian McDougal and Jane Brundage were responsible for their production.

In regard to the excellent package of electronic media that accompanies the book, we offer special thanks to Brienn Buchanan, who creatively pulled together all the elements of the student CD-ROM and website, and Christopher Delgado, who produced all of the instructor media resources, as well as the Art Notebook.

Linda Davis, President of Benjamin Cummings Publishing, has shared our commitment to excellence and provided strong support for three editions now, and we are happy to thank her once again. We also want to thank the Addison Wesley/Benjamin Cummings President, Jim Behnke (who was the editor of the first edition of this book), for his support of our new developmental process, and Editorial Director Frank Ruggirello for his vigorous commitment to the book's success.

Both before and after publication, we are fortunate to have experienced Benjamin Cummings marketing professionals on our book team. Senior Marketing Manager Josh Frost and Director of Marketing Stacy Treco provided consistent support and useful input throughout the entire development of this edition. Thanks, also, to Jeff Hester, who has recently joined the marketing team. We much appreciate the work of the talented Lillian Carr and her marketing communications team, who have created stunning brochures, posters, and other materials that have helped get the word out about

this new edition. And thanks to Mansour Bethany for developing the brochure and other assistance.

The Addison Wesley/Benjamin Cummings field staff, which represents *BIOLOGY* on campus, is our living link to the students and professors who use the text. The field representatives tell us what you like and don't like about the book, and they provide prompt service to biology departments. The field reps are good allies in science education.

and we thank them for their professionalism in communicating the features of our book.

Finally, we wish to thank our families and friends for their encouragement and for enduring our continuing obsession with *BIOLOGY*.

Neil Campbell and Jane Reece

October 2004

Supplements

Supplements for the Student

Campbell BIOLOGY Student CD-ROM and Website (www.campbellbiology.com)

The CD-ROM and website that accompany each book include 230 interactive Activities, 85 Videos, and 55 Investigations. In addition, new graphing exercises (Graph It!) help students learn how to build and interpret graphs.

The CD-ROM and website are fully integrated with the text, reinforcing students' focus on the big ideas. The media organization mirrors that of the textbook, with all the Activities, Videos, and investigations for a given chapter correlated to the key concepts in the book.

There are three separate quizzes per chapter: a Pre-Test, a Chapter Quiz, and an Activities Quiz. A new electronic Gradebook automatically records students' quiz scores. Another new feature of the Seventh Edition, Cumulative Test, allows students to build a self-test with questions from more than one chapter. Feedback is provided to students on all quizzes and tests in the media, which have been upgraded in level of difficulty.

New Flashcards, Word Roots, and Key Terms linked to the Glossary help students master terminology. Students can also access Art from the book with and without labels, the Glossary with audio pronunciations, the Campbell *BIOLOGY* Interviews from previous editions, an E-Book, the Biology Tutor Center, Web Links, News, and Further Readings.

The screenshot shows the 'Community Ecology' chapter page. On the left, a sidebar lists various resources: Chapter Guide, Art, Word Study Tools, Work Sheets & References, Instructor Media, E-Book, Cumulative Test, Glossary, Graph It!, Case Book, LabFaunch, Campbell Interviews, and About the Book. The main content area has a title bar '53: Community Ecology'. Below it, a navigation menu includes Home, FAQs, Site Reqs, Tech Support, Feedback, Credits, and Tutor Center. A sub-navigation bar shows 'Home > 53: Community Ecology > Chapter Guide'. The main content is divided into sections: 'Chapter 53: Community Ecology', 'Pre-Test', 'Concept 53.1', 'Concept 53.2', 'Concept 53.3', 'Concept 53.4', 'Concept 53.5', 'Chapter Review', 'Activities Quiz', and 'Chapter Quiz'. A video player window titled 'CHIMP AGONISTIC BEHAVIOR' shows a chimpanzee in a tree. A caption reads: 'This chimpanzee was found in Gombe, Africa. He engages in agonistic behavior in the form of an aggressive threat display. Behavior such as this is often used as a mechanism to threaten or gain the intent access to greater resources, such as food, a mate, or higher standing in the group.' Below the video, a note says 'Appropriate Chapters: 24, 51 (this is in Chapter 51)'. At the bottom, a footer states '©2005 Pearson Education, Inc., publishing as Benjamin Cummings'.

This screenshot shows the 'Investigations' section. It features a large image of four test tubes labeled 'Dilution Series' with different colored liquids. Below the image is a 'Data Recording' table with columns for 'Supplement 1', 'Aqua', 'Cyanine', and 'Cyanine'. The table has rows for 'Assimilate', 'Cyanine', and 'Cyanine'. A 'Question' box contains a question about dilution series and cyanine. A note at the top right says 'Start as the last dilution is added and record what results you see. If no cyanine is present, then click on "No Assimilate". If any cyanine is visible, then click on "Yes Assimilate". This will allow you to determine the concentration of cyanine. When you are finished, click the "Submit" button, click the "Questions" menu, and review Section 1.'

55 Investigations help students develop scientific skills such as posing hypotheses, collecting data, and analyzing results.

HEW! Biological Inquiry: A Workbook of Investigative Cases (0-8053-7176-1)

*Margaret Waterman, Southeast Missouri State University, and
Ethel Stanley, Beloit College*

This new workbook offers eight investigative cases, one for each unit of the textbook. In order to understand the science in each case, students will pose questions, analyze data, think critically, examine the relationship between evidence and conclusions, construct hypotheses, investigate options, graph data, interpret results, and communicate scientific arguments. Students will actively engage in the experimental nature of science as they gain new insight into how we know what we know⁷. For example, in "The Donor's Dilemma" (the Unit 3 case) students explore the concepts of protein synthesis, viral genomes, and transmission pathways while investigating the case of a blood donor who may have been exposed to the West Nile virus. Web links and other online resources referred to in the investigative cases are provided on the Campbell BIOLOGY website.

Student Study Guide (0-8053-7155-9)

Martha R. Taylor, Cornell University

This popular study guide offers an interactive approach to learning, providing framework sections to orient students to the overall picture, concept maps to complete or create for most chapters, chapter summaries, word roots, chapter tests, and a variety of questions, including multiple choice, short-answer essay, art labeling, and interpreting graphs.

Practicing Biology: A Student Workbook, Second Edition (0-8053-8184-2)

Jean Heitz, University of Wisconsin, Madison

This workbook's hands-on activities emphasize key ideas, principles, and concepts that are basic to understanding biology. Suitable for group work in lecture, discussion sections, and/or lab, the workbook includes class-tested Process of Science activities, concept map development, drawing exercises, and modeling activities.

NEW! Test Preparation Guide to MCAT/GRE for Campbell BIOLOGY, 7e (0-8053-7178-8)

Exclusively available with *BIOLOGY*, Seventh Edition, this new guide includes sample questions and answers from the Kaplan test preparation guides, correlated to specific pages in this edition of *BIOLOGY*.

Art Notebook (0-8053-7183-4)

This resource contains all the art from the text without labels, with plenty of room for students to take notes.

BIOLOGY—Basic Concepts Study Card (0-8053-7175-3)

Useful as a quick reference guide, this fold-out card summarizes the basic concepts and content covered in *BIOLOGY*, Seventh Edition.

Biology Tutor Center (www.aw.com/tutorcenter)

This center provides one-to-one tutoring for college students via phone, fax, and email during evening hours and on weekends. Qualified college instructors are available to answer questions and provide instruction regarding self-quizzes and other content found in *BIOLOGY*, Seventh Edition. Visit the website for more information.

The Benjamin Cummings Special Topics Booklets

- Understanding the Human Genome Project (0-8053-6774-8)
- Stem Cells and Cloning (0-8053-4864-6)
- Biological Terrorism (0-8053-4868-9)
- The Biology of Cancer (0-8053-4867-0)

The Chemistry of Life CD-ROM, Second Edition (0-8053-3063-1)

Robert M. Thornton, University of California, Davis

This CD-ROM helps biology students grasp the essentials of chemistry with animations, interactive exercises, and quizzes with feedback.

An Introduction to Chemistry for Biology Students, Eighth Edition (0-8053-3970-1)

George I. Sackheim, University of Illinois, Chicago

This printed workbook helps students master all the basic facts, concepts, and terminology of chemistry that they need for their life science course.

Biomath: Problem Solving for Biology Students (0-8053-06524-9)

Robert W. Keck and Richard R. Patterson

A Short Guide to Writing about Biology, Fourth Edition (0-321-07843-8)

Jan A. Pechenik, Tufts University

Spanish Glossary (0-8053-7182-6)

Laura P. Zanello

Supplements for the Instructor

Campbell Media Manager (set of 8 CD-ROMs) **(0-8053-7153-7)**

The Campbell Media Manager combines all the instructor and student media for Campbell/Reece *BIOLOGY* into one chapter-by-chapter resource. It includes eight CD-ROMs, one for each unit in the text. Instructor media includes PowerPoint Lectures, PowerPoint TextEdit Art, PowerPoint Active Lecture Questions, and the Image Library—1,600 photos, all art from the book with and without labels, selected art layered for step-by-step presentation, tables, 85 videos, and more than 100 animations. Also included are Lecture Outlines in Word format for each chapter. (These resources are also available in the Instructor Resources section at www.campbellbiology.com.) The Campbell Media Manager also includes printed thumbnail-sized images for easy viewing of all the resources in the Image Library and a convenient fold-out Quick Reference Guide.

A screenshot of the Campbell Media Manager software interface. The top navigation bar includes links for Home, FAQs, Tech Help, Tech Support, Credits, Tutor Center, and AW-BC.com. On the left, a sidebar lists 'CAMPBELL MEDIA MANAGER BIOLOGY Seventh Edition' and 'INSTRUCTOR RESOURCES' sections such as Image Library, PowerPoint Library & Lecture Outlines, and Media Library. The main content area shows 'Unit 1: The Chemistry of Life'. The 'Instructor Media' section displays a thumbnail of a PowerPoint slide titled 'Cell Structure' with a diagram of a cell. The 'Student Media' section shows a thumbnail of a worksheet titled 'Investigations' with various lab report components. Both sections include descriptive text about their contents.

Instructor's Guide to Text and Media (0-8053-7148-6)

Joan Sharp, Simon Fraser University

This reference tool includes a chapter-by-chapter listing of all the text and media resources available to instructors and students organized by key concepts. It also includes objectives, key terms, and word roots. New to this edition are de-

scriptions of frequent student misconceptions for each chapter and suggestions for how to address these concerns. The Instructors Guide is available in print and in Word format.

Lecture Outlines

Joan Sharp, Simon Fraser University

Chapter lecture outlines are available in Word format in the Instructor Resources section at www.campbellbiology.com.

Transparency Acetates (0-8053-7149-4)

Approximately 1,000 acetates include all full-color illustrations and tables from the text, many of which incorporate photos. In addition, selected figures illustrating key concepts are broken down into layers for step-by-step lecture presentation.

Printed Test Bank (0-8053-7154-0)

Computerized Test Bank (0-8053-7153-2)

Edited by William Barstow, University of Georgia

Thoroughly revised and updated, the Seventh Edition test bank also includes optional questions from the book's Self-Quizzes and questions related to the media to encourage students to use these resources. Available in print, on a cross-platform CD-ROM, and in the instructor section of CourseCompass™, Blackboard, and WebCT.

PowerPoint Lectures

Chris C. Romero, Front Range Community College, Larimer Campus

PowerPoint Lectures are provided for each chapter and include the art, photos, tables, and an editable lecture outline. The PowerPoint Lectures can be used as is or customized for your course with your own images and text and/or additional photos, videos, and animations from the Campbell Media Manager.

PowerPoint TextEdit Art

All the art, photos, and tables are provided in PowerPoint on the Campbell Media Manager. Selected figures are layered for step-by-step presentation. The PowerPoint TextEdit Art can be used as is or labels can be edited in PowerPoint.

NEW! Biological Inquiry: A Workbook of

Investigative Cases, Instructor Version

(0-8053-7177-X)

The Instructor Version provides specific and detailed suggestions on how to use each case study effectively, outlining links to specific content in *BIOLOGY*, Seventh Edition, and other

supplements, providing direction on how to facilitate problem-based learning, and listing suggested answers and opportunities for extended investigations.

{Practicing Biology, Instructor's Edition, Second Edition (0-8053-8184-2)}

The instructor's version is available online at:
<http://suppscen.tral.aw.com>.

Course Management Systems

The content from the Campbell *BIOLOGY* website is also available in these popular course management systems: CourseCompass, Blackboard, and WebCT. For more information, visit <http://cms.aw.com>.

Classroom Response Systems

Invigorate lectures with Active Lecture Questions. These multiple-choice questions are adapted from various sources, including the end-of-chapter questions, *Student Study Guide, Test Bank*, and *Biomath: Problem Solving for Biology* by Robert W Keck and Richard R. Patterson. The questions are available in PowerPoint format via Supplements Central (http://supps_central.aw.com) or preloaded on H-ITT and PRS. Sources and answers are located in the PowerPoint Notes field. Selected questions in each chapter include additional Discussion Points added as suggestions for the instructor.

Supplements for the Lab

Investigating Biology, Fifth Edition (0-8053-7196-6)

Judith Giles Morgan, Emory University, and M. Eloise Brown Carter, Oxford College of Emory University

With its distinctive investigative approach to learning, this laboratory manual encourages students to practice science. Students are invited to pose hypotheses, make predictions, conduct open-ended experiments, collect data, and then apply the results to new problems.

Investigating Biology, Annotated Instructor's Edition, Fifth Edition (0-8053-7180-X)

Teaching information, added to the original Student Edition text, includes margin notes with hints on lab procedures, additional art, and answers to in-text and end-of-chapter questions from the Student Edition. Also featured is a detailed Teaching Plan at the end of each lab with specific suggestions for organizing labs, including estimated time allotments and suggestions for encouraging independent thinking and collaborative discussion.

Preparation Guide for Investigating Biology, Fifth Edition (0-8053-7181-8)

Guides lab coordinators in ordering materials as well as in planning, setting up, and running labs.

NEW! Designs for Bio-Explorations (0-8053-7229-6)

Janet Lanza, University of Arkansas at Little Rock

Eight inquiry-based laboratory exercises offer students creative control over the projects they undertake. Students are provided background information that enables them to design and conduct their own experiments.

NEW! Designs for Bio-Explorations, Instructor's Version (0-8053-7228-8)

The instructor's version is available online at:
<http://suppscentral.aw.com>.

Symbiosis Book Building Kit—Customized Lab Manuals (0-201-72142-2)

Build a customized lab manual, choosing the labs you want, importing artwork from our graphics library, and even adding your own material, and get a macle-to-order black and white lab manual. Visit <http://vvAv.pearsonc1stam.camJdatabase/symbiosis.html> for more information.

Biology Labs On-Line (wTvw.biologylabsonline.com)

Twelve on-line labs enable students to expand their scientific horizons beyond the traditional wet lab setting and perform potentially dangerous, lengthy, or expensive experiments in an electronic environment. Each experiment can be repeated as often as necessary, employing a different set of variables each time. The labs are available for purchase individually or in a 12-pack with the printed Student Lab Manual.

Student Lab Manual for Biology Labs On-Line (0-8053-7017-X)

Instructor's Lab Manual for Biology Labs On-Line (0-8053-7018-8)

Inquiry Figures

- 1.29 Does the presence of poisonous coral snakes affect predation rates on their mimics, king snakes? 23
4.2 Could organic compounds have been synthesized abiotically on the early Earth? 59
7.6 Do membrane proteins move? 127
10.9 Which wavelengths of light are most effective in driving photosynthesis? 187
12.8 During anaphase, do kinetochore microtubules shorten at their spindle pole ends or their kinetochore ends? 225
12.13 Are there molecular signals in the cytoplasm that regulate the cell cycle? 228
12.17 Does platelet-derived growth factor (PDGF) stimulate the division of human fibroblast cells in culture? 231
14.3 When *Y*₁ pea plants with purple flowers are allowed to self-pollinate, what flower color appears in the F₂ generation? 253
14.8 Do the alleles for seed color and seed shape sort into gametes dependency (together) or independently? 257
15.4 In a cross between a wild-type female fruit fly and a mutant white-eyed male, what color eyes will the F₁ and F₂ offspring have? 277
15.5 Are the genes for body color and wing size in fruit flies located on the same chromosome or different chromosomes? 279
16.2 Can the genetic trait of pathogenicity be transferred between bacteria? 294
16.4 Is DNA or protein the genetic material of phage T2? 295
16.11 Does DNA replication follow the conservative, semiconservative, or dispersive model? 300
17.2 Do individual genes specify different enzymes in arginine biosynthesis? 311
18.15 Can a bacterial cell acquire genes from another individual? 347
21.5 Can a differentiated plant cell develop into a whole plant? 415
21.6 Can the nucleus from a differentiated animal cell direct development of an organism? 416
21.21 Which cell layers in the floral meristem determine the number of floral organs? 430
22.12 Can predation pressure select for size and age at maturity in guppies? 447

- 23.11** Does geographic variation in yarrow plants have a genetic component? 464
24.7 Can divergence of allopatric fruit fly populations lead to reproductive isolation? 477
24.10 Does sexual selection in cichlids result in reproductive isolation? 480
26.2 Can organic molecules form in a reducing atmosphere? 513
31.21 Does having mycorrhizae benefit a plant? 620
36.19 What causes phloem sap to flow from source to sink? 753
39.5 What part of a coleoptile senses light, and how is the signal transmitted? 792
39.6 Does asymmetric distribution of a growth-promoting chemical cause a coleoptile to grow toward the light? 793
39.7 What causes polar movement of auxin from shoot tip to base? 795
39.13 How does ethylene concentration affect the triple response in seedlings? 799
39.17 What wavelengths stimulate phototropic bending toward light? 803
39.18 How does the order of red and far-red illumination affect seed germination? 803
39.22 How does interrupting the dark period with a brief exposure to light affect flowering? 807
39.23 Is phytochrome the pigment that measures the interruption of dark periods in photoperiodic response? 807
39.24 Is there a flowering hormone? 808
44.6 What role does fur play in water conservation by camels? 926
47.4 What is the effect of sperm binding on Ca^{2+} distribution in the egg? 990
47.21 Does fibronectin promote cell migration? 1002
47.22 Is cadherin required for development of the blastula? 1003
47.24 How does distribution of the gray crescent at the first cleavage affect the potency of the two daughter cells? 1005
47.25 Can the dorsal lip of the blastopore induce cells in another part of the amphibian embryo to change their developmental fate? 1006
47.27 What role does the zone of polarizing activity (ZPA) play in limb pattern formation in vertebrates? 1008
48.25 Are mammalian biological clocks influenced by external cues? 1031
49.13 How do insects detect different tastes? 1055
49.37 What are the energy costs of locomotion? J074
50.8 Does feeding by sea urchins and limpets affect seaweed distribution? J086"
- 51.10** Are the different songs of closely related green lacewing species under genetic control? 1112
51.12 How does dietary environment affect mate choice by female *Drosophila mojavensis*? 1113
51.14 Does a digger wasp use landmarks to find her nest? 1115
52.7 How does caring for offspring affect parental survival in kestrels? 1142
52.18 How stable is the Isle Royale moose population? 1150
53.2 Can a species' niche be influenced by interspecific competition? J160
53.28 How does species richness relate to area? 1278
54.6 Which nutrient limits phytoplankton production along the coast of Long Island? 1189
54.9 Is phosphorus or nitrogen the limiting nutrient in a Hudson Bay salt marsh? 1191
55.10 What caused the drastic decline of the Illinois greater prairie chicken population? 1216

New to the Seventh Edition

The following list provides just a few highlights of what's new in *BIOLOGY*, Seventh Edition.

CHAPTER 1 Exploring Life

- Chapter 1 now includes a discussion of systems biology as one of the book's themes.
- The section on scientific inquiry is more robust and features a new case study of research on mimicry in snake populations.

UNIT ONE The Chemistry of Life

- At the suggestion of many instructors, the chapter on the basic principles of energy and metabolism, formerly Chapter 6, has been moved to Unit Two. In this edition, we provide a basic introduction to ATP in Chapter 4 and to enzymes in Chapter 5.

UNIT TWO The Cell

- The chapter 'An Introduction to Metabolism' is now Chapter 8 in Unit Two, where it directly precedes the chapters on cellular respiration and photosynthesis. In addition to an improved presentation of the thermodynamic laws, Chapter 8 expands upon the introduction to ATP and enzymes given in Unit One.

UNIT THREE Genetics

- Chapter 19 has been updated throughout, including expanded coverage of histone modifications, DNA methylation, and epigenetic inheritance; a new discussion of regulation of gene expression by miRNAs and siRNAs; an updated discussion of the types of DNA sequences in the human genome; and a new section on genome evolution.
- In Chapter 20, new material ranges from a discussion of the current estimate of the number of human genes, to a more global view of gene interactions within a given genome, to comparisons of genomes of different species, all part of the current thrust to understand the biology of whole systems.
- Chapter 21 provides an expanded section on the evolution of development ('evo-devo'), including a new comparison of the genes involved in animal and plant development.

UNIT FOUR Mechanisms of Evolution

- Changes to this unit aim to combat misconceptions about evolutionary processes, as well as to eliminate hints of circular reasoning that are a target of anti-evolution arguments.
- New examples highlight vibrant research in evolutionary biology, including the continued impact of molecular systematics on phylogenetic studies and the use of virtual populations to model evolutionary processes.
- Chapter 25 has been revised to focus on the inquiry process involved in exploring phylogeny. Expanded coverage of genome evolution includes a new discussion of neutral theory.

UNIT FIVE The Evolutionary History of Biological Diversity

- Chapter 26, now titled "The Tree of Life: An Introduction to Biodiversity," is newly focused on placing life's diversity in the context of Earth's history, with emphasis on the major branchings in the tree of life.
- Updates in Chapter 27 (now titled "Prokaryotes") reflect new data regarding prokaryote classification and the growing evidence for cooperative relationships among prokaryotes.
- Chapters 28 (now titled "Protists"), 29, 30, and 31 include more information on the natural history, ecological roles, and human impact of various groups of protists, plants, and fungi. Updates include the implications of recent phylogenetic findings on classification, such as the recognition of a new fungal phylum (Glomeromycota).
- Chapters 32, 33, and 34 present a cohesive view of animal diversity, including an overview of hypotheses regarding animal phylogeny, an expanded survey of invertebrate phyla, added detail on natural history, updating of vertebrate classification, and recent findings relating to human origins.

UNIT SIX Plant Form and Function

- New examples highlight the role of biotechnology in agriculture, such as the development of genetically engineered "smart plants" that signal phosphorus deficiencies and the potential application of "terminator technology" to the problem of transgene escape from GM crops.
- New content in Chapter 39 focuses on the potential application of systems biology to the study of plant hormone interactions.

UNIT SEVEN Animal Form and Function

- New research examples highlight the physiology of diverse animals and relate physiological adaptations to the animals' ecological context.
- Content on thermoregulation has been moved from Chapter 44 (now titled "Osmoregulation and Excretion") to Chapter 40 ("Basic Principles of Animal Form and Function"), where it serves as an extended example of various animals' ability to maintain homeostasis.
- New sections on the vertebrate brain and on neurological disorders highlight recent discoveries as well as the tantalizing opportunities in these dynamic areas of research.

UNIT EIGHT Ecology

- A new Chapter 51 ("Behavioral Ecology") brings the subject into the 21st century, with expanded coverage of game theory, mate choice, and animal cognition.
- New examples throughout the unit highlight current research and applications, including facilitation and community structure, the FACTS-1 study of CO₂ impact on forests, and novel approaches in restoration ecology.

CONCEPT 2.3 The formation and function of molecules depend on chemical bonding between atoms 39

 Covalent Bonds 39

 Ionic Bonds 41

 Weak Chemical Bonds 42

 Molecular Shape and Function 42

CONCEPT 2.4 Chemical reactions make and break chemical bonds 44

3 Water and the Fitness of the Environment 47

OVERVIEW: The Molecule That Supports All of Life 47

CONCEPT 3.1 The polarity of water molecules results in hydrogen bonding 47

CONCEPT 3.2 Four emergent properties of water contribute to Earth's fitness for life 48

 Cohesion 48

 Moderation of Temperatures 49

 Insulation of Bodies of Water by Floating Ice 50

 The Solvent of Life 51

CONCEPT 3.3 Dissociation of water molecules leads to acidic and basic conditions that affect living organisms 53

 Effects of Changes in pH 53

 The Threat of Acid Precipitation 55

4 Carbon and the Molecular Diversity of Life 58

OVERVIEW: Carbon—The Backbone of Biological Molecules 58

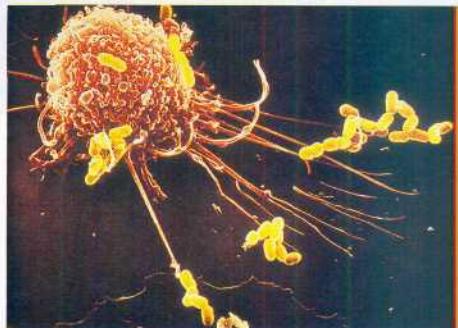

CONCEPT 4.1 Organic chemistry is the study of carbon compounds 58

CONCEPT 4.2 Carbon atoms can form diverse molecules by bonding to four other atoms 59

- The Formation of Bonds with Carbon 59
- Molecular Diversity Arising from Carbon Skeleton Variation 61

CONCEPT 4.3 Functional groups are the parts of molecules involved in chemical reactions 63

- The Functional Groups Most Important in the Chemistry of Life 63
- ATP: An Important Source of Energy for Cellular Processes 66
- The Chemical Elements of Life: A Review 66

5 The Structure and Function of Macromolecules 68

OVERVIEW: The Molecules of Life 68

CONCEPT 5.1 Most macromolecules are polymers, built from monomers 68

- The Synthesis and Breakdown of Polymers 68
- Diversity of Polymers 69

CONCEPT 5.2 Carbohydrates serve as fuel and building material 69

- Sugars 70
- Polysaccharides 71

CONCEPT 5.3 Lipids are a diverse group of hydrophobic molecules 74

- Fats 75
- Phospholipids 76
- Steroids 77

CONCEPT 5.4 Proteins have many structures, resulting in a wide range of functions 77

- Polypeptides 78
- Protein Conformation and Function 81

CONCEPT 5.5 Nucleic acids store and transmit hereditary information 85

- The Roles of Nucleic Acids 86
- The Structure of Nucleic Acids 87
- The DNA Double Helix 88
- DNA and Proteins as Tape Measures of Evolution 89

The Theme of Emergent Properties in the Chemistry of Life: A Review 89

UNIT TWO

The Cell 92

6 A Tour of the Cell 94

OVERVIEW: The Importance of Cells 94

CONCEPT 6.1 To study cells, biologists use microscopes and the tools of biochemistry 94

- Microscopy 95
- Isolating Organelles by Cell Fractionation 97

CONCEPT 6.2 Eukaryotic cells have internal membranes that compartmentalize their functions 98

- Comparing Prokaryotic and Eukaryotic Cells 98
- A Panoramic View of the Eukaryotic Cell 99

CONCEPT 6.3 The eukaryotic cell's genetic instructions are housed in the nucleus and carried out by the ribosomes 102

- The Nucleus: Genetic Library of the Cell 102
- Ribosomes: Protein Factories in the Cell 102

CONCEPT 6.4 The endomembrane system regulates protein traffic and performs metabolic functions in the cell 104

- The Endoplasmic Reticulum: Biosynthetic Factory 104
- The Golgi Apparatus: Shipping and Receiving Center 105
- Lysosomes: Digestive Compartments 107
- Vacuoles: Diverse Maintenance Compartments 108
- The Endomembrane System: A Review 108

CONCEPT 6.5 Mitochondria and chloroplasts change energy from one form to another 109

- Mitochondria: Chemical Energy Conversion 109
- Chloroplasts: Capture of Light Energy 110
- Peroxisomes: Oxidation 110

CONCEPT 6.6 The cytoskeleton is a network of fibers that organizes structures and activities in the cell 112

- Roles of the Cytoskeleton: Support, Motility, and Regulation 112
- Components of the Cytoskeleton 113

CONCEPT 6.7 Extracellular components and connections between cells help coordinate cellular activities 118

- Cell Walls of Plants 118
- The Extracellular Matrix (ECM) of Animal Cells 119
- Intercellular Junctions 120

THE CELL: A Living Unit Greater Than the Sum of Its Parts 120

7 Membrane Structure and Function 124

OVERVIEW: Life at the Edge 124

CONCEPT 7.1 Cellular membranes are fluid mosaics of lipids and proteins 124

- Membrane Models: *Scientific Inquiry* 125
- The Fluidity of Membranes 126
- Membrane Proteins and Their Functions 127

| | | | |
|---|------------|---|------------|
| The Role of Membrane Carbohydrates in Cell-Cell Recognition | 129 | Catabolic Pathways and Production of ATP | 161 |
| Synthesis and Sidedness of Membranes | 129 | Redox Reactions: Oxidation and Reduction | 161 |
| CONCEPT 7.2 Membrane structure results in selective permeability | 130 | The Stages of Cellular Respiration: <i>A Preview</i> | 164 |
| The Permeability of the Lipid Bilayer | 130 | CONCEPT 9.2 Glycolysis harvests chemical energy by oxidizing glucose to pyruvate | 165 |
| Transport Proteins | 130 | CONCEPT 9.3 The citric acid cycle completes the energy-yielding oxidation of organic molecules | 168 |
| CONCEPT 7.3 Passive transport is diffusion of a substance across a membrane with no energy investment | 130 | CONCEPT 9.4 During oxidative phosphorylation, chemiosmosis couples electron transport to ATP synthesis | 170 |
| Effects of Osmosis on Water Balance | 131 | The Pathway of Electron Transport | 170 |
| Facilitated Diffusion: Passive Transport Aided by Proteins | 133 | Chemiosmosis: The Energy-Coupling Mechanism | 171 |
| CONCEPT 7.4 Active transport uses energy to move solutes against their gradients | 134 | An Accounting of ATP Production by Cellular Respiration | 173 |
| The Need for Energy in Active Transport | 134 | CONCEPT 9.5 Fermentation enables some cells to produce ATP without the use of oxygen | 174 |
| Maintenance of Membrane Potential by Ion Pumps | 134 | Types of Fermentation | 175 |
| Cotransport: Coupled Transport by a Membrane Protein | 136 | Fermentation and Cellular Respiration Compared | 175 |
| CONCEPT 7.5 Bulk transport across the plasma membrane occurs by exocytosis and endocytosis | 137 | The Evolutionary Significance of Glycolysis | 176 |
| Exocytosis | 137 | CONCEPT 9.6 Glycolysis and the citric acid cycle connect to many other metabolic pathways | 176 |
| Endocytosis | 137 | The Versatility of Catabolism | 176 |
| 3 An Introduction to Metabolism | 141 | Biosynthesis (Anabolic Pathways) | 177 |
| OVERVIEW: The Energy of Life | 141 | Regulation of Cellular Respiration via Feedback Mechanisms | 177 |
| CONCEPT 8.1 An organism's metabolism transforms matter and energy⁷, subject to the laws of thermodynamics | 141 | 10 Photosynthesis | 181 |
| Organization of the Chemistry of Life into Metabolic Pathways | 141 | OVERVIEW: The Process That Feeds the Biosphere | 181 |

| The Laws of Energy Transformation | 143 | Chloroplasts: The Sites of Photosynthesis in Plants | 182 |
| CONCEPT 8.2 The free-energy change of a reaction tells us whether the reaction occurs spontaneously | 145 | Tracking Atoms Through Photosynthesis: <i>Scientific Inquiry</i> | 183 |
| Free-Energy Change, AG | 145 | The Two Stages of Photosynthesis: <i>A Preview</i> | 184 |
| Free Energy, Stability, and Equilibrium | 145 | CONCEPT 10.2 The light reactions convert solar energy to the chemical energy of ATP and NADPH | 186 |
| Free Energy and Metabolism | 146 | The Nature of Sunlight | 186 |
| CONCEPT 8.3 ATP powers cellular work by coupling exergonic reactions to endergonic reactions | 148 | Photosynthetic Pigments: The Light Receptors | 186 |
| The Structure and Hydrolysis of ATP | 148 | Excitation of Chlorophyll by Light | 188 |
| How ATP Performs Work | 149 | A Photosystem: A Reaction Center Associated with Light-Harvesting Complexes | 189 |
| The Regeneration of ATP | 150 | Noncyclic Electron Flow | 190 |
| CONCEPT 8.4 Enzymes speed up metabolic reactions by lowering energy barriers | 150 | Cyclic Electron Flow | 191 |
| The Activation Energy Barrier | 150 | A Comparison of Chemiosmosis in Chloroplasts and Mitochondria | 192 |
| How Enzymes Lower the E _A Barrier | 152 | CONCEPT 10.3 The Calvin cycle uses ATP and NADPH to convert CO₂ to sugar | 193 |
| Substrate Specificity of Enzymes | 152 | Photorespiration: An Evolutionary Relic? | 195 |
| Catalysis in the Enzymes Active Site | 152 | C ₄ Plants | 196 |
| Effects of Local Conditions on Enzyme Activity | 154 | CAM Plants | 196 |
| CONCEPT 8.5 Regulation of enzyme activity helps control metabolism | 156 | The Importance of Photosynthesis: <i>A Review</i> | 197 |
| Allosteric Regulation of Enzymes | 156 | | |
| Specific Localization of Enzymes Within the Cell | 157 | | |
| 9 Cellular Respiration: Harvesting Chemical Energy | 160 | | |
| OVERVIEW: Life Is Work | 160 | | |
| CONCEPT 9.1 Catabolic pathways yield energy by oxidizing organic fuels | 161 | | |

11 Cell Communication 201

OVERVIEW: The Cellular Internet 201

CONCEPT 11.1 External signals are converted into responses within the cell 201

Evolution of Cell Signaling 201

Local and Long-Distance Signaling 202

The Three Stages of Cell Signaling: A Preview 203

CONCEPT 11.2 Reception: A signal molecule binds to a receptor protein, causing it to change shape 204

Intracellular Receptors 205

Receptors in the Plasma Membrane 205

CONCEPT 11.3 Transduction: Cascades of molecular interactions relay signals from receptors to target molecules in the cell 208

Signal Transduction Pathways 208

Protein Phosphorylation and Dephosphorylation 209

Small Molecules and Ions as Second Messengers 210

CONCEPT 11.4 Response: Cell signaling leads to regulation of cytoplasmic activities or transcription 212

Cytoplasmic and Nuclear Responses 212

Fine-Tuning of the Response 213

12 The Cell Cycle 218

OVERVIEW: The Key Roles of Cell Division 218

CONCEPT 12.1 Cell division results in genetically identical daughter cells 219

Cellular Organization of the Genetic Material 219

Distribution of Chromosomes During Cell Division 219

CONCEPT 12.2 The mitotic phase alternates with interphase in the cell cycle 221

Phases of the Cell Cycle 221

The Mitotic Spindle: *A Closer Look* 221

Cytokinesis: *A Closer Look* 224

Binary Fission 226

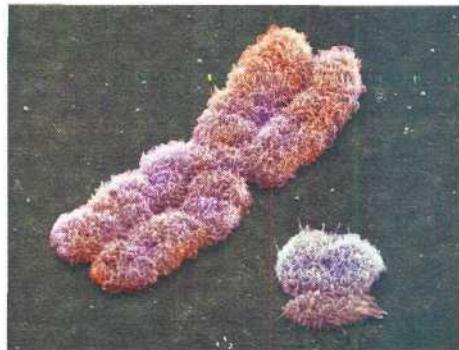

The Evolution of Mitosis 227

CONCEPT 12.3 The cell cycle is regulated by a molecular control system 228

Evidence for Cytoplasmic Signals 228

The Cell Cycle Control System 229

Loss of Cell Cycle Controls in Cancer Cells 232

CONCEPT 13.3 Meiosis reduces the number of chromosome sets from diploid to haploid 243

The Stages of Meiosis 243

A Comparison of Mitosis and Meiosis 247

CONCEPT 13.4 Genetic variation produced in sexual life cycles contributes to evolution 247

Origins of Genetic Variation Among Offspring 247

Evolutionary Significance of Genetic Variation Within Populations 248

14 Mendel and the Gene Idea 251

OVERVIEW: Drawing from the Deck of Genes 251

CONCEPT 14.1 Mendel used the scientific approach to identify two laws of inheritance 251

Mendel's Experimental, Quantitative Approach 252

The Law of Segregation 253

The Law of Independent Assortment 256

CONCEPT 14.2 The laws of probability govern Mendelian inheritance 258

The Multiplication and Addition Rules Applied to Monohybrid Crosses 258

Solving Complex Genetics Problems with the Rules of Probability 259

CONCEPT 14.3 Inheritance patterns are often more complex than predicted by simple Mendelian genetics 260

Extending Mendelian Genetics for a Single Gene 260

Extending Mendelian Genetics for Two or More Genes 262

Nature and Nurture: The Environmental Impact on Phenotype 264

Integrating a Mendelian View of Heredity and Variation 264

CONCEPT 14.4 Many human traits follow Mendelian patterns of inheritance 265

Pedigree Analysis 265

Recessively Inherited Disorders 266

Dominantly Inherited Disorders 267

Multifactorial Disorders 268

Genetic Testing and Counseling 268

UNIT THREE

Genetics 236

13 Meiosis and Sexual Life Cycles 238

OVERVIEW: Hereditary Similarity and Variation 238

CONCEPT 13.1 Offspring acquire genes from parents by inheriting chromosomes 238

Inheritance of Genes 239

Comparison of Asexual and Sexual Reproduction 239

CONCEPT 13.2 Fertilization and meiosis alternate in sexual life cycles 240

Sets of Chromosomes in Human Cells 240

Behavior of Chromosome Sets in the Human Life Cycle 241

The Variety of Sexual Life Cycles 242

115 The Chromosomal Basis of Inheritance 274

OVERVIEW: Locating Genes on Chromosomes 274

CONCEPT 15.1 Mendelian inheritance has its physical basis in the behavior of chromosomes 274

Morgan's Experimental Evidence: *Scientific Inquiry* 276

CONCEPT 15.2 Linked genes tend to be inherited together because they are located near each other on the same chromosome 277

How Linkage Affects Inheritance: *Scientific Inquiry* 277

Genetic Recombination and Linkage 278

Linkage Mapping Using Recombination Data: *Scientific Inquiry* 279

CONCEPT 15.3 Sex-linked genes exhibit unique patterns of inheritance 282

The Chromosomal Basis of Sex 282

Inheritance of Sex-Linked Genes 283

X Inactivation in Female Mammals 284

CONCEPT 15.4 Alterations of chromosome number or structure cause some genetic disorders 285

Abnormal Chromosome Number 285

Alterations of Chromosome Structure 286

Human Disorders Due to Chromosomal Alterations 287

CONCEPT 15.5 Some inheritance patterns are exceptions to the standard chromosome theory 288

Genomic Imprinting 288

Inheritance of Organelle Genes 289

16 The Molecular Basis of Inheritance 293

OVERVIEW: Life's Operating Instructions 293

CONCEPT 16.1 DNA is the genetic material 293

The Search for the Genetic Material: *Scientific Inquiry* 293

Building a Structural Model of DNA: *Scientific Inquiry* 296

CONCEPT 16.2 Many proteins work together in DNA replication and repair 299

The Basic Principle: Base Pairing to a Template Strand 299

DNA Replication: *A Closer Look* 300

Proofreading and Repairing DNA 305

Replicating the Ends of DNA Molecules 306

17 From Gene to Protein 309

OVERVIEW: The Flow of Genetic Information 309

CONCEPT 17.1 Genes specify proteins via transcription and translation 309

Evidence from the Study of Metabolic Defects 309

Basic Principles of Transcription and Translation 311

The Genetic Code 312

CONCEPT 17.2 Transcription is the DNA-directed synthesis of RNA: closer look 315

Molecular Components of Transcription 315

Synthesis of an RNA Transcript 316

CONCEPT 17.3 Eukaryotic cells modify RNA after transcription 317

Alteration of mRNA Ends 317

Split Genes and RNA Splicing 318

CONCEPT 17.4 Translation is the RNA-directed synthesis of a polypeptide: a closer look 320

Molecular Components of Translation 320

Building a Polypeptide 323

Completing and Targeting the Functional Protein 324

CONCEPT 17.5 RNA plays multiple roles in the cell: a review 327

CONCEPT 17.6 Comparing gene expression in prokaryotes and eukaryotes reveals key differences 327

CONCEPT 17.7 Point mutations can affect protein structure and function 328

Types of Point Mutations 328

Mutagens 329

What is a Gene? Revisiting the Question 330

18 The Genetics of Viruses and Bacteria 334

OVERVIEW: Microbial Model Systems 334

CONCEPT 18.1 A virus has a genome but can reproduce only within a host cell 334

The Discovery of Viruses: *Scientific Inquiry* 334

Structure of Viruses 335

General Features of Viral Reproductive Cycles 336

Reproductive Cycles of Phages 337

Reproductive Cycles of Animal Viruses 339

Evolution of Viruses 342

CONCEPT 18.2 Viruses, viroids, and prions are formidable pathogens in animals and plants 343

Viral Diseases in Animals 343

Emerging Viruses 344

Viral Diseases in Plants 345

Viroids and Prions: The Simplest Infectious Agents 345

CONCEPT 18.3 Rapid reproduction, mutation, and genetic recombination contribute to the genetic diversity of bacteria 346

The Bacterial Genome and Its Replication 346

Mutation and Genetic Recombination as Sources of Genetic Variation 346

Mechanisms of Gene Transfer and Genetic Recombination in Bacteria 348

Transposition of Genetic Elements 351

CONCEPT 19.4 Individual bacteria respond to environmental change by regulating their gene expression 352

Operons: The Basic Concept 353

Repressible and Inducible Operons: Two Types of Negative Gene Regulation 354

Positive Gene Regulation 356

19 Eukaryotic Genomes: Organization, Regulation, and Evolution 359

OVERVIEW: How Eukaryotic Genomes Work and Evolve 359

CONCEPT 19.1 Chromatin structure is based on successive levels of DNA packing 359

Nucleosomes, or "Beads on a String" 360

Higher Levels of DNA Packing 360

| | |
|--|--|
| CONCEPT 19.2 Gene expression can be regulated at any stage, but the key step is transcription 362 | CONCEPT 20.5 The practical applications of DNA technology affect our lives in many ways 402 |
| Differential Gene Expression 362 | Medical Applications 402 |
| Regulation of Chromatin Structure 363 | Pharmaceutical Products 101 |
| Regulation of Transcription Initiation 364 | Forensic Evidence 404 |
| Mechanisms of Post-Transcriptional Regulation 368 | Environmental Cleanup 405 |

| Widespread Conservation of Developmental Genes Among Animals 431 | |
| Comparison of Animal and Plant Development 433 | |
| UNIT FOUR | |
| Mechanisms of Evolution 436 | |
| 22 Descent with Modification: A Darwinian View of Life 438 | |
| OVERVIEW: Darwin Introduces a Revolutionary Theory 438 | |
| CONCEPT 22.1 The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species 438 | |
| Resistance to the Idea of Evolution 439 | |
| Theories of Gradualism 440 | |
| Lamarck's Theory of Evolution 440 | |
| CONCEPT 22.2: In <i>The Origin of Species</i> , Darwin proposed that species change through natural selection 441 | |
| Darwin's Research 441 | |
| <i>The Origin of Species</i> 443 | |
| CONCEPT 22.3 Darwin's theory explains a wide range of observations 446 | |
| Natural Selection in Action 446 | |
| Homology, Biogeography, and the Fossil Record 448 | |

What Is Theoretical about the Darwinian View of Life? 451

23 The Evolution of Populations 454

OVERVIEW: The Smallest Unit of Evolution 454

CONCEPT 23.1 Population genetics provides a foundation for studying evolution 454

The Modern Synthesis 455

Gene Pools and Allele Frequencies 455

The Hardy-Weinberg Theorem 456

CONCEPT 23.2 Mutation and sexual recombination produce the variation that makes evolution possible 459

Mutation 459

Sexual Recombination 460

CONCEPT 23.3 Natural selection, genetic drift, and gene flow can alter a population's genetic composition 460

Natural Selection 460

Genetic Drift 460

Gene Flow 462

CONCEPT 23.4 Natural selection is the primary mechanism of adaptive evolution 462

Genetic Variation 462

A Closer Look at Natural Selection 464

The Preservation of Genetic Variation 466

Sexual Selection 468

The Evolutionary Enigma of Sexual

Reproduction 469

Why Natural Selection Cannot Fashion Perfect

Organisms 469

24 The Origin of Species 472

OVERVIEW: That "Mystery of Mysteries" 472

CONCEPT 24.1 The biological species concept emphasizes reproductive isolation 473

The Biological Species Concept 473

Other Definitions of Species 476

CONCEPT 24.2 Speciation can take place with or without geographic separation 476

AUopatric ("Other Country") Speciation 477

Sympatric ("Same Country") Speciation 478

Allopatric and Sympatric Speciation: A

Summary 480

Adaptive Radiation 480

Studying the Genetics of Speciation 481

The Tempo of Speciation 481

CONCEPT 24.3 Macroevolutionary changes can accumulate through many speciation events 482

Evolutionary Novelties 482

Evolution of the Genes That Control

Development 484

Evolution Is Not Goal Oriented 486

25 Phylogeny and Systematics 491

OVERVIEW: Investigating the Tree of Life 491

CONCEPT 25.1 Phylogenies are based on common ancestries inferred from fossil, morphological, and molecular evidence 492

The Fossil Record 492

Morphological and Molecular Homologies 492

CONCEPT 25.2 Phylogenetic systematics connects classification with evolutionary history 495

Binomial Nomenclature 496

Hierarchical Classification 496

Linking Classification and Phylogeny 496

CONCEPT 25.3 Phylogenetic systematics informs the construction of phylogenetic trees based on shared characters 497

Cladistics 498

Phylogenetic Trees and Timing 499

Maximum Parsimony and Maximum

Likelihood 501

Phylogenetic Trees as Hypotheses 501

CONCEPT 25.4 Much of an organism's evolutionary history is documented in its genome 504

Gene Duplications and Gene Families 505

Genome Evolution 505

CONCEPT 25.5 Molecular clocks help track evolutionary time 506

Molecular Clocks 506

The Universal Tree of Life 507

UNIT FIVE

The Evolutionary History of Biological Diversity 510

26 The Tree of Life: An Introduction to Biological Diversity 512

OVERVIEW: Changing Life on a Changing Earth 512

CONCEPT 26.1 Conditions on early Earth made the origin of life possible 513

Synthesis of Organic Compounds on Early Earth 513

Abiotic Synthesis of Polymers 514

Protobionts 515

The "RNA World" and the Dawn of Natural Selection 515

CONCEPT 26.2 The fossil record chronicles life on Earth 517

How Rocks and Fossils Are Dated 517

The Geologic Record 518

Mass Extinctions 518

CONCEPT 26.3 As prokaryotes evolved, they exploited and changed young Earth 521

The First Prokaryotes 521

Electron Transport Systems 521

Photosynthesis and the Oxygen Revolution 522

CONCEPT 26.4 Eukaryotic cells arose from symbioses and genetic exchanges between prokaryotes 523

The First Eukaryotes 523

Endosymbiotic Origin of Mitochondria and

Plastids 523

Eukaryotic Cells as Genetic Chimeras 524

CONCEPT 26.5 Multicellularity evolved several times in eukaryotes 525

The Earliest Mukicellular Eukaryotes 525

The Colonial Connection 526

The "Cambrian Explosion" 526

Colonization of Land by Plants, Fungi, and

Animals 527

Continental Drift 527

CONCEPT 26.6 New information has revised our understanding of the tree of life 529

Previous Taxonomic Systems 529

Reconstructing the Tree of Life: A Work in

Progress 529

27 Prokaryotes 534

OVERVIEW: They're (Almost) Everywhere! 534

CONCEPT 27.1 Structural, functional, and genetic adaptations contribute to prokaryote success 534

Cell-Surface Structures 534

Motility 536

Internal and Genomic Organization 537

Reproduction and Adaptation 537

CONCEPT 27.2 A great diversity of nutritional and metabolic adaptations have evolved in prokaryotes 538

Metabolic Relationships to Oxygen 538

Nitrogen Metabolism 538

Metabolic Cooperation 538

CONCEPT 27.3 Molecular systematics is illuminating prokaryote phylogeny 540

Lessons from Molecular Systematics 540

Bacteria 541

Archaea 541

CONCEPT 27.4 Prokaryotes play crucial roles in the biosphere 544

Chemical Recycling 544

Symbiotic Relationships 545

CONCEPT 27.5 Prokaryotes have both harmful and beneficial impacts on humans 545

Pathogenic Prokaryotes 545

Prokaryotes in Research and Technology 546

28 Protists 549

OVERVIEW: A World in a Drop of Water 549

CONCEPT 28.1 Protists are an extremely diverse assortment of eukaryotes 549

Endosymbiosis in Eukaryotic Evolution 550

CONCEPT 28.2 Diplomonads and parabasalids have modified mitochondria 552

Diplomonads 552

Parabasalids 553

CONCEPT 28.3 Euglenozoans have flagella with a unique internal structure 553

Kinetoplastids 553

Euglenids 554

CONCEPT 28.4 Alveolates have sacs beneath the plasma membrane 555

Dinoflagellates 555

Apicomplexans 555

Gliates 556

CONCEPT 28.5 Slrmenopiles have "hairy" and smooth flagella 558

Oomycetes (Water Molds and Their Relatives) 558

Diatoms 559

Golden Algae 560

Brown Algae 560

CONCEPT 28.6 Cercozoans and radiolarians have threadlike pseudopodia 563

Foraminiferans (Forams) 563

Radiolarians 563

CONCEPT 28.7 Amoebozoans have lobe-shaped pseudopodia 564

Gymnamoebas 564

Entamoebas 564

Slime Molds 564

CONCEPT 28.8 Red algae and green algae are the closest relatives of land plants 567

Red Algae 567

Green Algae 567

29 Plant Diversity I: How Plants Colonized Land 573

OVERVIEW: The Greening of Earth 573

CONCEPT 29.1 Land plants evolved from green algae 573

Morphological and Biochemical Evidence 573

Genetic Evidence 574

Adaptations Enabling the Move to Land 574

CONCEPT 29.2 Land plants possess a set of derived terrestrial adaptations 575

Defining the Plant Kingdom 575

Derived Traits of Plants 575

| | |
|---|------------|
| The Origin and Diversification of Plants | 585 |
| CONCEPT 29.3 The life cycles of mosses and other bryophytes are dominated by the gametophyte stage | 580 |
| Bryophyte Gametophytes | 580 |
| Bryophyte Sporophytes | 580 |
| The Ideological and Economic Importance of Mosses | 583 |
| CONCEPT 29.4 Ferns and other seedless vascular plants formed the first forests | 584 |
| Origins of Vascular Plants | 584 |
| Classification of Seedless Vascular Plants | 586 |
| The Significance of Seedless Vascular Plants | 588 |
| 30 Plant Diversity II: The Evolution of Seed Plants | 591 |
| OVERVIEW: Feeding the World | 591 |
| CONCEPT 30.1 The reduced gametophytes of seed plants are protected in ovules and pollen grains | 591 |
| Advantages of Reduced Gametophytes | 591 |
| Homospory: The Rule Among Seed Plants | 592 |
| Ovules and Production of Eggs | 592 |
| Pollen and Production of Sperm | 592 |
| The Evolutionary Advantage of Seeds | 593 |
| CONCEPT 30.2 Gymnosperms bear "naked" seeds, typically on cones | 593 |
| Gymnosperm Evolution | 596 |
| A Closer Look at the Life Cycle of a Pine | 596 |
| CONCEPT 30.3 The reproductive adaptations of angiosperms include flowers and fruits | 598 |
| Characteristics of Angiosperms | 598 |
| Angiosperm Evolution | 601 |
| Angiosperm Diversity | 602 |
| Evolutionary Links Between Angiosperms and Animals | 604 |
| CONCEPT 30.4 Human welfare depends greatly on seed plants | 605 |
| Products from Seed Plants | 605 |
| Threats to Plant Diversity | 606 |
| 31 Fungi | 608 |
| OVERVIEW: Mighty Mushrooms | 608 |
| CONCEPT 31.1 Fungi are heterotrophs that feed by absorption | 608 |
| Nutrition and Fungal Lifestyles | 608 |
| Body Structure | 609 |
| CONCEPT 31.2 Fungi produce spores through sexual or asexual life cycles | 610 |
| Sexual Reproduction | 610 |
| Asexual Reproduction | 611 |
| CONCEPT 31.3 Fungi descended from an aquatic, single-celled, flagellated protist | 612 |
| The Origin of Fungi | 612 |
| The Move to Land | 612 |
| CONCEPT 31.4 Fungi have radiated into a diverse set of lineages | 612 |
| Chytrids | 613 |
| Zygomycetes | 613 |
| Glomeromycetes | 615 |
| Ascomycetes | 616 |
| Basidiomycetes | 618 |
| CONCEPT 31.5 Fungi have a powerful impact on ecosystems and human welfare | 620 |
| Decomposers | 620 |
| Symbionts | 620 |
| Pathogens | 622 |
| Practical Uses of Fungi | 623 |
| 32 An Introduction to Animal Diversity | 626 |
| OVERVIEW: Welcome to Your Kingdom | 626 |
| CONCEPT 3a.i Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers | 626 |
| Nutritional Mode | 626 |
| Cell Structure and Specialization | 626 |
| Reproduction and Development | 627 |
| CONCEPT 32.2 The history of animals may span more than a billion years | 628 |
| Neoproterozoic Era (1 Billion—542 Million Years Ago) | 628 |
| Paleozoic Era (542–251 Million Years Ago) | 629 |
| Mesozoic Era (251–65.5 Million Years Ago) | 629 |
| Cenozoic Era (65.5 Million Years Ago to the Present) | 629 |
| CONCEPT 32.3 Animals can be characterized by "body plans" | 630 |
| Symmetry | 630 |
| Tissues | 630 |
| Body Cavities | 631 |
| Protostome and Deuterostome Development | 631 |
| CONCEPT 32.4 Leading hypotheses agree on major features of the animal phylogenetic tree | 633 |
| Points of Agreement | 633 |
| Disagreement over the Bilaterians | 634 |
| Future Directions in Animal Systematics | 636 |
| 33 Invertebrates | 638 |
| OVERVIEW: Life Without a Backbone | 638 |
| CONCEPT 33.1 Sponges are sessile and have a porous body and choanocytes | 642 |
| CONCEPT 33.2 Cnidarians have radial symmetry, a gastrovascular cavity, and cnidocytes | 643 |
| Hydrozoans | 644 |
| Scyphozoans | 644 |
| Cubozoans | 645 |
| Anthozoa | 645 |
| CONCEPT 33.3 Most animals have bilateral symmetry | 646 |
| Flatworms | 646 |
| Rotifers | 648 |
| Lophophorates: Ectoprocts, Phoronids, and Brachiopods | 649 |
| Nematarians | 649 |
| CONCEPT 33.4 Molluscs have a muscular foot, a visceral mass, and a mantle | 650 |
| Chitons | 651 |
| Gastropods | 651 |

Bivalves 652
Cephalopods 652

CONCEPT 33.s Annelids are segmented worms 653

Oligochaetes 653
Polychaetes 655
Leeches 655

CONCEPT 33.6 Nematodes are nonsegmented

pseudocoelomates covered by a tough cuticle 655

CONCEPT 33.7 Arthropods are segmented ecdysozoans that have an exoskeleton and jointed appendages 656

General Characteristics of Arthropods 656
Cheliceriforms 658
Mynapods 659
Insects 660
Crustaceans 664

CONCEPT 33.8 Echinoderms and chordates are deuterostomes 665

Echinoderms 665
Chordates 667

34 Vertebrates 671

OVERVIEW: Half a Billion Years of Backbones 671

CONCEPT 34.1 Chordates have a notochord and a dorsal, hollow nerve cord 671

Derived Characters of Chordates 673
Tunicates 673
Lancelets 674

Early Chordate Evolution 674

CONCEPT 34.2 Craniates are chordates that have a head 675

Derived Characters of Craniates 676
The Origin of Craniates 676
I Iagfishes 676

CONCEPT 34.3 Vertebrates are craniates that have a backbone 678

Derived Characters of Vertebrates 678
Lampreys 678
Fossils of Early Vertebrates 678
Origins of Bones and Teeth 679

CONCEPT 34.4 Gnathostomes are vertebrates that have jaws 679

Derived Characters of Gnathostomes 679
Fossil Gnathostomes 680
Chondrichthyans (Sharks, Rays, and Their Relatives) 680

Ray-Finned Fishes and Lobe-Fins 682

CONCEPT 34.5 Tetrapods are gnathostomes that have limbs and feet 684

Derived Characters of Tetrapods 684
The Origin of Tetrapods 684
Amphibians 685

CONCEPT 34.6 Amniotes are tetrapods that have a terrestrially adapted egg 687

Derived Characters of Amniotes 688
Early Amniotes 688
Reptiles 688
Birds 691

CONCEPT 34.7 Mammals are amniotes that have hair and produce milk 694

Derived Characters of Mammals 694

Early Evolution of Mammals 694

Monotremes 695

Marsupials 695

Eutherians (Placental Mammals) 697

CONCEPT 34.8 Humans are bipedal hominids with a large brain 701

Derived Characters of Humans 701
The Earliest Hominids 702
Australopithecus 703
Bipedalism 704
Tool Use 704
Early *Homo* 704
Neanderthals 705
Homo sapiens 705

UNIT SIX

Plant Form and Function 710

35 Plant Structure, Growth, and Development 712

OVERVIEW: No Two Plants Are Alike 712

CONCEPT 35.1 The plant body has a hierarchy of organs, tissues, and cells 712

The Three Basic Plant Organs: Roots, Stems, and Leaves 713

The Three Tissue Systems: Dermal, Vascular, and Ground 717

Common Types of Plant Cells 717

CONCEPT 35.2 Meristems generate cells for new organs 720

CONCEPT 35.3 Primary growth lengthens roots and shoots 721

Primary Growth of Roots 721

Primary Growth of Shoots 723

CONCEPT 35.4 Secondary growth adds girth to stems and roots in woody plants 725

The Vascular Cambium and Secondary Vascular Tissue 725

Cork Cambium and the Production of Periderm 728

CONCEPT 35.5 Growth, morphogenesis, and differentiation produce the plant body 728

Molecular Biology: Revolutionizing the Study of Plants 728

Growth: Cell Division and Cell Expansion 729

Morphogenesis and Pattern Formation 730

Gene Expression and Control of Cellular Differentiation 732

Location and a Cell's Developmental Fate 732

Shifts in Development: Phase Changes 733

Genetic Control of Flowering 734

36 Transport in Vascular Plants 738

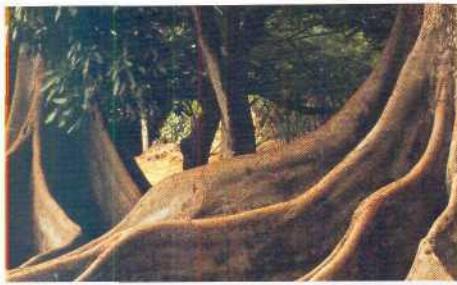

OVERVIEW: Pathways for Survival 738

CONCEPT 36.1 Physical forces drive the transport of materials in plants over a range of distances 738

Selective Permeability of Membranes: A Review 738

The Central Role of Proton Pumps 739

Effects of Differences in Water Potential 740

Epiphytes, Parasitic Plants, and Carnivorous
Plants 767

38 Angiosperm Reproduction and
Biotechnology 771

OVERVIEW: To Seed or Not to Seed 771

CONCEPT 38.1 Pollination enables gametes to come together
within a flower 771

Flower Structure 772

Gametophyte Development and Pollination 774

Mechanisms That Prevent Self-Fertilization 775

CONCEPT 38.2 After fertilization, ovules develop into seeds
and ovaries into fruits 776

Double Fertilization 776

From Ovule to Seed 777

From Ovary to Fruit 778

Seed Germination 779

CONCEPT 38.3 Many flowering plants clone themselves by
asexual reproduction 781

Mechanisms of Asexual Reproduction 781

Vegetative Propagation and Agriculture 781

CONCEPT 38.4 Plant biotechnology is transforming
agriculture 783

Artificial Selection 783

Reducing World Hunger and Malnutrition 784

The Debate over Plant Biotechnology 784

39 Plant Responses to Internal and External
Signals 788

OVERVIEW: Stimuli and a Stationary Life 788

CONCEPT 39.1 Signal transduction pathways link signal
reception to response 788

Reception 789

Transduction 789

Response 790

CONCEPT 39.2 Plant hormones help coordinate growth,
development, and responses to stimuli 791

The Discovery of Plant Hormones 792

A Survey of Plant Hormones 793

Systems Biology and Hormone Interactions 801

CONCEPT 39.3 Responses to light are critical for plant
success 802

Blue-Light Photoreceptors 802

Phytochromes as Photoreceptors 802

Biological Clocks and **Oscadian** Rhythms 805

The Effect of Light on the Biological Clock 806

Photoperiodism and Responses to Seasons 806

CONCEPT 39.4 Plants respond to a wide variety of stimuli
other than light 808

Gravity 809

Mechanical Stimuli 809

Environmental Stresses 810

CONCEPT 39.5 Plants defend themselves against herbivores
and pathogens 812

Defenses Against Herbivores 813

Defenses Against Pathogens 813

UNIT SEVEN

Animal Form and Function 818

40 Basic Principles of Animal Form and Function 820

OVERVIEW: Diverse Forms, Common Challenges 820

CONCEPT 40.i Physical laws and the environment constrain animal size and shape 820

Physical Laws and Animal Form 821

Exchange with the Environment 821

CONCEPT 40.2 Animal form and function are correlated at all levels of organization 823

Tissue Structure and Function 823

Organs and Organ Systems 827

CONCEPT 40.3 Animals use the chemical energy in food to sustain form and function 828

Bioenergetics 828

Influences on Metabolic Rates 829

Energy Budgets 830

CONCEPT 40.4 Many animals regulate their internal environment within relatively narrow limits 831

Regulating and Conforming 832

Mechanisms of Homeostasis 832

CONCEPT 40.5 Thermoregulation contributes to homeostasis and involves anatomy, physiology, and behavior 833

Ectotherms and Endotherms 833

Modes of Heat Exchange 834

Balancing Heat Loss and Gain 834

Feedback Mechanisms in Thermoregulation 839

Adjustment to Changing Temperatures 839

Torpor and Energy Conservation 840

41 Animal Nutrition 844

OVERVIEW: The Need to Feed 844

CONCEPT 41.1 Homeostatic mechanisms manage an animal's energy budget 844

Glucose Regulation as an Example of Homeostasis 846

Caloric Imbalance 846

CONCEPT 41.2 An animal's diet must supply carbon skeletons and essential nutrients 849

Essential Amino Acids 849

Essential Fatty Acids 850

Vitamins 850

Minerals 851

CONCEPT 41.3 The main stages of food processing are ingestion, digestion, absorption, and elimination 853

Digestive Compartments 853

CONCEPT 41.4 Each organ of the mammalian digestive system has specialized food-processing functions 855

The Oral Cavity, Pharynx, and Esophagus 856

The Stomach 857

The Small Intestine 858

The Large Intestine 861

CONCEPT 41.5 Evolutionary adaptations of vertebrate digestive systems are often associated with diet 862

Some Dental Adaptations 862

Stomach and Intestinal Adaptations 863

Symbiotic Adaptations 863

42 Circulation and Gas Exchange 867

OVERVIEW: Trading with the Environment 867

CONCEPT 42.1 Circulatory systems reflect phylogeny 867

Invertebrate Circulation 868

Survey of Vertebrate Circulation 869

CONCEPT 42.2 Double circulation in mammals depends on the anatomy and pumping cycle of the heart 871

Mammalian Circulation: *The Pathway* 872

The Mammalian Heart: A Closer Look 872

Maintaining the Heart's Rhythmic Beat 873

CONCEPT 42.3 Physical principles govern blood circulation 874

Bloodvessel Structure and Function 874

Blood Flow Velocity 875

Blood Pressure 876

Capillary Function 877

Fluid Return by the Lymphatic System 878

CONCEPT 42.4 Blood is a connective tissue with cells suspended in plasma 879

Blood Composition and Function 879

Cardiovascular Disease 882

CONCEPT 42.5 Gas exchange occurs across specialized respiratory surfaces 884

Gills in Aquatic Animals 884

Tracheal Systems in Insects 886

Lungs 886

CONCEPT 42.6 Breathing ventilates the lungs 888

How an Amphibian Breathes 888

How a Bird Breathes 889

Control of Breathing in Humans 890

CONCEPT 42.7 Respiratory pigments bind and transport gases 891

The Role of Partial Pressure Gradients 891

Respiratory Pigments 892

Elite Animal Athletes 894

| | | | | |
|--|-------------------------------------|------------|--|------------|
| 43 | The Immune System | 898 | CONCEPT 44.6 Diverse adaptations of the vertebrate kidney have evolved in different environments | 938 |
| OVERVIEW: Reconnaissance, Recognition, and Response 898 | | | 45 Hormones and the Endocrine System 943 | |
| CONCEPT 43.1 Innate immunity provides broad defenses against infection 898 | | | OVERVIEW: The Body's Long-Distance Regulators 943 | |
| External Defenses 899 | | | CONCEPT 45.1 The endocrine system and the nervous system act individually and together in regulating an animal's physiology 943 | |
| Internal Cellular and Chemical Defenses 899 | | | Overlap Between Endocrine and Neural Regulation 944 | |
| Invertebrate Immune Mechanisms 902 | | | Control Pathways and Feedback Loops 944 | |
| CONCEPT 43.2 In acquired immunity, lymphocytes provide specific defenses against infection 903 | | | CONCEPT 45.2 Hormones and other chemical signals bind to target cell receptors in target cells, initiating pathways that culminate in specific cell responses 945 | |
| Antigen Recognition by Lymphocytes 903 | | | Cell-Surface Receptors for Water-Soluble Hormones 946 | |
| Lymphocyte Development 905 | | | Intracellular Receptors for Lipid-Soluble Hormones 947 | |
| CONCEPT 43.3 Humoral and cell-mediated immunity defend against different types of threats 908 | | | Paracrine Signaling by Local Regulators 947 | |
| Helper T Cells: A Response to Nearly All Antigens 909 | | | CONCEPT 45.3 The hypothalamus and pituitary integrate many functions of the vertebrate endocrine system 948 | |
| Cytotoxic T Cells: A Response to Infected Cells and Cancer Cells 910 | | | Relationship Between the Hypothalamus and Pituitary Gland 950 | |
| B Cells: A Response to Extracellular Pathogens 910 | | | Posterior Pituitary Hormones 951 | |
| Active and Passive Immunization 914 | | | Anterior Pituitary Hormones 951 | |
| CONCEPT 43.4 The immune system's ability to distinguish self from nonself limits tissue transplantation 915 | | | CONCEPT 45.4 Nonpituitary hormones help regulate metabolism, homeostasis, development, and behavior 953 | |
| Blood Groups and Transfusions 915 | | | Thyroid Hormones 953 | |
| Tissue and Organ Transplants 916 | | | Parathyroid Hormone and Calcitonin: Control of Blood Calcium 954 | |
| CONCEPT 43.5 Exaggerated, self-directed, or diminished immune responses can cause disease 916 | | | Insulin and Glucagon: Control of Blood Glucose 955 | |
| Allergies 916 | | | Adrenal Hormones: Response to Stress 956 | |
| Autoimmune Diseases 917 | | | Gonadal Sex Hormones 958 | |
| Immunodeficiency Diseases 917 | | | Melatonin and Biorhythms 959 | |
| 44 | Osmoregulation and Excretion | 922 | CONCEPT 45.5 Invertebrate regulatory systems also involve endocrine and nervous system interactions 959 | |
| OVERVIEW: A Balancing Act 922 | | | 46 Animal Reproduction 964 | |
| CONCEPT 44.1 Osmoregulation balances the uptake and loss of water and solutes 922 | | | OVERVIEW: Doubling Up for Sexual Reproduction 964 | |
| Osmosis 922 | | | CONCEPT 46.i Both asexual and sexual reproduction occur in the animal kingdom 964 | |
| Osmotic Challenges 923 | | | Mechanisms of Asexual Reproduction 964 | |
| Transport Epithelia 926 | | | Reproductive Cycles and Patterns 965 | |
| CONCEPT 44.2 An animal's nitrogenous wastes reflect its phylogeny and habitat 927 | | | CONCEPT 46.2 Fertilization depends on mechanisms that help sperm meet eggs of the same species 967 | |
| Forms of Nitrogenous Waste 927 | | | Ensuring the Survival of Offspring 967 | |
| The Influence of Evolution and Environment on Nitrogenous Wastes 928 | | | Gamete Production and Delivery 968 | |
| CONCEPT 44.3 Diverse excretory systems are variations on a tubular theme 928 | | | CONCEPT 46.3 Reproductive organs produce and transport gametes: focus on humans 969 | |
| Excretory Processes 929 | | | Female Reproductive Anatomy 969 | |
| Survey of Excretory Systems 929 | | | Male Reproductive Anatomy 971 | |
| CONCEPT 44.4 Nephrons and associated blood vessels are the functional units of the mammalian kidney 931 | | | Human Sexual Response 972 | |
| Structure and Function of the Nephron and Associated Structures 931 | | | CONCEPT 46.4 In humans and other mammals, a complex interplay of hormones regulates gametogenesis 973 | |
| From Blood Filtrate to Urine: A Closer Look 933 | | | The Reproductive Cycles of Females 973 | |
| CONCEPT 44.5 The mammalian kidney's ability to conserve water is a key terrestrial adaptation 934 | | | Hormonal Control of the Male Reproductive System 977 | |
| Solute Gradients and Water Conservation 935 | | | | |
| Regulation of Kidney Function 936 | | | | |

| | | | |
|---|-------------|--|-------------|
| CONCEPT 4G.5 In humans and other placental mammals, an embryo grows into a newborn in the mother's uterus | 978 | CONCEPT 4B.5 The vertebrate nervous system is regionally specialized | 1026 |
| Conception, Embryonic Development, and Birth | 978 | The Peripheral Nervous System | 1026 |
| The Mother's Immune Tolerance of the Embryo and Fetus | 982 | Embryonic Development of the Brain | 1028 |
| Contraception and Abortion | 982 | The Brainstem | 1029 |
| Modern Reproductive Technology | 983 | The Cerebellum | 1030 |
| 47 Animal Development | 987 | The Diencephalon | 1030 |
| OVERVIEW: A Body-Building Plan for Animals | 987 | The Cerebrum | 1031 |
| CONCEPT 47.1 After fertilization, embryonic development proceeds through cleavage, gastrulation, and organogenesis | 988 | CONCEPT 4B.6 The cerebral cortex controls voluntary movement and cognitive functions | 1032 |
| Fertilization | 988 | Information Processing in the Cerebral Cortex | 1032 |
| Cleavage | 992 | Laterization of Cortical Function | 1033 |
| Gastrulation | 994 | Language and Speech | 1034 |
| Organogenesis | 997 | Emotions | 1034 |
| Developmental Adaptations of Amniotes | 998 | Memory and Learning | 1035 |
| Mammalian Development | 999 | Consciousness | 1036 |
| CONCEPT 47.2 Morphogenesis in animals involves specific changes in cell shape, position, and adhesion | 1001 | CONCEPT 4B.7 CNS injuries and diseases are the focus of much research | 1037 |
| The Cytoskeleton, Cell Motility and Convergent Extension | 1001 | Nerve Cell Development | 1037 |
| Roles of the Extracellular Matrix and Cell Adhesion Molecules | 1002 | Neural Stem Cells | 1038 |
| CONCEPT 47.3 The developmental fate of cells depends on their history and on inductive signals | 1003 | Diseases and Disorders of the Nervous Systems | 1039 |
| Fate Mapping | 1004 | | |
| Establishing Cellular Asymmetries | 1004 | | |
| Cell-Fate Determination and Pattern Formation by Inductive Signals | 1006 | | |
| 48 Nervous Systems | 1011 | 49 Sensory and Motor Mechanisms | 1045 |
| OVERVIEW: Command and Control Center | 1011 | OVERVIEW: Sensing and Acting | 1045 |
| CONCEPT 48.1 Nervous systems consist of circuits of neurons and supporting cells | 1012 | CONCEPT 49.1 Sensory receptors transduce stimulus energy and transmit signals to the central nervous system | 1046 |
| Organization of Nervous Systems | 1012 | Functions Performed by Sensory Receptors | 1046 |
| Information Processing | 1013 | Types of Sensory Receptors | 1046 |
| Neuron Structure | 1013 | CONCEPT 49.2 The mechanoreceptors involved with hearing and equilibrium detect settling particles or moving fluid | 1050 |
| Supporting Cells (Glia) | 1014 | Sensing Gravity and Sound in Invertebrates | 1050 |
| CONCEPT 48.2 Ion pumps and ion channels maintain the resting potential of a neuron | 1015 | Hearing and Equilibrium in Mammals | 1050 |
| The Resting Potential | 1016 | Hearing and Equilibrium in Other Vertebrates | 1053 |
| Gated Ion Channels | 1017 | CONCEPT 49.3 The senses of taste and smell are closely related in most animals | 1054 |
| CONCEPT 48.3 Action potentials are the signals conducted by axons | 1017 | Taste in Humans | 1055 |
| Production of Action Potentials | 1018 | Smell in Humans | 1056 |
| Conduction of Action Potentials | 1020 | CONCEPT 49.4 Similar mechanisms underlie vision throughout the animal kingdom | 1057 |
| CONCEPT 48.4 Neurons communicate with other cells at synapses | 1021 | Vision in Invertebrates | 1057 |
| Direct Synaptic Transmission | 1022 | The Vertebrate Visual System | 1058 |
| Indirect Synaptic Transmission | 1023 | CONCEPT 49.5 Animal skeletons function in support, protection, and movement | 1063 |
| Neurotransmitters | 1024 | Types of Skeletons | 1063 |
| | | Physical Support on Land | 1064 |
| | | CONCEPT 49.6 Muscles move skeletal parts by contracting | 1066 |
| | | Vertebrate Skeletal Muscle | 1066 |
| | | Other Types of Muscle | 1072 |
| | | CONCEPT 49.7 Locomotion requires energy to overcome friction and gravity | 1073 |
| | | Swimming | 1073 |
| | | Locomotion on Land | 1073 |
| | | Flying | 1074 |
| | | Comparing Costs of Locomotion | 1074 |

UNIT EIGHT

Ecology 1072

50 An Introduction to Ecology and the Biosphere 1080

OVERVIEW: The Scope of Ecology 1080

CONCEPT 50.1 Ecology is the study of interactions between organisms and the environment 1080

Ecology and Evolutionary Biology 1081

Organisms and Environment 1081

Subfields of Ecology 1082

Ecology and Environmental Issues 1083

CONCEPT 50.2 Interactions between organisms and the environment limit the distribution of species 1083

Dispersal and Distribution 1084

Behavior and Habitat Selection 1085

Biotic Factors 1085

Abiotic Factors 1086

Climate 1087

CONCEPT 50.3 Abiotic and biotic factors influence the structure and dynamics of aquatic biomes 1092

CONCEPT 50.4 Climate largely determines the distribution and structure of terrestrial biomes 1098

Climate and Terrestrial Biomes 1098

General Features of Terrestrial Biomes 1098

51 Behavioral Ecology 1106

OVERVIEW: Studying Behavior 1106

CONCEPT 51.1 Behavioral ecologists distinguish between proximate and ultimate causes of behavior 1106

What Is Behavior? 1107

Proximate and Ultimate Questions 1107

Ethology 1107

CONCEPT 51.2 Many behaviors have a strong genetic component 1109

Directed Movements 1110

Animal Signals and Communication 1111

Genetic Influences on Mating and Parental

Behavior 1112

CONCEPT 51.3 Environment, interacting with an animal's genetic makeup, influences the development of behaviors 1113

Dietary Influence on Mate Choice Behavior 1113

Social Environment and Aggressive Behavior 1114

Learning 1114

CONCEPT 51.4 Behavioral traits can evolve by natural selection 1118

Behavioral Variation in Natural Populations 1118

Experimental Evidence for Behavioral

Evolution 1120

CONCEPT 51.5 Natural selection favors behaviors that increase survival and reproductive success 1121

Foraging Behavior 1122

Mating Behavior and Mate Choice 1123

Applying Game Theory 1127

CONCEPT 51.6 The concept of inclusive fitness can account for most altruistic social behavior 1128

Altruism 1128

Inclusive Fitness 1129

Social Learning 1131

Evolution and Human Culture 1132

52 Population Ecology 1136

OVERVIEW: Earth's Fluctuating Populations 1136

CONCEPT 52.1 Dynamic biological processes influence population density, dispersion, and demography 1136

Density and Dispersion 1137

Demography 1139

CONCEPT 52.2 Life history traits are products of natural selection 1141

Life History Diversity 1141

"Trade-offs" and Life Histories 1142

CONCEPT 52.3 The exponential model describes population growth in an idealized, unlimited environment 1143

Per Capita Rate of increase 1143

Exponential Growth 1144

CONCEPT 52.4 The logistic growth model includes the concept of carrying capacity 1145

The Logistic Growth Model 1145

The Logistic Model and Real Populations 1146

The Logistic Model and Life Histories 1147

CONCEPT 52.5 Populations are regulated by a complex interaction of biotic and abiotic influences 1148

Population Change and Population Density 1148

Density-Dependent Population Regulation 1148

Population Dynamics 1150

Population Cycles f 151

CONCEPT 52.6 Human population growth has slowed after centuries of exponential increase 1152

The Global Human Population 1152

Global Carrying Capacity 1155

53 Community Ecology 1159

OVERVIEW: What Is a Community? 1159

CONCEPT 53.1 A community's interactions include competition, predation, herbivory, symbiosis, and disease 1159

- Competition 1160
- Predation 1161
- Herbivory 1163
- Parasitism 1163
- Disease 1163
- Mutualism 1164
- Commensalism 1164
- Interspecific Interactions and Adaptation 1164

CONCEPT 53.2 Dominant and keystone species exert strong controls on community structure 1165

- Species Diversity 1165
- Trophic Structure 1166
- Species with a Large Impact 1168
- Bottom-up and Top-Down Controls 1170

CONCEPT 53.3 Disturbance influences species diversity and composition 1171

- What Is Disturbance? 1172

biology

the study of living things

biology is the study of living things. it is concerned with all aspects of living organisms, from the smallest microorganism to the largest tree or animal. biology is also concerned with the relationships between living things and their environment. the study of biology can be divided into several main branches. one branch is botany, which studies plants. another branch is zoology, which studies animals. a third branch is microbiology, which studies microorganisms such as bacteria and viruses. other branches include ecology, which studies the relationships between living things and their environment, and genetics, which studies the inheritance of traits from parents to offspring.

cell theory

all living things are made up of cells. an organism is a collection of cells that work together to perform various functions.

the first person to propose this idea was a french scientist named roger bernard.

he suggested that all living things are composed of cells and that these cells are the basic units of life.

another french scientist, antoine lavoisier, also proposed this idea. he believed that all living things were composed of small units called "cells".

these ideas were later developed by other scientists, such as ralph moseley and karl von groves.

in 1839, two german scientists, matthias schleiden and karl von groves, published a paper in which they proposed the cell theory.

they suggested that all living things are composed of cells and that these cells are the basic units of life. they also proposed that cells are the fundamental units of life and that they are the basic units of life.

the cell theory has since been modified and expanded. for example, it is now known that some viruses are not composed of cells and that some cells do not contain nuclei.

the cell theory is still considered to be a fundamental principle of biology.

it is used to explain many biological processes, such as cell division and cell differentiation.

the cell theory is also used to explain the development of complex organisms from simple single-celled organisms.

the cell theory is a fundamental principle of biology.

the cell theory is a fundamental principle of biology.

the cell theory is a fundamental principle of biology.

Exploring Life

- Figure 1.1 Biology is the science that focuses on life.

Key Concepts

- 1.1 Biologists explore life from the microscopic to the global scale
- 1.2 Biological systems are much more than the sum of their parts
- 1.3 Biologists explore life across its great diversity of species
- 1.4 Evolution accounts for life's unity and diversity
- 1.5 Biologists use various forms of inquiry to explore life
- 1.6 A set of themes connects the concepts of biology

Overview

Biology's Most Exciting Era

Welcome to biology, the scientific study of life. You are becoming involved with biology during its most exciting era. The largest and best-equipped community of scientists in history is beginning to solve biological puzzles that once seemed unsolvable. We are moving ever closer to understanding how a single microscopic cell develops into a complex plant or animal; how plants convert solar energy to the chemical energy of food; how the human mind works; how various forms of life network in biological communities such as forests and coral reefs; and how the great diversity of life on Earth evolved from the first microbes. The more we learn about life, the more fascinating it becomes, as progress on one question leads to even more questions that will captivate curious minds for decades to come. More than anything else, biology is a quest, an ongoing inquiry about the nature of life.

Modern biology is as important as it is inspiring—Research breakthroughs in genetics and cell biology are transforming medicine and agriculture. Molecular biology is providing new tools for fields as diverse as anthropology and criminal science. Neuroscience and evolutionary biology are reshaping psychology and sociology. New models in ecology are helping societies evaluate environmental issues, such as the causes and biological consequences of global warming. These are just a few examples of how biology weaves into the fabric of our culture more than ever before. There has never been a better time to explore life.

The phenomenon we call life defies a simple, one-sentence definition. Yet almost any child perceives that a dog or a bug or a plant, such as the lern "fiddlehead" that graces the cover of this book (**Figure 1.1**), is alive, while a rock is not. We recognize life by what living things do. **Figure 1.2** highlights some of the properties and processes we associate with life.

As we set off to explore life, it helps to have a panoramic view of the vast field of study before us. This opening chapter introduces the wide scope of biology highlights the diversity of life, describes themes, such as evolution, that unify all of biology, and examines methods of inquiry that biologists use to explore life.

Concept 1.1

Biologists explore life from the microscopic to the global scale

The study of life extends from the microscopic scale of the molecules and cells that make up organisms to the global scale of the entire living planet. We can divide this enormous range into different levels of biological organization.

(a) **Order.** This close-up of a sunflower illustrates the highly ordered structure that characterizes life.

(b) **Evolutionary adaptation.** The appearance of this pygmy seahorse camouflages the animal in its environment. Such adaptations evolve over many generations by the reproductive success of those individuals with heritable traits that are best suited to their environments.

(c) **Response to the environment.** This Venus' flytrap closed its trap rapidly in response to the environmental stimulus of a dragonfly landing on the open trap.

(d) **Regulation.** The regulation of blood flow through the blood vessels of this jackrabbit's ears helps maintain a constant body temperature by adjusting heat exchange with the surrounding air.

(e) **Energy processing.** This hummingbird obtains fuel in the form of nectar from flowers. The hummingbird will use the chemical energy stored in its food to power flight and other work.

(g) **Reproduction.** Organisms (living things) reproduce their own kind. Here an emperor penguin protects its baby.

(f) **Growth and development.**
Inherited information carried by genes controls the pattern of growth and development of organisms, such as this Nile crocodile.

A Figure 1.2 Some properties of life.

A Hierarchy of Biological Organization

Imagine zooming in from space to take a closer and closer look at life on Earth. Our destination is a forest in Ontario, Canada, where we will eventually use microscopes and other instru-

ments to explore a maple leaf right down to the molecular level. **Figure 1.3** (on the next two pages) narrates this journey into life, with the circled numbers leading you through the levels of biological organization illustrated by the photographs.

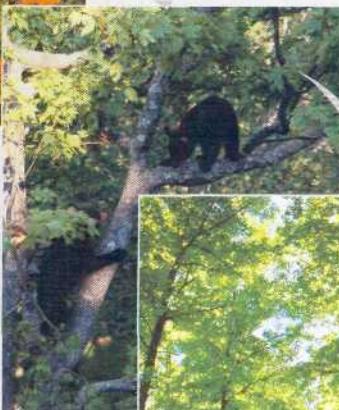

Figure 1.3

Exploring Levels of Biological Organization

O The biosphere. As soon as we are near enough to Earth to make out its continents and oceans, we begin to see signs of life — in the green mosaic of the planet's forests, for example. This is our first view of the biosphere, which consists of all the environments on Earth that are inhabited by life. The biosphere includes most regions of land; most bodies of water, such as oceans, lakes, and rivers; and the atmosphere to an altitude of several kilometers.

C Ecosystems. As we approach Earth's surface for an imaginary landing in Ontario, we can begin to make out a forest with an abundance of deciduous trees (trees that lose their leaves in the autumn and grow new ones in the spring). Such a deciduous forest is an example of an ecosystem. Grasslands, deserts, and the ocean's coral reefs are other types of ecosystems. An ecosystem consists of all the living things in a particular area, along with all the nonliving components of the environment with which life interacts, such as soil, water, atmospheric gases, and light. All of Earth's ecosystems combined make up the biosphere.

E Communities. The entire array of organisms inhabiting a particular ecosystem is called a biological community. The community in our forest ecosystem includes many kinds of trees and other plants, a diversity of animals, various mushrooms and other fungi, and enormous numbers of diverse microorganisms, which are living forms such as bacteria that are too small to see without a microscope. Each of these forms of life is called a species.

Q Populations.

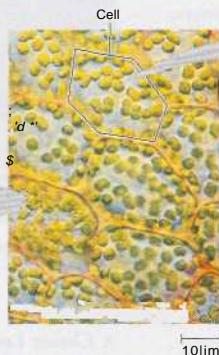

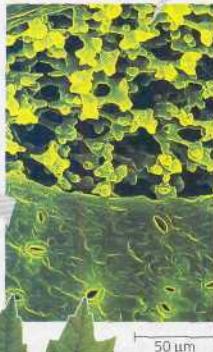

A population consists of all the individuals of a species living within the bounds of a specified area.

For example, our Ontario forest includes a population of sugar maple trees and a population of American black bears. We can now refine our definition of a community as the set of populations that inhabit a particular area.

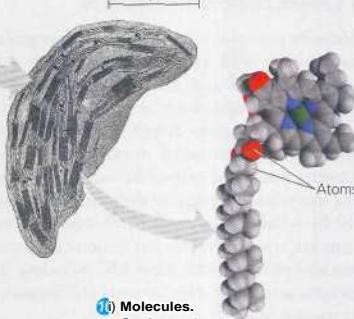

O Organisms. Individual living things are called organisms. Each of the maple trees and other plants in the forest is an organism, and so is each forest animal such as a frog, squirrel, bear, and insect. The soil teems with microorganisms such as bacteria.

Cells. The cell is life's fundamental unit of structure and function. Some organisms, such as amoebas and most bacteria, are single cells. Other organisms, including plants and animals, are multicellular. Instead of a single cell performing all the functions of life, a multicellular organism has a division of labor among specialized cells. A human body consists of trillions of microscopic cells of many different kinds, including muscle cells and nerve cells, which are organized into the various specialized tissues. For example, muscle tissue consists of bundles of muscle cells. And note again the cells of the tissue within a leaf's interior. Each of the cells you see is only about 25 μm (micrometers) across. It would take more than 700 of these cells to reach across a penny. As small as these cells are, you can see that each contains numerous green structures called chloroplasts, which are responsible for photosynthesis.

Organelles. Chloroplasts are examples of organelles, the various functional components that make up cells. In this figure, a very powerful tool called an electron microscope brings a single chloroplast into sharp focus.

1 μm

7 Molecules.

Our last scale change vaults us into a chloroplast for a view of life at the molecular level. A molecule is a chemical structure consisting of two or more small chemical units called *atoms*, which are represented as balls in this computer graphic of a chlorophyll molecule. Chlorophyll is the pigment molecule that makes a maple leaf green. One of the most important molecules on Earth, chlorophyll absorbs sunlight during the first step of photosynthesis. Within each chloroplast, millions of chlorophylls and other molecules are organized into the equipment that converts light energy to the chemical energy of food.

0 Organs and organ systems. The structural hierarchy of life continues to unfold as we explore the architecture of the more complex organisms. A maple leaf is an example of an organ, a body part consisting of two or more tissues (which we'll see upon our next scale change). Stems and roots are the other major organs of plants. Examples of human organs are the brain, heart, and kidney. The organs of humans and other complex animals are organized into organ systems, each a team of organs that cooperate in a specific function. For example, the human digestive system includes such organs as the tongue, stomach, and intestines.

In Figure 1.3, we traced the greenness that we first saw in our extraterrestrial view of life’s biosphere all the way down to the molecular level of chlorophyll. As a follow-up to this overview of life’s structural hierarchy, we’ll take a closer look at just two biological levels near opposite ends of the size scale: ecosystems and cells.

A Closer Look at Ecosystems

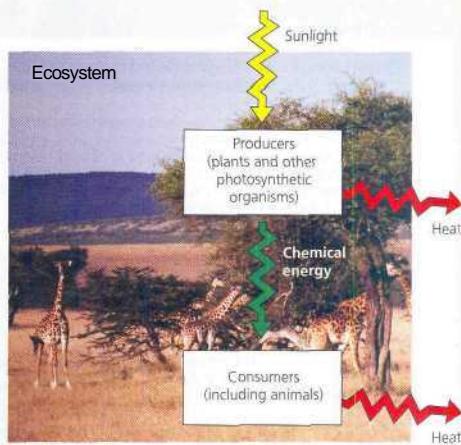

Life does not exist in a vacuum. Each organism interacts continuously with its environment, which includes other organisms as well as nonliving factors. The roots of a tree, for example, absorb water and minerals from the soil. The leaves take in carbon dioxide from the air. Solar energy absorbed by chlorophyll drives photosynthesis, which converts water and carbon dioxide to sugar and oxygen. The tree releases oxygen to the air, and its roots help form soil by breaking up rocks. Both organism and environment are affected by the interactions between them. The tree also interacts with other life, including soil microorganisms associated with its roots and animals that eat its leaves and fruit.

Ecosystem Dynamics

The dynamics of any ecosystem include two major processes. One process is the cycling of nutrients. For example, minerals acquired by plants will eventually be returned to the soil by microorganisms that decompose leaf litter, dead roots, and other organic debris. The second major process in an ecosystem is the flow of energy from sunlight to producers to consumers. **Producers** are plants and other photosynthetic organisms that convert light energy to chemical energy. **Consumers** are organisms, such as animals, that feed on producers and other consumers.

Energy Conversion

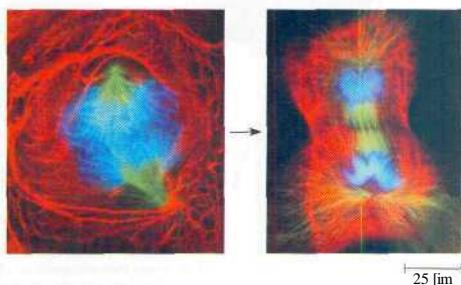

Moving, growing, reproducing, and other activities of life require organisms to perform work. And work depends on a source of energy. The exchange of energy between an organism and its surroundings often involves the transformation of one form of energy to another. For example, when a leaf produces sugar, it converts solar energy to chemical energy in sugar molecules. When an animal’s muscle cells use sugar as fuel to power movements, they convert chemical energy to kinetic energy, the energy of motion. And in all these energy conversions, some of the available energy is converted to thermal energy, which working organisms dissipate to their surroundings as heat. In contrast to chemical nutrients, which recycle within an ecosystem, energy flows *through* an ecosystem, usually entering as light and exiting as heat (Figure 1.4).

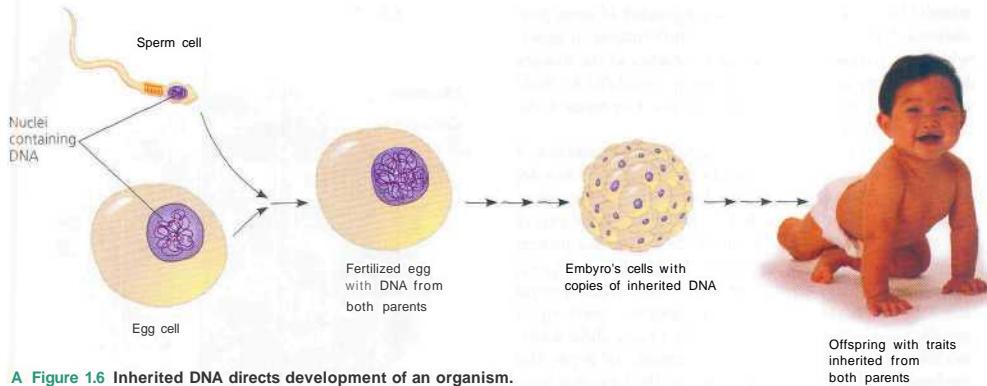

A Figure 1.4 Basic scheme for energy flow through an ecosystem.

A Closer Look at Cells

In life’s structural hierarchy, the cell has a special place as the lowest level of organization that can perform *all* activities required for life. For example, the ability of cells to divide to form new cells is the basis for all reproduction and for the growth and repair of multicellular organisms (Figure 1.5). Your every movement and thought are based on the activities of muscle cells and nerve cells. Even a global process such as the recycling of carbon, a chemical element essential to life, is the cumulative product of cellular activities, including the photosynthesis that occurs in the chloroplasts of leaf cells. Understanding how cells work is a major research focus of modern biology.

A Figure 1.5 A lung cell from a newt divides into two smaller cells that will grow and divide again.

A Figure 1.6 Inherited DNA directs development of an organism.

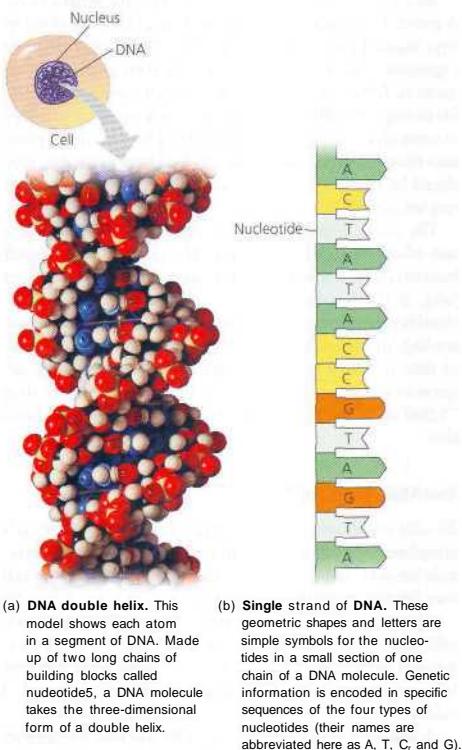

The Cell's Heritable Information

Take another look at the dividing cell in Figure 1.5. Within the cells you can see structures called chromosomes, which are stained with a blue-glowing dye. The chromosomes are partly made of a substance called **deoxyribonucleic acid**, or **DNA** for short. DNA is the substance of genes, the units of inheritance that transmit information from parents to offspring. Your blood group (A, B, AB, or O), for example, is the result of certain genes that you inherited from your parents.

Each chromosome has one very long DNA molecule, with hundreds or thousands of genes arranged along its length. The DNA of chromosomes replicates as a cell prepares to divide; thus, each of the two cellular offspring inherits a complete set of genes.

Each of us began life as a single cell stocked with DNA inherited from our parents. Replication of that DNA transmitted those genes to our trillions of cells. In each cell, the genes along the length of DNA molecules encode the information for building the cells other molecules. In this way, DNA directs the development and maintenance of the entire organism (Figure 1.6).

The molecular structure of DNA accounts for its information-rich nature. Each DNA molecule is made up of two long chains arranged into what is called a double helix. Each link of a chain is one of four kinds of chemical building blocks called nucleotides (Figure 1.7). The way DNA encodes a cell's information is analogous to the way we arrange the letters of the alphabet into precise sequences with specific meanings. The word *rat*, for example, conjures up an image of a rodent; the words *tar* and *art*, which contain the same letters, mean very different things. Libraries are filled with books containing information encoded in varying sequences of only 26 letters. We can think of nucleotides as the alphabet of

A Figure 1.7 DNA: The genetic material.

inheritance. Specific sequential arrangements of these four chemical letters encode the precise information in genes, which are typically hundreds or thousands of nucleotides long. One gene in a bacterial cell may be translated as "Build a purple pigment." A particular human gene may mean "Make the hormone insulin."

More generally, most genes program the cell's production of large molecules called proteins. The sequence of nucleotides along each gene codes for a specific protein with a unique shape and function in the cell. One protein might be part of the contractile apparatus of muscle cells. Another protein might be an antibody, part of the body's defense system against viruses and other disease agents. Still another protein might be an enzyme, a protein that catalyzes (speeds up) a specific chemical reaction in a cell. Almost all cellular activities involve the action of one or more proteins. DNA provides the heritable blueprints, but proteins are the tools that actually build and maintain the cell.

All forms of life employ essentially the same genetic code. A particular sequence of nucleotides says the same thing to one organism as it does to another. Differences between organisms reflect differences between their nucleotide sequences. But because the genetic code is universal, it is possible to engineer cells to produce proteins normally found only in some other organism. One of the first pharmaceutical products obtained using this technology was human insulin, produced by bacteria into which a gene for this human protein was inserted.

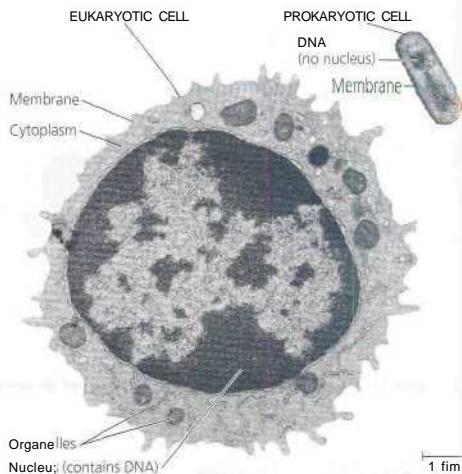

The entire "library" of genetic instructions that an organism inherits is called its genome. The chromosomes of each human cell pack a genome that is about 3 billion nucleotides long. If the one-letter symbols for this sequence of nucleotides were written in letters the size of those you are now reading, the genetic text would fill about 600 books the size of this one. Within this genomic library of nucleotide sequences are genes coding for the production of more than 75,000 different kinds of proteins, each with a specific function.

Two Main Forms of Cells

All cells share certain characteristics. For example, even a cell is enclosed by a membrane that regulates the passage of materials between the cell and its surroundings. And every cell uses DNA as its genetic information.

We can distinguish two main forms of cells: prokaryotic cells and eukaryotic cells. The cells of two groups of microorganisms called bacteria and archaea are prokaryotic. All other forms of life, including plants and animals, are composed of eukaryotic cells.

A eukaryotic cell is subdivided by internal membranes into various membrane-enclosed organelles, including the chloroplasts of Figure 1.3. In most eukaryotic cells, the largest

A Figure 1.8 Contrasting eukaryotic and prokaryotic cells in size and complexity.

organelle is the nucleus, which contains the cell's DNA (as chromosomal molecules). The other organelles are located in the cytoplasm, the entire region between the nucleus and outer membrane of the cell.

Prokaryotic cells are much simpler and generally smaller than eukaryotic cells (Figure 1.8). In a prokaryotic cell, the DNA is not separated from the rest of the cell by enclosure in a membrane-bound nucleus. Prokaryotic cells also lack the other kinds of membrane-enclosed organelles that characterize eukaryotic cells.

The prokaryote-eukaryote difference is an example of the biological diversity we will explore in Concept 1.3. But first, let's take one more look at the hierarchy of biological order, this time in the context of a research movement called systems biology.

Concept Check 1.1

- For each biological level in Figure 1.3, write a sentence that includes the next "lower" level. Example: "A community consists of populations of the various species inhabiting a specific area."
- What are the relationships between these three genetic terms: DNA, genes, and chromosomes?
- Explain why, at the cellular level, plants have more in common with animals than they do with bacteria.

For suggested answers, see Appendix A.

Concept 1.2

Biological systems are much more than the sum of their parts

The whole is greater than the sum of its parts.¹ That familiar adage captures the important concept that a combination of components can form a more complex organization called a **system**. Examples of biological systems are cells, organisms, and ecosystems. To understand how such systems work, it is not enough to have a "parts list," even a complete one. The future of biology is in understanding the behavior of whole, integrated systems.

The Emergent Properties of Systems

Take another look at the levels of life in Figure 1.3. With each step upward in this hierarchy of biological order, novel properties emerge that are not present at the level just below. These **emergent properties** are due to the arrangement and interactions of parts as complexity increases. For example, a test-tube mixture of chlorophyll and all the other molecules found in a chloroplast cannot perform photosynthesis. The process of photosynthesis emerges from the very specific way in which the chlorophyll and other molecules are arranged in an intact chloroplast. To take another example, if a serious head injury disrupts the intricate architecture of a human brain, the mind may cease to function properly even though all of the brain parts are still present. Our thoughts and memories are emergent properties of a complex network of nerve cells. At an even higher level of biological organization—at the ecosystem level—the recycling of nutrients such as carbon depends on a network of diverse organisms interacting with each other and with the soil and air.

Emergent properties are neither supernatural nor unique to life. We can see the importance of arrangement in the distinction between a box of bicycle parts and a working bicycle. And while graphite and diamonds are both pure carbon, they have very different properties based on how their carbon atoms are arranged. But compared to such nonliving examples, the emergent properties of life are particularly challenging to study because of the unrivaled complexity of biological systems.

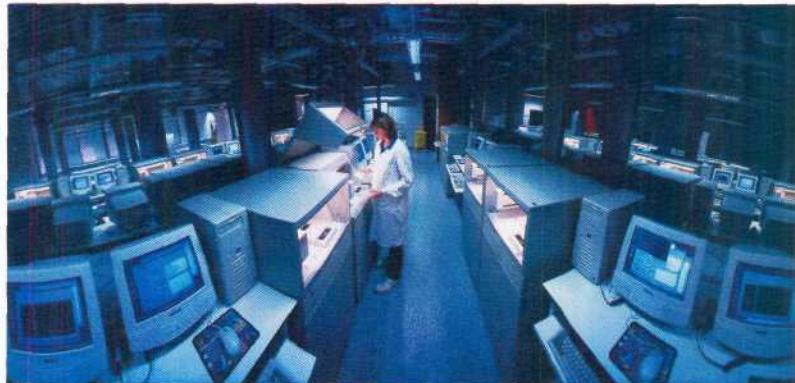

The Power and Limitations of Reductionism

Because the properties of life emerge from complex organization, scientists seeking to understand biological systems confront a dilemma. On the one hand, we cannot fully explain a higher level of order by breaking it down into its parts. A dissected animal no longer functions; a cell reduced to its chemical ingredients is no longer a cell. Disrupting a living system interferes with the meaningful understanding of its processes. On the other hand, something as complex as an organism or a cell cannot be analyzed without taking it apart.

Reductionism—reducing complex systems to simpler components that are more manageable to study—is a powerful strategy in biology. For example, by studying the molecular structure of DNA that had been extracted from cells, James Watson and Francis Crick inferred, in 1953, how this molecule could serve as the chemical basis of inheritance.

In 2001, almost half a century after the famous work of Watson and Crick, an international team of scientists published a "rough draft" of the sequence of 3 billion chemical letters in a human genome (**Figure 1.9**). (Researchers have also sequenced the genomes of many other species.) The press and world leaders acclaimed the Human Genome Project as one of the greatest scientific achievements ever. But unlike past cultural zeniths, such as the moonwalk of Apollo astronauts, the sequencing of the human genome is more a

• **Figure 1.9**
Modern biology as an information science. Automatic DNA-sequencing machines and abundant computing power accelerated the Human Genome Project. This facility in Cambridge, United Kingdom, was one of many labs that collaborated in the international project.

commencement than a climax. As the quest continues, scientists are learning the functions of thousands of genes and their protein products. And research is now moving on to how the activities of these myriad molecules are coordinated in the development and maintenance of cells and whole organisms. At the cutting edge of this research is the approach called systems biology.

Systems Biology

Biology is turning in an exciting new direction as many researchers begin to complement reductionism with new strategies for understanding the emergent properties of life—how all the parts of biological systems such as cells are functionally integrated. This changing perspective is analogous to moving from ground level on a certain street corner to an aerial view above a city, where you can now see how variables such as time of day, construction projects, accidents, and traffic signal malfunctions affect traffic dynamics throughout the city.

The ultimate goal of **systems biology** is to model the dynamic behavior of whole biological systems. Accurate models will enable biologists to predict how change in one or more variables will impact other components and the whole system. How, for example, will a slight increase in a muscle cell's calcium concentration affect the activities of the dozens of proteins that regulate muscle contraction? How will a drug that lowers blood pressure affect the function of organs throughout the human body and possibly cause harmful side effects? How will increasing the water supply to a crop impact key processes in the plants, such as the use of certain

soil minerals and the storage of proteins essential for human nutrition? How will a gradual increase in atmospheric carbon dioxide alter ecosystems and the entire biosphere? The aim of systems biology is to make progress answering such big questions.

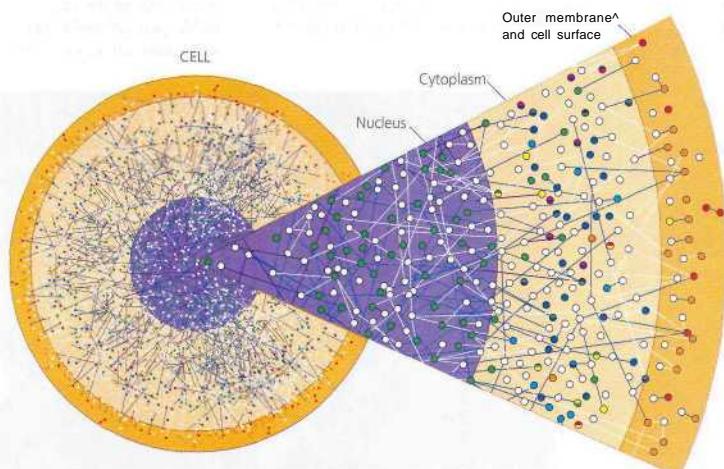

Systems biology is relevant to the study of life at all levels. Scientists investigating ecosystems pioneered the systems approach in the 1960s with elaborate models diagramming the network of interactions between species and nonliving components in salt marshes and other ecosystems. Even earlier, biologists studying the physiology (functioning) of humans and other organisms were integrating data on how multiple organs coordinate processes such as the regulation of sugar concentration in the blood. Such models of ecosystems and organisms have already been useful for predicting the responses of these systems to changing variables.

Systems biology is now taking hold in the study of life at the cellular and molecular levels, driven partly by the deluge of data from the sequencing of genomes and the growing catalog of known protein functions. In 2003, for example, a large research team published a network of protein interactions within the cell of a fruit fly, a popular research organism. The model is based on an extensive database of thousands of known proteins and their known interactions with other proteins. For example, protein A may bind to and alter the activities of proteins B, C, and D, which then go on to interact with still other proteins. **Figure 1.10** maps these protein partnerships to their cellular locales.

The basics of the systems strategy are straightforward enough. First, it is necessary to inventory as many parts as possible, such as all the known genes and proteins in a cell

> **Figure 1.10** A systems map of interactions between proteins in a cell.

This diagram maps about 3,500 proteins (dots) and their network of interactions (lines connecting the proteins) in a fruit fly cell. Systems biologists develop such models from huge databases of information about molecules and their interactions in the cell. A major goal of this systems approach is to use such models to predict how one change, such as an increase in the activity of a particular protein, can ripple through the cell's molecular circuitry to cause other changes. One of the applications will be a more accurate prediction of the side effects of various drugs.

(reductionism). Then it is necessary to investigate how each part behaves in relation to others in the working system—all the protein-protein interactions, in the case of our fly cell example. Finally, with the help of computers and innovative software, it is possible to pool all the data from many research teams into the kind of system network modeled in Figure 1.10.

Though the basic idea of systems biology is simple, the practice is not, as you would expect from the complexity of biological systems. It has taken three key research developments to bring systems biology within reach:

➤* **High-throughput** technology. Systems biology depends on methods that can analyze biological materials very rapidly and produce enormous volumes of data. Such mega-data-collection methods are said to be "high-throughput." The automatic DNA-sequencing machines that made the Human Genome Project possible are examples of high-throughput devices (see Figure 1.9).

I- **Bioinformatics.** The huge databases that result from high-throughput methods would be chaotic without the computing power, software, and mathematical models to process and integrate all this biological information. The new field of **bioinformatics** is extracting useful biological information from the enormous, ever-expanding data sets, such as DNA sequences and lists of protein interactions. The Internet is nurturing systems biology through dissemination of the digital data that feed bioinformatics.

I* **Interdisciplinary research teams.** In 2003, Harvard Medical School formed a department of systems biology, its first new department in two decades. Nearby MIT is busy organizing over 80 faculty members from many departments into a new program for computational and systems biology. These and other systems biology start-ups are melting pots of diverse specialists, including engineers, medical scientists, chemists, physicists, mathematicians, computer scientists, and, of course, biologists from a variety of fields.

A number of prominent scientists are promoting systems biology with missionary zeal, but so far, the excitement exceeds the achievements. However, as systems biology gathers momentum, it is certain to have a growing impact on the questions biologists ask and the research they design. After all, scientists aspired to reach beyond reductionism to grasp how whole biological systems work long before new technology made modern systems biology possible. In fact, decades ago, biologists had already identified some of the key mechanisms that regulate the behavior of complex systems such as cells, organisms, and ecosystems.

Feedback Regulation in Biological Systems

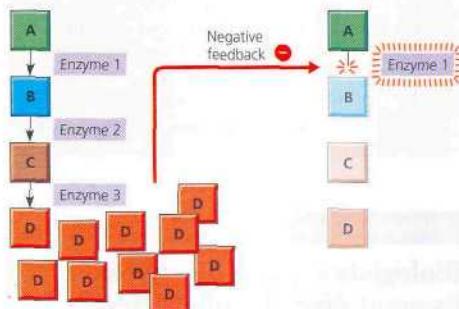

A kind of supply-and-demand economy applies to some of the dynamics of biological systems. For example, when your

muscle cells require more energy during exercise, they increase their consumption of the sugar molecules that provide fuel. In contrast, when you rest, a different set of chemical reactions converts surplus sugar to substances that store the fuel.

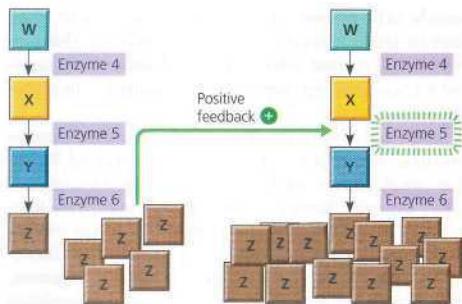

Like most of the cell's chemical processes, those that decompose or store sugar are accelerated, or catalyzed, by the specialized proteins called enzymes. Each type of enzyme catalyzes a specific chemical reaction. In many cases, these reactions are linked into chemical pathways, each step with its own enzyme. How does the cell coordinate its various chemical pathways? In our specific example of sugar management, how does the cell match fuel supply to demand by regulating its opposing pathways of sugar consumption and storage? The key is the ability of many biological processes to self-regulate by a mechanism called feedback.

In feedback regulation, the output, or product, of a process regulates that very process. In life, the most common form of regulation is **negative feedback**, in which accumulation of an end product of a process slows that process (Figure 1.11). For example, the cell's breakdown of sugar generates chemical energy in the form of a substance called ATP. An excess accumulation of ATP "feeds back" and inhibits an enzyme near the beginning of the pathway.

Though less common than negative feedback, there are also many biological processes regulated by **positive feedback**, in which an end product *speeds up* its production. The clotting of your blood in response to injury is an example. "When a blood vessel is damaged, structures in the blood called platelets begin to aggregate at the site. Positive feedback occurs as chemicals released by the platelets attract *more* platelets. The platelet pile then initiates a complex process that seals the

A Figure 1.11 Negative feedback. This three-step chemical pathway converts substance A to substance D. A specific enzyme catalyzes each chemical reaction. Accumulation of the final product (D) inhibits the first enzyme in the sequence, thus slowing down production of more D.

A Figure 1.12 Positive feedback. In positive feedback, a product stimulates an enzyme in the reaction sequence, increasing the rate of production of the product. Positive feedback is less common than negative feedback in living systems.

wound with a clot. **Figure 1.12** shows a simple model of positive feedback.

Feedback is a regulatory motif common to life at all levels, from the molecular level to the biosphere. Such regulation is an example of the Integration that makes living systems much greater than the sum of their parts.

Concept Check 1.2

1. Apply the principle of emergent properties to explain the relationship of a sentence to the alphabet of letters from which that sentence is constructed.
2. How does high-throughput technology complement bioinformatics?
3. When you flush a toilet, water begins to fill the tank and lift a float attached to a lever. When the water level reaches a certain height, the lever shuts the water valve and prevents the tank from overflowing. What type of regulatory mechanism is at work in this nonliving system?

For suggested answers, see Appendix A.

Concept 1.3

Biologists explore life across its great diversity of species

We can think of biology's enormous scope as having two dimensions. The "vertical" dimension, which we examined in this chapter's first two concepts, is the size scale that reaches all the way from molecules to the biosphere. But biology's

A Figure 1.13 Drawers of diversity. This is just a small sample of the tens of thousands of species in the moth and butterfly collection at the National Museum of Natural History in Washington, D.C.

scope also has a "horizontal" dimension stretching across the great diversity of species, now and over life's long history.

Diversity is a hallmark of life. Biologists have so far identified and named about 1.8 million species. This enormous diversity of life includes approximately 5,200 known species of prokaryotes, 100,000 fungi, 290,000 plants, 52,000 vertebrates (animals with backbones), and 1,000,000 insects (more than half of all known forms of life). Researchers identify thousands of additional species each year. Estimates of the total species count range from about 10 million to over 200 million. Whatever the actual number, the vast variety of life makes biology's scope very wide (**Figure 1.13**).

Grouping Species: The Basic Idea

There seems to be a human tendency to group diverse items according to similarities. For instance, perhaps you organize your music collection according to artist. And then maybe you group the various artists into broader categories, such as dance music, party music, exercise music, and study-time music. In the same way, grouping species that are similar is natural for us. We may speak of squirrels and butterflies, though we recognize that many different species belong to each group. We may even sort groups into broader categories, such as rodents (which include squirrels) and insects (which include butterflies). Taxonomy, the branch of biology⁷ that names and classifies species, formalizes this ordering of species into a series of groups of increasing breadth (**Figure 1.14**). You will learn more about this taxonomic scheme in Chapter 25. For now, we will focus on kingdoms and domains, the broadest units of classification.

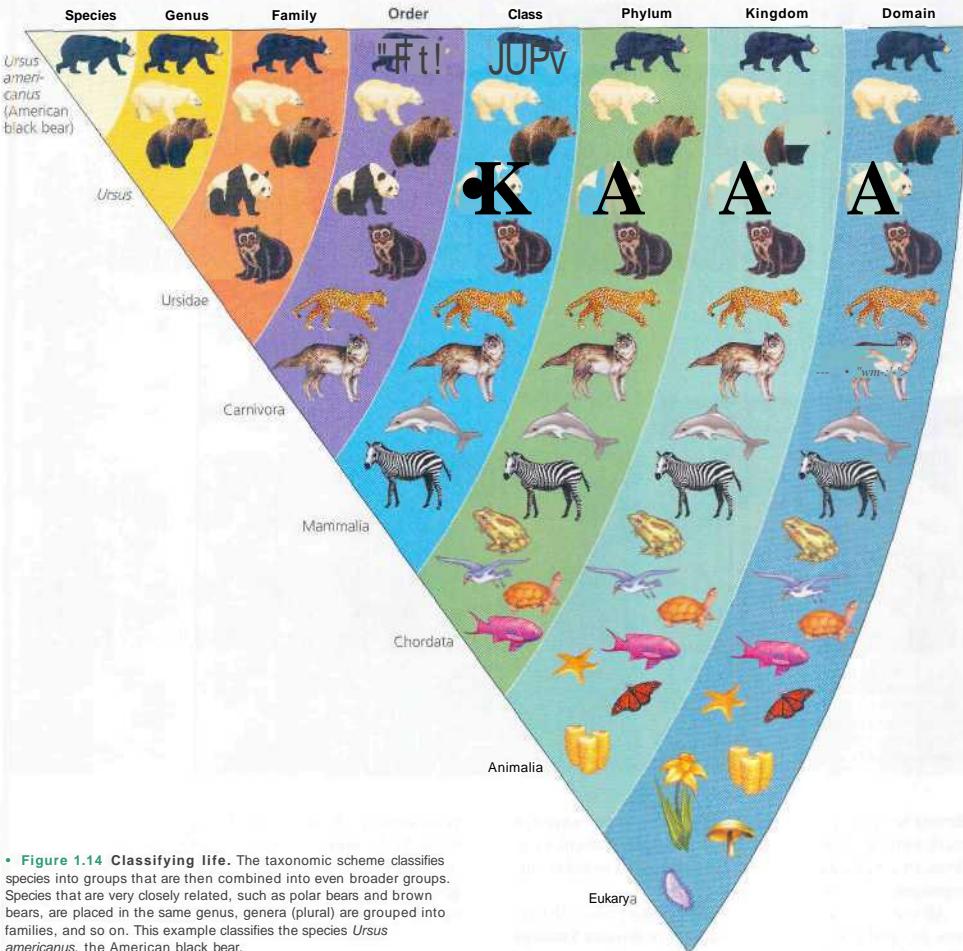

Figure 1.14 **Classifying life.** The taxonomic scheme classifies species into groups that are then combined into even broader groups. Species that are very closely related, such as polar bears and brown bears, are placed in the same genus; genera (plural) are grouped into families, and so on. This example classifies the species *Ursus americanus*, the American black bear.

The Three Domains of Life

Until the last decade, most biologists adopted a taxonomic scheme that divided the diversity of life into five kingdoms, including the plant and animal kingdoms. But new methods, such as comparing the DNA sequences of diverse species, have led to an ongoing reevaluation of the number and boundaries of kingdoms. Different researchers have proposed anywhere from six kingdoms to dozens of kingdoms. But as debate continues at the kingdom level, there is more of a consensus that

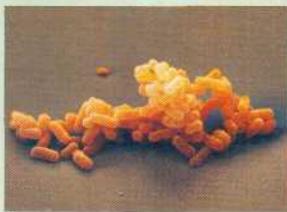

the kingdoms of life can now be grouped into three even higher levels of classification called domains. The three domains are named Bacteria, Archaea, and Eukarya.

The first two domains, domain Bacteria and domain Archaea, both consist of prokaryotes (organisms with prokaryotic cells). Most prokaryotes are unicellular and microscopic. In the five-kingdom system, bacteria and archaea were combined in a single kingdom, called kingdom Monera, because they shared the prokaryotic form of cell structure. But evidence now supports the view that bacteria and archaea represent two very

Figure 1.15

Exploring Life's Three Domains

DOMAIN BACTERIA

Bacteria are the most diverse and widespread prokaryotes and are now divided among multiple kingdoms. Each of the rod-shaped structures in this photo is a bacterial cell.

DOMAIN EUKARYA

Protists (multiple kingdoms) are unicellular eukaryotes and their relatively simple multicellular relatives. Pictured here is an assortment of protists inhabiting pond water. Scientists are currently debating how to split the protists into several kingdoms that better represent evolution and diversity.

Kingdom Plantae consists of multicellular eukaryotes that carry out photosynthesis, the conversion of light energy to food.

DOMAIN ARCHAEA

Many of the prokaryotes known as archaea live in Earth's extreme environments, such as salty lakes and boiling hot springs. Domain Archaea includes multiple kingdoms. The photo shows a colony composed of many cells.

Kingdom Fungi is defined in part by the nutritional mode of its members, such as this mushroom, which absorb nutrients after decomposing organic material.

Kingdom Animalia consists of multicellular eukaryotes that ingest other organisms.

distinct branches of prokaryotic life, different in key ways that you'll learn about in Chapter 27. There is also molecular evidence that archaea are at least as closely related to eukaryotic organisms as they are to bacteria.

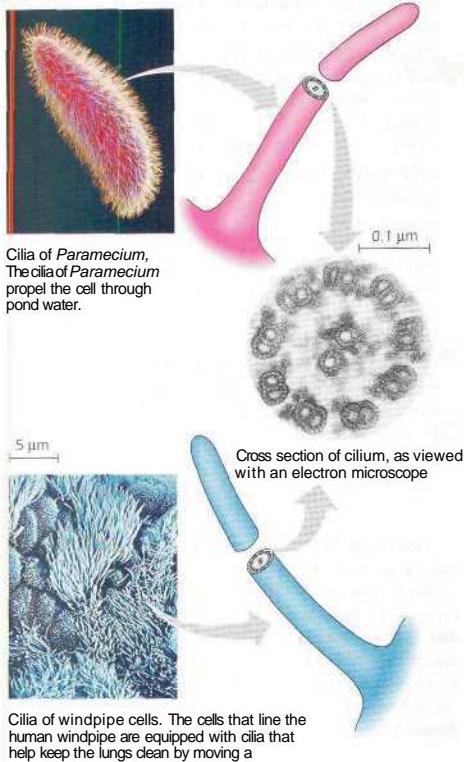

All the eukaryotes (organisms with eukaryotic cells) are now grouped into the various kingdoms of domain Eukarya (Figure 1.15). In the era of the five-kingdom scheme, most of the single-celled eukaryotes, including the microorganisms known as protozoans, were placed in a single kingdom, the kingdom Protista. Many biologists extended the boundaries of the kingdom Protista to include some multicellular forms, such as seaweeds, that are closely related to certain unicellular protists. The recent taxonomic trend has been to split the protists into several kingdoms. In addition to these protistan kingdoms, the domain Eukarya includes three kingdoms of multicellular eukaryotes: the kingdoms Plantae, Fungi, and Animalia. These three kingdoms are distinguished partly by their modes of nutrition. Plants produce their own sugars and other foods by

photosynthesis. Fungi are mostly decomposers that absorb nutrients by breaking down dead organisms and organic wastes, such as leaf litter and animal feces. Animals obtain food by Digestion, which is the eating and digesting of other organisms. It is, of course, the kingdom to which we belong.

Unity in the Diversity of Life

As diverse as life is, there is also evidence of remarkable unity, especially at the molecular and cellular levels. An example is the universal genetic language of DNA, which is common to organisms as different as bacteria and animals. And among eukaryotes, unity is evident in many features of cell structure (Figure 1.16).

How can we account for life's dual nature of unity and diversity? The process of evolution, introduced in the next concept, illuminates both the similarities and differences among Earth's life.

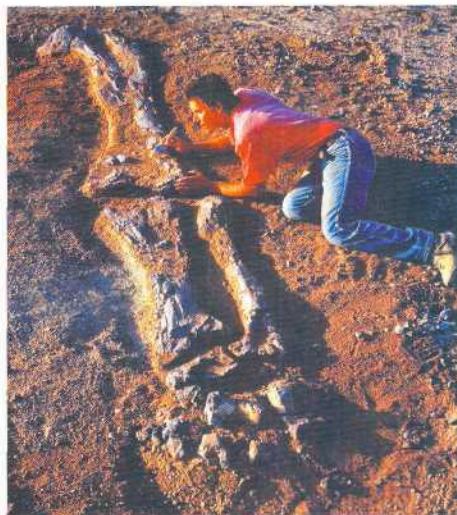

Cilia of Paramecium. The cilia of Paramecium propel the cell through pond water.

A Figure 1.16 An example of unity underlying the diversity of life: the architecture of cilia in eukaryotes. Cilia (singular, cilium) are extensions of cells that function in locomotion. They occur in eukaryotes as diverse as the single-celled *Paramecium* and humans. But even organisms so different share a common architecture for their cilia, which have an elaborate system of tubules that is revealed in cross-sectional views.

Concept Check 1.3

- How is a mailing address analogous to biology's hierarchical taxonomic system?
- What is the key difference that distinguishes organisms of domain Eukarya from the other two domains?

For suggested answers, see Appendix A.

Concept 1.4

Evolution accounts for life's unity and diversity

The history of life, as documented by fossils and other evidence, is a saga of a changing Earth billions of years old, inhabited by an evolving cast of living forms (Figure 1.17). This evolutionary view of life came into sharp focus in November 1859, when Charles Robert Darwin published one of the most important and controversial books ever written. Entitled *On the Origin of Species by Natural Selection*, Darwin's book was an immediate best-seller and soon made "Darwinism" almost synonymous with the concept of evolution (Figure 1.18).

The *Origin of Species* articulated two main points. First, Darwin presented evidence to support his view that contemporary species arose from

A Figure 1.18 Charles Darwin in 1859, the year he published *The Origin of Species*.

A. Figure 1.19 Unity and diversity in the orchid family.
These three rain forest orchids are variations on a common floral theme. For example, each of these flowers has a liplike petal that helps attract pollinating insects and provides a landing platform for the pollinators.

a succession of ancestors. (We will discuss the evidence for evolution in detail in Chapter 22.) Darwin called this evolutionary history of species "descent with modification." It was an insightful phrase, as it captured the duality of life's unity and diversity—unity in the kinship among species that descended from common ancestors; diversity in the modifications that evolved as species branched from their common ancestors (**Figure 1.19**). Darwin's second main point was to propose a mechanism for descent with modification. He called this evolutionary mechanism natural selection.

Natural Selection

Darwin synthesized his theory of natural selection from observations that by themselves were neither new nor profound. Others had the pieces of the puzzle, but Darwin saw how they fit together. He inferred natural selection by connecting two readily observable features of life:

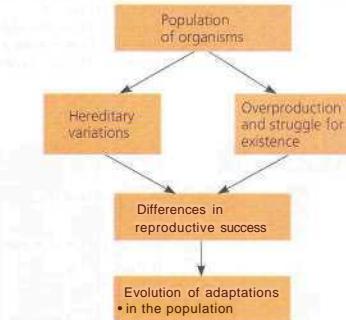

OBSERVATION: Individual variation. Individuals in a population of any species vary in many heritable traits.

OBSERVATION: Overproduction and competition. A population of any species has the potential to produce far more offspring than will survive to produce offspring of their own. With more individuals than the environment can support, competition is inevitable.

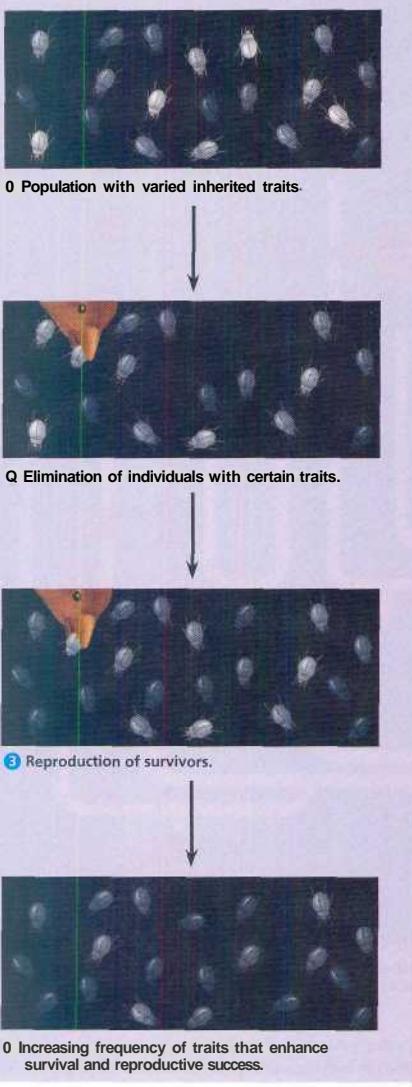

INFERENCE: Unequal reproductive success. From the observable facts of heritable variation and overproduction of offspring, Darwin inferred that individuals are unequal in their likelihood of surviving and reproducing. Those individuals with heritable traits best suited to the local environment will generally produce a disproportionately large number of healthy, fertile offspring.

INFERENCE: Evolutionary adaptation. This unequal reproductive success can adapt a population to its environment. Over the generations, heritable traits that enhance survival and reproductive success tend to increase in frequency among a population's individuals. The population evolves.

Darwin called this mechanism of evolutionary adaptation "natural selection"⁷ because the natural environment "selects" for the propagation of certain traits. Figure 1.20 summarizes Darwin's theory of natural selection. The example in **Figure 1.21** illustrates the ability of natural selection to "edit" a population's heritable variations. We see the products of natural selection in the exquisite adaptations of organisms to the special circumstances of their way of life and their environment (**Figure 1.22**).

A Figure 1.20 Summary of natural selection.

A Figure 1.21 Natural selection. This imaginary beetle population has colonized a locale where the soil has been blackened by a recent brush fire. Initially, the population varies extensively in the inherited coloration of the individuals, from very light gray to charcoal. For hungry birds that prey on the beetles, it is easiest to spot the beetles that are lightest in color.

A Figure 1.22 Form fits function.

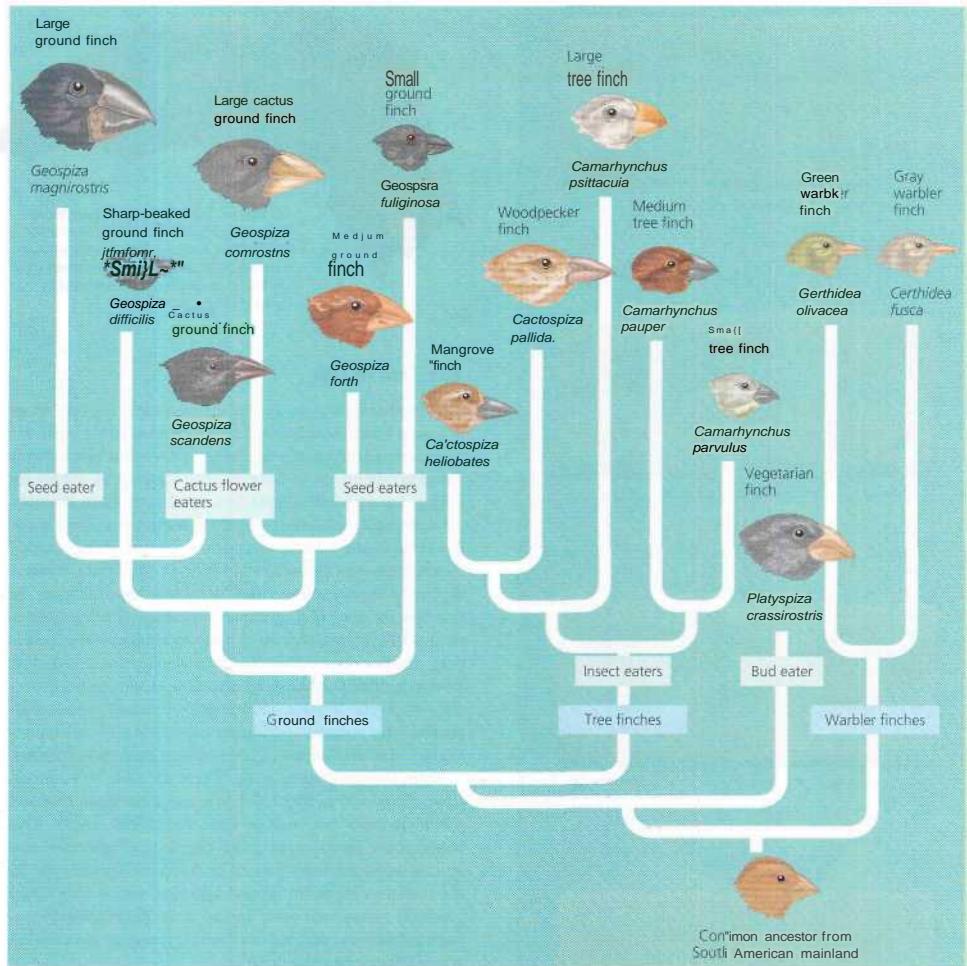

Bats, the only mammals capable of active flight, have wings with webbing between extended "fingers." In the Darwinian view of life, such adaptations are refined by natural selection.

The Tree of Life

Take another look at the skeletal architecture of the bats' wings in Figure 1.22. These forelimbs, though adapted for flight, actually have all the same bones, joints, nerves, and blood vessels found in other limbs as diverse as the human arm, the horse's foreleg, and the whale's flipper. Indeed, all mammalian forelimbs are anatomical variations of a common architecture, much as the flowers in Figure 1.19 are variations on an underlying "orchid" theme. Such examples of kinship connect life's "unity in diversity" to the Darwinian concept of "descent with modification." In this view, the unity of mammalian limb anatomy reflects inheritance of that structure from a common ancestor—the "prototype" mammal from which all other mammals descended, their diverse forelimbs modified by natural selection operating over millions of generations in different environmental contexts. Fossils and other evidence corroborate anatomical unity in supporting this view of mammalian descent from a common ancestor.

Thus, Darwin proposed that natural selection, by its cumulative effects over vast spans of time, could enable an ancestral species to "split" into two or more descendant species. This would occur, for example, if one population fragmented into several subpopulations isolated in different environments. In these various arenas of natural selection, one species could gradually radiate into many species as the geographically isolated populations adapted over many generations to different sets of environmental factors.

The "family tree" of 14 finches in **Figure 1.23**, on the next page, illustrates a famous example of adaptive radiation of new species from a common ancestor. Darwin collected specimens of these birds during his 1835 visit to the remote Galapagos Islands, 900 kilometers (km) off the Pacific coast of South America. These relatively young, volcanic islands are home to many species of plants and animals found nowhere else in the world, though Galapagos organisms are clearly related to species on the South American mainland. After volcanism built the Galapagos several million years ago, finches probably diversified on the various islands from an ancestral finch

A Figure 1.23 Descent with modification: adaptive radiation of finches on the Galápagos Islands. Note the specialization of beaks, which are adapted to various food sources on the different islands.

species that by chance reached the archipelago from the mainland. Years after Darwin's collection of Galápagos finches, researchers began to sort out the relationships among the finch species, first from anatomical and geographic data and more recently with the help of DNA sequence comparisons.

Biologists' diagrams of evolutionary relationships generally take treelike forms, and for good reason. Just as an individual has a genealogy that can be diagrammed as a family tree, each

species is one twig of a branching tree of life extending back in time through ancestral species more and more remote. Species that are very similar, such as the Galápagos finches, share a common ancestor at a relatively recent branch point on the tree of life. But through an ancestor that lived much farther back in time, finches are related to sparrows, hawks, penguins, and all other birds. And birds, mammals, and all other vertebrates (animals with backbones) share a common ancestor even more

ancient. We find evidence of still broader relationships in such similarities as the matching machinery of all eukaryotic cilia (see Figure 1.16). Trace life back far enough, and there are only fossils of the primeval prokaryotes that inhabited Earth over 3.5 billion years ago. We can recognize their vestiges in our own cells—in the universal genetic code, for example. All of life is connected through its long evolutionary history.

Concept Check 1.4

- Explain why "editing" is better than "creating" as a metaphor for how natural selection acts on a population's heritable variation.
- The three domains you learned about in Concept 1.3 can be represented in the tree of life as the three main branches. On the eukaryotic branch, three of the subbranches are the kingdoms Plantae, Fungi, and Animalia. Evidence supports the view that fungi and animals are more closely related to each other than either of these kingdoms is to plants. Draw a simple branching pattern that symbolizes the relationship between these three eukaryotic kingdoms.

For suggested answers, see Appendix A.

Concept 1.5

Biologists use various forms of inquiry to explore life

The word *science* is derived from a Latin verb meaning "to know." Science is a way of knowing. It developed out of our curiosity about ourselves, other life-forms, the world, and the universe. Striving to understand seems to be one of our basic urges.

At the heart of science is **inquiry**, a search for information and explanation, often focusing on specific questions. Inquiry drove Darwin to seek answers in nature for how species adapt to their environments. And inquiry is driving the analyses of genomes that are helping us understand biological unity and diversity at the molecular level. In fact, the inquisitive mind is the engine that drives all progress in biology.

There is no formula for successful scientific inquiry, no single scientific method with a rule book that researchers must rigidly follow. As in all quests, science includes elements of challenge, adventure, and surprise, along with careful planning, reasoning, creativity, cooperation, competition, patience, and the persistence to overcome setbacks. Such diverse elements of inquiry make science far less structured than most people realize. That said, it is possible to distill certain characteristics that help to distinguish science from other ways of describing and explaining nature.

Biology blends two main processes of scientific inquiry: discovery science and hypothesis-based science. Discovery science is mostly about *describing* nature. Hypothesis-based science is mostly about *explaining* nature. Most scientific inquiries combine these two research approaches.

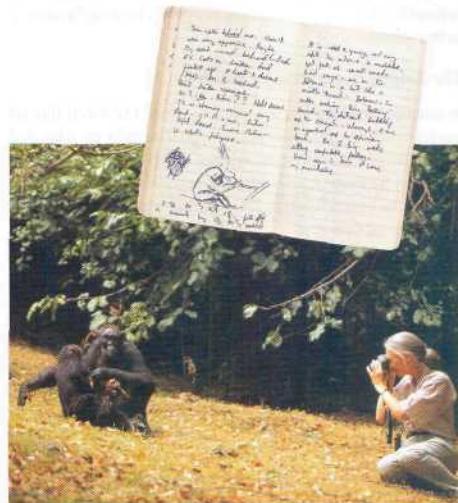

Discovery Science

Sometimes called descriptive science, **discovery science** describes natural structures and processes as accurately as possible through careful observation and analysis of data. For example, discovery science gradually built our understanding of cell structure, and it is discovery science that is expanding our databases of genomes of diverse species.

Types of Data

Observation is the use of the senses to gather information, either directly or indirectly with the help of tools such as microscopes that extend our senses. Recorded observations are called **data**. Put another way, data are items of information on which scientific inquiry is based.

The term *data* implies numbers to many people. But some data are *qualitative*, often in the form of recorded descriptions rather than numerical measurements. For example, Jane Goodall spent decades recording her observations of chimpanzee behavior during field research in a Gambian jungle (Figure 1.24). She also documented her observations with

A Figure 1.24 Jane Goodall collecting qualitative data on chimpanzee behavior. Goodall recorded her observations in field notebooks, often with sketches of the animals' behavior.

photographs and movies. Along with these qualitative data, Goodall also enriched the field of animal behavior with volumes of *quantitative* data, which are generally recorded as measurements. Skim through, any of the scientific journals in your college library, and you'll see many examples of quantitative data organized into tables and graphs.

Induction in Discovery Science

Discovery science can lead to important conclusions based on a type of logic called induction, or inductive reasoning. Through induction, we derive generalizations based on a large number of specific observations. "The sun always rises in the east" is an example. And so is "All organisms are made of cells." That generalization, part of the so-called cell theory, was based on two centuries of biologists discovering cells in the diverse biological specimens they observed with microscopes. The careful observations and data analyses of discovery science, along with the inductive generalizations they sometimes produce, are fundamental to our understanding of nature.

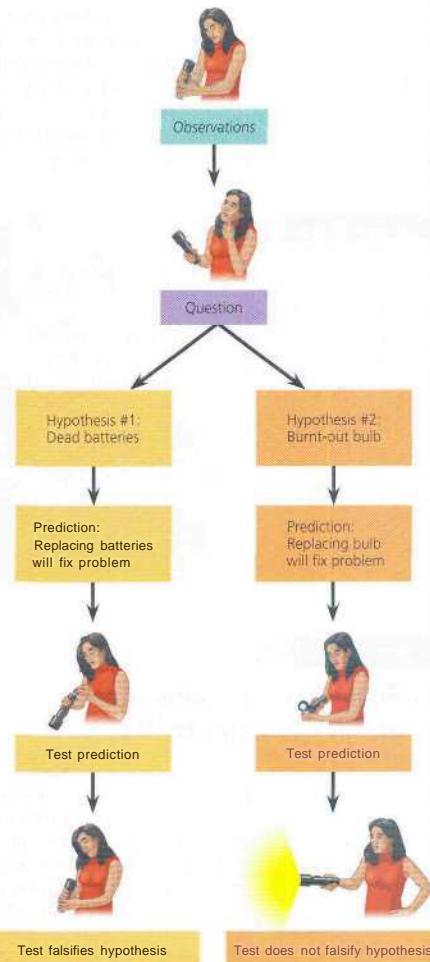

Hypothesis-Based Science

The observations and inductions of discovery science engage inquisitive minds to seek natural causes and explanations for those observations. What *caused* the diversification of finches on the Galápagos Islands? What *causes* the roots of a plant seedling to grow downward and the leaf-bearing shoot to grow upward? What *explains* the generalization that the sun always rises in the east? In science, such inquiry usually involves the proposing and testing of hypothetical explanations, or hypotheses.

The Role of Hypotheses in Inquiry

In science, a hypothesis is a tentative answer to a well-framed question—an explanation on trial. It is usually an educated postulate, based on past experience and the available data of discovery science. A scientific hypothesis makes predictions that can be tested by recording additional observations or by designing experiments.

We all use hypotheses in solving everyday problems. Let's say, for example, that your flashlight fails during a camp-out. That's an observation. The question is obvious: Why doesn't the flashlight work? Two reasonable hypotheses based on past experience are that (1) the batteries in the flashlight are dead or (2) the bulb is burn out. Each of these alternative hypotheses makes predictions you can test with experiments. For example, the dead-battery hypothesis predicts that replacing the batteries will fix the problem. **Figure 1.25** diagrams this campground inquiry. Of course, we rarely dissect our thought processes this way when we are solving a problem using hypotheses, predictions, and experiments. But hypothesis-based science clearly has its origins in the human tendency to figure things out by tinkering.

A **Figure 1.25** A campground example of hypothesis-based inquiry.

Deduction: The "If . . . then" Logic of Hypothesis-Based Science

A type of logic called deduction is built into hypothesis-based science. Deduction contrasts with induction, which, remember, is reasoning from a set of specific observations to reach a general conclusion. In deductive reasoning, the logic flows in the opposite direction, from the general to the

specific. From general premises, we extrapolate to the specific results we should expect if the premises are true. If all organisms are made of cells (premise 1), and humans are organisms (premise 2), then humans are composed of cells (deductive prediction about a specific case).

In hypothesis-based science, deduction usually takes the form of predictions about what outcomes of experiments or observations we should expect if a particular hypothesis (premise) is correct. We then test the hypothesis by performing the experiment to see whether or not the results are as predicted. This deductive testing takes the form of "*If* . . . *then*" logic. In the case of the flashlight example: *If* the dead-battery hypothesis is correct, and you replace the batteries with new ones, *then* the flashlight should work.

A Closer Look at Hypotheses in Scientific Inquiry

The flashlight example illustrates two important qualities of scientific hypotheses. First, a hypothesis must be *testable*; there must be some way to check the validity of the idea. Second, a hypothesis must be *falsifiable*; there must be some observation or experiment that *could* reveal if such an idea is actually *not* true. The hypothesis that dead batteries are the sole cause of the broken flashlight could be falsified by replacing the old batteries with new ones. But try to devise a test to falsify the hypothesis that invisible campground ghosts are fooling with your flashlight. Does restoring flashlight function by replacing the bulb falsify the ghost hypothesis? Not if the playful ghosts are continuing their mischief.

The flashlight inquiry illustrates another key point about hypothesis-based science. The ideal is to frame two or more alternative hypotheses and design experiments to falsify those candidate explanations. In addition to the two explanations tested in Figure 1.25, one of the many additional hypotheses is that *both* the batteries and the bulb are bad. What does this hypothesis predict about the outcome of the experiments in Figure 1.25? What additional experiment would you design to test this hypothesis of multiple malfunction?

We can refine the flashlight scenario for still one more important lesson about hypothesis-based science. Although the burnt-out bulb hypothesis stands up as the most likely explanation, notice that the testing supports that hypothesis *not* by proving that it is correct, but by not eliminating it through falsification. Perhaps the bulb was simply loose and the new bulb was inserted correctly. We could attempt to falsify the burnt-out bulb hypothesis by trying another experiment—removing the bulb and carefully reinstalling it. But no amount of experimental testing can prove a hypothesis beyond a shadow of doubt, because it is impossible to exhaust the testing of all alternative hypotheses. A hypothesis gains credibility by surviving various attempts to falsify it while testing eliminates (falsifies) alternative hypotheses.

The Myth of the Scientific Method

The steps in the flashlight example of Figure 1.25 trace an idealized process of inquiry called *the scientific method*. We can recognize the elements of this process in most of the research articles published by scientists, but rarely in such structured form. Very few scientific inquiries adhere rigidly to the sequence of steps prescribed by the "textbook" scientific method. For example, a scientist may start to design an experiment, but then backtrack upon realizing that more observations are necessary. In other cases, puzzling observations simply don't prompt well-defined questions until other research projects place those observations in a new context. For example, Darwin collected specimens of the Galápagos finches, but it wasn't until years later, as the idea of natural selection began to gel, that biologists began asking key questions about the history of those birds.

Moreover, scientists sometimes redirect their research when they realize they have been "barking up the wrong tree" by asking the wrong question. For example, in the early 20th century, much research on schizophrenia and manic-depressive disorder (now called bipolar disorder) got sidetracked by focusing too much on the question of how life experiences cause these serious maladies. Research on the causes and potential treatments became more productive when it was refocused on questions of how certain chemical imbalances in the brain contribute to mental illness. To be fair, we acknowledge that such twists and turns in scientific inquiry become more evident with the advantage of historical perspective.

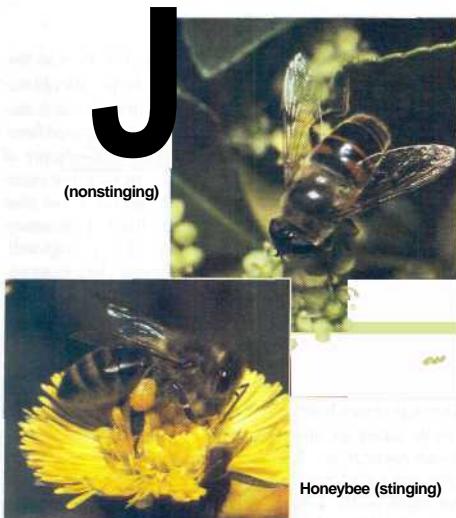

There is still another reason that good science need not conform exactly to any one method of inquiry: Discovery science has contributed much to our understanding of nature without most of the steps of the so-called scientific method.

It is important for you to get some experience with the power of the scientific method—by using it for some of the laboratory inquiries in your biology course, for example. But it is also important to avoid stereotyping science as lock-step adherence to this method.

A Case Study in Scientific Inquiry: Investigating Mimicry in Snake Populations

Now that we have highlighted the key features of discovery science and hypothesis-based science, you should be able to recognize these forms of inquiry in a case study of actual scientific research.

The story begins with a set of observations and generalizations from discovery science. Many poisonous animals are brightly colored, often with distinctive patterns that stand out against the background. This is called warning coloration because it apparently signals "dangerous species" to potential predators. But there are also mimics. These imposters look like poisonous species, but are actually relatively harmless. An example is the flower fly, a nonstinging insect that mimics the appearance of a stinging honeybee ([Figure 1.26](#) on the next page).

A Figure 1.26 A stinging honeybee and its nonstinging mimic, a flower fly.

What is the function of such mimicry? What advantage does it confer on the mimics? In 1862, British scientist Henry Bates proposed the reasonable hypothesis that mimics such as flower flies benefit when predators confuse them with the harmful species. In other words, the deception may be an evolutionary adaptation that evolved by reducing the mimics risk of being eaten. As intuitive as this hypothesis may be, it has been relatively difficult to test, especially with field experiments. But then, in 2001, biologists David and Karin Pfennig, along with William Harcombe, an undergraduate at the University of North Carolina, designed a simple but elegant set of field experiments to test Bates's mimicry hypothesis.

The team investigated a case of mimicry among snakes that live in North and South Carolina. A poisonous snake called the eastern coral snake has warning coloration: bold, alternating rings of red, yellow, and black. Predators rarely attack these snakes. It is unlikely that predators *learn* this avoidance behavior, as a first strike by a coral snake is usually deadly. Natural selection may have increased the frequency of predators that have inherited an instinctive recognition and avoidance of the warning coloration of the coral snake.

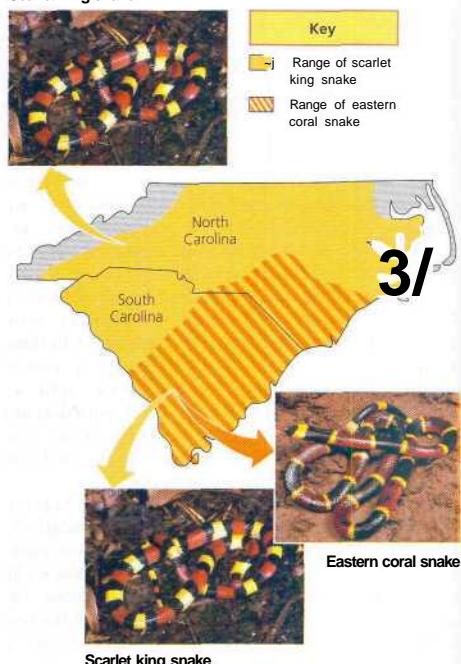

A nonpoisonous snake named the scarlet king snake mimics the ringed coloration of the coral snake. Both king snakes and coral snakes live in the Carolines, but the king snakes' geographic range extends farther north and west into regions where no coral snakes are found ([Figure 1.27](#)).

The geographic distribution of the Carolina snakes made it possible to test the key prediction of the mimicry hypothesis. Mimicry should help protect king snakes from predators, but *only* in regions where coral snakes also live. The mimicry hypothesis predicts that predators in non-coral snake areas will attack king snakes more frequently than will predators that live where coral snakes are present.

Field Experiments with Artificial Snakes

To test the mimicry hypothesis, Harcombe made hundreds of artificial snakes out of wire covered with a claylike substance called plasticine. He fashioned two versions of fake snakes: an *experimental group* with the red, black, and yellow ring pattern of king snakes; and a *control group* of plain brown artificial snakes as a basis of comparison.

Scarlet king snake

A Figure 1.27 Geographic ranges of Carolina coral snakes and king snakes. The scarlet king snake (*Lampropeltis triangulum*) mimics the warning coloration of the poisonous eastern coral snake (*Micruurus fulvius*). Though these two snake species cohabit many regions throughout North and South Carolina, the geographic range of the king snake extends north and west of the range of the coral snake.

The researchers placed equal numbers of the two types of artificial snakes in Held sites throughout North and South Carolina, including the region where coral snakes are absent (see Figure 1.27). After four weeks, the scientists retrieved the fake snakes and recorded how many had been attacked by looking for bite or claw⁷ marks. The most common predators were foxes, coyotes, and raccoons, but black bears also attacked some of the artificial snakes (Figure 1.28).

The data fit the key prediction of the mimicry hypothesis. Compared to the brown artificial snakes, the ringed snakes were attacked by predators less frequently *only* in field sites within the geographic range of the poisonous coral snakes. Figure 1.29 summarizes the field experiments. This figure also introduces an illustration format we will use throughout the book to feature other examples of biological inquiry.

Designing Controlled Experiments

The snake mimicry experiment provides an example of how scientists design experiments to test the effect of one variable by canceling out the effects of any unwanted variables, such as the number of predators in this case. The design is called a controlled experiment, where an experimental group (the artificial king snakes, in this case) is compared with a control

(a) Artificial king snake

(b) Brown artificial snake that has been attacked

A Figure 1.28 Artificial snakes used in field experiments to test the mimicry hypothesis. You can see where a bear chomped on the brown artificial snake in (b).

Figure 1.29

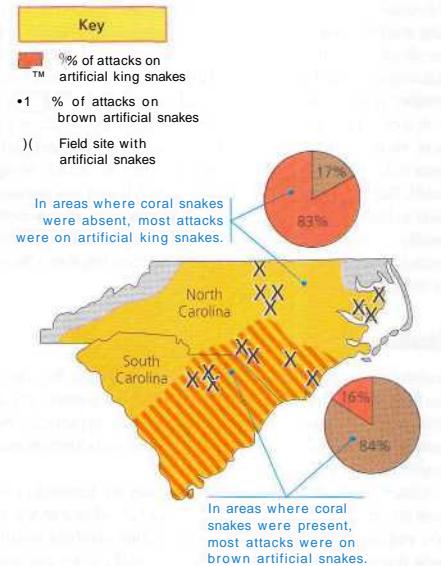

Inquiry Does the presence of poisonous coral snakes affect predation rates on their mimics, king snakes?

EXPERIMENT

David Pfennig and his colleagues made artificial snakes to test a prediction of the mimicry hypothesis: that king snakes benefit from mimicking the warning coloration of coral snakes *only* in regions where poisonous coral snakes are present. The Xs on the map below are field sites where the researchers placed equal numbers of artificial king snakes (experimental group) and brown artificial snakes (control group). The researchers recovered the artificial snakes after four weeks and tabulated predation data based on teeth and claw marks on the snakes (see Figure 1.28).

RESULTS

In field sites where coral snakes were present, predators attacked far fewer artificial king snakes than brown artificial snakes. The warning coloration of the "king snakes" afforded no such protection where coral snakes were absent. In fact, at those field sites, the artificial king snakes were *more* likely to be attacked than the brown artificial snakes, perhaps because the bright pattern is particularly easy to spot against the background.

CONCLUSION

The field experiments support the mimicry hypothesis by not falsifying the key prediction that imitation of coral snakes is only effective where coral snakes are present. The experiments also tested an alternative hypothesis that predators generally avoid all snakes with brightly colored rings, whether or not poisonous snakes with that coloration live in the environment. That alternative hypothesis was falsified by the data showing that the ringed coloration failed to repel predators where coral snakes were absent.

group (the brown artificial snakes). Ideally, the experimental and control groups differ only in the one factor the experiment is designed to test—in our example, the effect of the snakes' coloration on the behavior of predators.

What if the researchers had failed to control their experiment? Without the brown mock snakes as a control group, the number of attacks on the fake king snakes in different geographic regions would tell us nothing about the effect of snake coloration on predator behavior at the different field sites. Perhaps, for example, fewer predators attacked the artificial king snakes in the eastern and southern field sites simply because fewer predators live there. Or maybe warmer temperatures in those regions make predators less hungry; The brown artificial snakes enabled the scientists to rule out such variables as predator density and temperature because those factors would have had equal effects on the control group and experimental group. Yet predators in the eastern and southern field sites attacked more brown artificial snakes than "king snakes." The clever experimental design left coloration as the only factor that could account for the low predation rate on the artificial king snakes placed within the range of coral snakes. It was not the absolute number of attacks on the artificial king snakes that counted, but the difference between that number and the number of attacks on the brown snakes.

A common misconception is that the term *controlled experiment* means that scientists control the experimental environment to keep everything constant except the one variable being tested. But that's impossible in field research and not realistic even in highly regulated laboratory environments. Researchers usually "control" unwanted variables nOL by *eliminating* them through environmental regulation, but by ramming their effects by using control groups.

Limitations of Science

Scientific inquiry is a powerful way to know nature, bui there are limitations to the kinds of questions it can answer. These limits are set by science's requirements that hypotheses be testable and falsifiable and that observations and experimental results be repeatable.

Observations that can't be verified may be interesting or even entertaining, but they cannot count as evidence in scientific inquiry. The headlines of supermarket tabloids would have you believe that humans are occasionally born with the head of a dog and that some of your classmates are extraterrestrials. The unconfirmed eyewitness accounts and the computer-rigged photos are amusing but unconvincing. In science, evidence from observations and experiments is only convincing if it stands up to the criterion of repeatability. The scientists who investigated snake mimicry in the Carolinas obtained similar data when they repeated their experiments with different species of coral snakes and king snakes in Ari-

zona. And *you* should be able to obtain similar results if you were to repeat the snake experiments.

Ultimately, the limitations of science are imposed by its naturalism—it's seeking of natural causes for natural phenomena. Science can neither support nor falsify hypotheses that angels, ghosts, or spirits, both benevolent and evil, cause storms, rainbows, illnesses, and cures. Such supernatural explanations are simply outside the bounds of science.

Theories in Science

"It's just a theory!" Our everyday use of the term *theory* often implies an untested speculation. But the term *theory* has a very different meaning in science. What is a scientific theory, anc. how is it different from a hypothesis or from mere speculation?

First, a scientific theory is much broader in scope than a hypothesis. *This* is a hypothesis: "Mimicking poisonous snakes is an adaptation that protects nonpoisonous snakes from predators."¹¹ But *this* is a theory: "Evolutionary adaptations evolve by natural selection." Darwin's theory of natural selection accounts for an enormous diversity of adaptations, including mimicry

Second, a theory is general enough to spin off many new, specific hypotheses that can be tested. For example, Peter and Rosemary Grant, of Princeton University, were motivated by the theory of natural selection LO test the specific hypothesis that the beaks of the Galapagos finches evolve in response to changes in the types of available food.

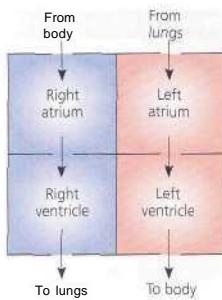

And third, compared to any one hypothesis, a theory is generally supported by a much more massive body of evidence. Those theories that become widely adopted in science (such as the theory of natural selection) explain a great diversity of observations and are supported by an accumulation of evidence, in fact, scrutiny of general theories continues through testing of the specific, falsifiable hypotheses they spawn.

In spite of the body of evidence supporting a widely accepted theory, scientists must sometimes modify or even reject theories when new research methods produce results that don't fit. For example, the five-kingdom theory of biological diversity began to erode when new methods for comparing cells and molecules made it possible to test some of the hypothetical relationships between organisms that were based on the theory. If there is "truth" in science, it is conditional, based on the preponderance of available evidence.

Model Building in Science

You may work with many models in your biology course this year. Perhaps you'll model cell division by using pipe cleaners or other objects as chromosomes. Or maybe you'll practice using mathematical models LO predict the growth of a bacterial population. Scientists often construct models as less abstract representations of ideas such as theories or

^ Figure 1.30 Modeling the pattern of blood flow through the four chambers of a human heart.

natural phenomena such as biological processes. Scientific models can take many forms, such as diagrams, graphs, three-dimensional objects, computer programs, or mathematical equations.

The choice of a model type depends on how it will be used to help explain and communicate the object, idea, or process it represents. Some models are meant to be as lifelike as possible. Other models are more useful if they are symbolic schematics. For example, the simple diagram in **Figure 1.30** does a good job of modeling blood flow through the chambers of a human heart without looking anything like a real heart. A heart model designed to help train a physician to perform heart surgery would look very different. Whatever its design, the test of a model is how well it fits the available data, how comfortably it accommodates new observations, how accurately it predicts the outcomes of new experiments, and how effectively it clarifies and communicates the idea or process it represents.

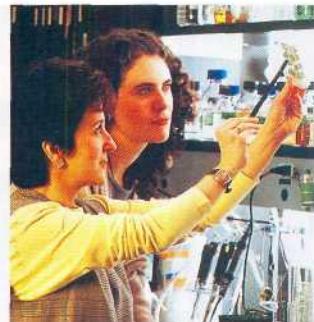

The Culture of Science

Movies and cartoons sometimes portray scientists as loners working in isolated labs. In reality, science is an intensely social activity. Most scientists work in teams, which often include both graduate and undergraduate students (**Figure 1.31**). And to succeed in science, it helps to be a good communicator. Research results have no impact until shared with a community of peers through seminars, publications, and websites.

Both cooperation and competition characterize the scientific culture. Scientists working in the same research field often check one another's claims by attempting to confirm observations or repeat experiments. And when several scientists converge on the same research question, there is all the excitement of a race. Scientists enjoy the challenge of "getting there first" with an important discovery or key experiment.

The biology community is part of society at large, embedded in the cultural milieu of the times. For example, changing attitudes about career choices have increased the

• Figure 1.31 Science as a social process. In her New York University laboratory, plant biologist Gloria Coruzzi mentors one of her students in the methods of molecular biology.

proportion of women in biology, which has in turn affected the emphasis in certain research fields. A few decades ago, for instance, biologists who studied the mating behavior of animals focused mostly on competition among males for access to females. More recent research, however, emphasizes the important role that females play in choosing mates. For example, in many bird species, females prefer the bright coloration that "advertises" a male's vigorous health, a behavior that enhances the female's probability of having healthy offspring.

Some philosophers of science argue that scientists are so influenced by cultural and political values that science is no more objective than other ways of "knowing nature." At the other extreme are people who speak of scientific theories as though they were natural laws instead of human interpretations of nature. The reality of science is probably somewhere in between—rarely perfectly objective, but continuously vetted through the expectation that observations and experiments be repeatable and hypotheses be testable and falsifiable.

Science, Technology, and Society

The relationship of science to society becomes clearer when we add technology to the picture. Though science and technology sometimes employ similar inquiry patterns, their basic goals differ. The goal of science is to understand natural phenomena. In contrast, technology generally *applies* scientific knowledge for some specific purpose. Biologists and other scientists often speak of "discoveries," while engineers and other technologists more often speak of "inventions." And the beneficiaries of those inventions include scientists, who put new technology to work in their research; the impact of information technology on systems biology is just one example. Thus, science and technology are interdependent.

A Figure 1.32 DNA technology and crime scene investigation. Forensic technicians can use traces of DNA extracted from a blood sample or other body tissue collected at a crime scene to produce molecular fingerprints. The stained bands you see in this photograph represent fragments of DNA, and the pattern of bands varies from person to person.

The potent combination of science and technology has dramatic effects on society. For example, discovery of the structure of DNA by Watson and Crick 50 years ago and subsequent achievements in DNA science led to the many technologies of DNA engineering that are transforming a diversity of fields, including medicine, agriculture, and forensics (**Figure 1.32**). Perhaps Watson and Crick envisioned that their discovery would someday produce important applications, but it is unlikely that they could have predicted exactly what those applications would be.

The directions that technology takes depend less on the curiosity that drives basic science than it does on the current needs and wants of people and on the social environment of the times. Debates about technology center more on "should we do it" than "can we do it." With advances in technology come difficult choices. For example, under what circumstances is it acceptable to use DNA technology to check if people have genes for hereditary diseases? Should such tests always be voluntary, or are there any circumstances when genetic testing should be mandatory? Should insurance companies or employers have access to the information, as they do for many other types of personal health data?

Such ethical issues have as much to do with politics, economics, and cultural values as with science and technology. But scientists and engineers have a responsibility to help educate politicians, bureaucrats, corporate leaders, and voters about how science works and about the potential benefits and risks of specific technologies. The crucial science-technology-society relationship is a theme that increases the significance of any biology course.

Concept Check 1.5

1. Contrast induction with deduction.
2. Critique this statement: "Scientists design controlled experiments to study a single variable by preventing all other factors from changing."
3. In the snake mimicry experiments, why did the researchers place some of their artificial snakes beyond the geographic range of coral snakes?
4. Contrast "theory" with "hypothesis."

For suggested answers, see Appendix A.

Concept 1.6

A set of themes connects the concepts of biology

In some ways, biology is the most demanding of all sciences, partly because living systems are so complex and partly because biology is an interdisciplinary science that requires knowledge of chemistry, physics, and mathematics. Modern biology is the decathlon of natural science. And of all the sciences, biology is the most connected to the humanities and social sciences. As biology students, you are definitely in the right place at the right time!

No matter what brings you to biology, you will find the study of life to be endlessly challenging and uplifting. But this ever-expanding subject can also be a bit intimidating, even to professional biologists. How, then, can beginning students develop a coherent view of life instead of hopelessly trying to memorize the details of a subject that is now far too big to memorize? One approach is to fit the many things you learn into a set of themes that pervade all of biology—ways of thinking about life that will still apply decades from now, when much of the specific information fossilized in any textbook will be obsolete. **Table 1.1** outlines a number of broad themes you will recognize from this first chapter of *Biology*. These unifying themes will reemerge throughout the book to provide touchstones as you explore life and begin asking important questions of your own.

Concept Check 1.6

1. Write a sentence relating the theme of "scientific inquiry" to the theme of "science, technology, and society."

For suggested answers, see Appendix A.

Table 1.1 Eleven Themes that Unify Biology

| Theme | Description | Theme | Description |
|---|---|----------------------------------|---|
| The cell | Cells are every organisms, basic units of Structure and function. The two main types of cells are prokaryotic cells (in bacteria and archaea) and eukaryotic cells (in protists, plants, fungi, and animals). | Unity and diversity | Biologists group the diversity of life into three domains: Bacteria, Archaea, and Eukarya. As diverse as life is, we can also find unity, such as a universal genetic code. The more closely related two species are, the more characteristics they share. |
| Heritable information | The continuity of life depends on the inheritance of biological information in the form of DNA molecules. This genetic information is encoded in the nucleotide sequences of the DNA. | Evolution | Evolution, biology's core theme, explains both the unity and diversity of life. The Darwinian theory of natural selection accounts for adaptation of populations to their environment through the differential reproductive success of varying individuals. |
| Emergent properties of biological systems | The living world has a hierarchical organization, extending from molecules to the biosphere. With each step upward in level, system properties emerge as a result of interactions among components at the lower levels. | Structure and function | Form and function are correlated at all levels of biological organization. |
| Regulation | Feedback mechanisms regulate biological systems. In some cases, the regulation maintains a relatively steady state for internal factors such as body temperature. | Scientific inquiry | The process of science includes observation-based discovery and the testing of explanations through hypothesis-based inquiry. Scientific credibility depends on the repeatability of observations and experiments, |
| Interaction with the environment | Organisms are open systems that exchange materials and energy with their surroundings. An organism's environment includes other organisms as well as nonliving factors. | Science, technology, and society | Many technologies are goal-oriented applications of science. The relationships of science and technology to society are now more crucial to understand than ever before. |
| Energy and life | All organisms must perform work, which requires energy. Energy flows from sunlight to producers to consumers. | | |

Chapter *| Review

SUMMARY OF KEY CONCEPTS

Concept 1.1

Biologists explore life from the microscopic to the global scale

- **A Hierarchy of Biological Organization** (pp. 3–6) The hierarchy of life unfolds as follows: biosphere > ecosystem > community > population > organism > organ system > organ > tissue > cell > organelle > molecule > atom.

Activity The Levels of Life Card Game

- **A Closer Look at Ecosystems** (p. 6) Whereas chemical nutrients recycle within an ecosystem, energy flows through an ecosystem.

Activity Energy Flow and Chemical Cycling

- **A Closer Look at Cells** (pp. 6–8) The cell is the lowest level of organization that can perform all activities required for life. Cells contain DNA, the substance of genes, which program the cell's production of proteins and transmit information from parents to offspring. Eukaryotic cells contain membrane-enclosed organelles, including a DNA-containing nucleus. Prokaryotic cells lack such organelles.

Activity Heritable Information: DNA

Activity Comparing Prokaryotic and Eukaryotic Cells

Concept 1.2

Biological systems are much more than the sum of their parts

- **The Emergent Properties of Systems** (p. 9) Due to increasing complexity new properties emerge with each step upward in the hierarchy of biological order.

- **The Power and Limitations of Reductionism** (pp. 9–10) Reductionism involves reducing complex systems to simpler components that are more manageable to study.

- **Systems Biology** (pp. 10–11) Systems biology seeks to create models of the dynamic behavior of whole biological systems. With such models, scientists will be able to predict how a change in one part of the system will affect the rest of the system.

- **Feedback Regulation in Biological Systems** (pp. 11–12) In negative feedback, accumulation of an end product slows the process that produces that product. In positive feedback, the end product speeds up its production.

Activity Regulation: Negative and Positive Feedback

Concept 1.3

Biologists explore life across its great diversity of species

- **Grouping Species: The Basic Idea** (pp. 12–13) Taxonomy is the branch of biology that names and classifies species according to a system of broader and broader groups.

- **The Three Domains of Life** (pp. 13–14) Domain Bacteria and Domain Archaea consist of prokaryotes. Domain Eukarya, the eukaryotes, includes the various protist kingdoms and the kingdoms Plantae, Fungi, and Animalia.

Activity Classification Schemes

- **Unity in the Diversity of Life** (pp. 14–15) As diverse as life is, there is also evidence of remarkable unity.

Concept 1.4

Evolution accounts for life's unity and diversity

- **Natural Selection** (pp. 16–17) Darwin called the evolutionary history of species "descent with modification." He proposed natural selection as the mechanism for evolutionary adaptation of populations to their environments. Natural selection is the evolutionary process that occurs when a population's heritable variations are exposed to environmental factors that favor the reproductive success of some individuals over others.

Investigation How Do Environmental Changes Affect a Population?

Activity Form Fits Function: Cells

- **The Tree of Life** (pp. 17–19) Each species is one twig of a branching tree of life extending back in time through ancestral species more and more remote. All of life is connected through its long evolutionary history.

Concept 1.5

Biologists use various forms of inquiry to explore life

- **Discovery Science** (pp. 19–20) In discovery science, scientists describe some aspect of the world and use inductive reasoning to draw general conclusions.

Graph it An Introduction to Graphing

- **Hypothesis-Based Science** (pp. 20–21) Based on observations, scientists propose hypotheses that lead to predictions and then test the hypotheses by seeing if the predictions come true. Deductive reasoning is used in testing hypotheses: If a hypothesis is correct, and we test it, then we can expect a particular outcome. Hypotheses must be testable and falsifiable.

Investigation How Does Acid Precipitation Affect Trees?

- **A Case Study in Scientific Inquiry: Investigating Mimicry in Snake Populations** (pp. 21–24) Experiments must be designed to test the effect of one variable by testing control groups and experimental groups that vary in only that one variable.

- **Limitations of Science** (p. 24) Science cannot address supernatural phenomena because hypotheses must be testable and falsifiable and observations and experimental results must be repeatable.

- **Theories in Science** (p. 24) A scientific theory is broad in scope, generates new hypotheses, and is supported by a large body of evidence.

- **Model Building in Science** (pp. 24–25) Models of ideas, structures, and processes help us understand scientific phenomena and make predictions.

- **The Culture of Science** (p. 25) Science is a social activity characterized by both cooperation and competition.

- **Science, Technology, and Society** (pp. 25–26) Technology applies scientific knowledge for some specific purpose.

Activity Science, Technology, and Society: DDT

Concept 1.6

A set of themes connects the concepts of biology

- Underlying themes provide a framework for understanding biology (pp. 26–27).

TESTING YOUR KNOWLEDGE

Evolution Connection

A typical prokaryotic cell has about 3,000 genes in its DNA, while a human cell has about 25,000 genes. About 1,000 of these genes are present in both types of cells. Based on your understanding of evolution, explain how such different organisms could have the same subset of genes.

Scientific Inquiry

Based on the results of the snake mimicry case study suggest another hypothesis researchers might investigate further.

Investigation How Do Environmental Changes Affect a Population?

Investigation How Does Acid Precipitation Affect Trees?

Science, Technology, and Society

The fruits of wild species of tomato are tiny compared to the giant beefsteak tomatoes available today. This difference in fruit size is almost entirely due to the larger number of cells in the domesticated fruits. Plant molecular biologists have recently discovered genes that are responsible for controlling cell division in tomatoes. Why would such a discovery be important to producers of other kinds of fruits and vegetables? To the study of human development and disease? To our basic understanding of biology?

UNIT 1

The Chemistry of Life

AN INTERVIEW WITH **Lydia Makhubu**

Until her recent retirement, Lydia Makhubu was the Vice Chancellor (in American terms, President) of the University of Swaziland, where she was also Professor of Chemistry. She received her higher education in Lesotho and at the Universities of Alberta and Toronto, where she earned a Ph.D. in Medicinal Chemistry. Building on her study of chemistry, Dr. Makhubu has had a distinguished career as a scientist in the area of health and traditional medicine, as a leader in higher education, and as a commentator on science, technology, and development in Africa and other developing regions. Among the many instances of her international service, she has been a consultant to several United Nations agencies and to the American Association for the Association of Science and has chaired the Association of Commonwealth Universities. Jane Reece met with her in Paris, where Dr. Makhubu was attending a meeting of the Executive Board of UNESCO, the United Nations Educational, Scientific and Cultural Organization.

Please tell us a little about Swaziland and its people.

Swaziland is a small landlocked country, only 17,400 square kilometers in area (smaller than New Jersey). It borders Mozambique on the east and South Africa on the west and south. The country ranges in altitude from high to low, and it has a great diversity of organisms, especially plants. The capital, Mbabane, is in the ecological zone called the highveld, where the altitude is close to 1,800 meters above sea level. The altitude drops to the middleveld, which has rich soils especially good for agriculture. As you go toward Mozambique and the sea, the land gets low and flat—the lowveld. The climate and the plant and animal species change as the altitudes changes.

Swaziland is unusual these days because it is a kingdom, with a king who has executive authority. In the population of about 1 million, there is only one ethnic group, the Swazis, so we haven't had the conflicts that have afflicted some other African nations. Swaziland was a British colony, gaining independence in 1968. These days, the economy isn't as good as it used to be, in part because we've had a lot of drought and we're heavily dependent on agriculture.

What influenced you to become a medicinal chemist?

In the early days, my parents were teachers, but then my father took up a career in the Ministry of Health, becoming an orderly in a medical clinic. We lived at the clinic, and I could see him check people—since doctors were scarce, an orderly had a lot of responsibility! I warned me to be a medical doctor at that time. I ended up studying chemistry at college in Lesotho. From there, I went to Canada, where I did a masters degree and doctorate. I liked chemistry because it seemed to make sense: You mix this and that, and a product appears. I became interested in organic chemistry, and then, probably influenced by the importance of medicine in my society, I chose medicinal chemistry. I wanted to study the effects of drugs on the body.

What do you mean by "medicine in my society"?

The traditional medicine of my people. At college in Lesotho, we students used to argue about m-xitundu medicine: Some believed it was absolute nonsense; others thought it worked. I was interested in this question. So when I came back from Canada, I immediately sought out traditional healers, including some of my relatives, and I was shown a few of the medicinal preparations they used. I started working in the laboratory to try to identify what was in those medicines.

In other countries of Southern Africa, traditional healers have organized themselves into associations and have even established some clinics. But in Swaziland, the British banned traditional medicine by the Witchcraft Act of 1901—and this law has not been repealed yet. Even people who had access to modern clinics, though, often continued to go to traditional healers, as well, and this continues today.

Tell us about the research on the plant *Phytolacca dodecandra* and its potential for preventing disease.

This plant, also called edod or soapberry, is a common bush in Africa. One day in 1964, an Ethiopian scientist, the late Aklilu Lemma of Addis Ababa University, was walking near a small stream, where he saw women washing clothes. He noticed a large pile of dead snails, of the type that transmits the disease schistosomiasis. He asked the women, "What are you using for soap?" and learned that they were using the berries of *Phytolacca*. He then took berries to the lab, along with some living snails, and found that extracts of the berries killed the snails.

What is schistosomiasis?

Also called bilharzia or snail fever, this is a debilitating disease that afflicts more than 200 million people worldwide, it is one of the greatest scourges in the developing world. The disease is caused by a parasitic flatworm (a fluke) that uses an aquatic snail as a host during part of its life cycle (see Figure 33.11). Fluke larvae released by the snails pierce the skin of people standing or swimming in the water, infecting them. You can control schistosomiasis by killing the parasite with a drug or by killing the snail with a synthetic molluscicide—but both are too expensive in Africa.

Is this where *Phytolacca* comes in?

Yes. *Phytolacca* berries are a better control method for *schistosomiasis* in Africa than

synthetic chemicals of any sort because people can easily grow the plant and harvest the berries. Chemists have isolated the *Phytolacca* chemical that is lethal to snails, although it is not yet known exactly how it acts. Researchers have discovered that the chemical also kills some other parasites that live in African rivers, as well as the larvae of mosquitoes (which transmit malaria). And there are no bad environmental effects because the chemical readily decomposes.

At the University of Swaziland, we obtained seeds of *Phytolacca* from Ethiopia, grew the plants, and harvested the berries. The Ethiopians came to show us how to do everything; it was a true collaboration between Swazi and Ethiopian scientists, with help from some Zimbabwans and an American. Working in the lab, we discovered the concentration at which the berry extract killed the snails, and then we went into the field for further tests. Now we have selected an area in Swaziland where schistosomiasis is very prevalent, and we're working with the people there, teaching them how to grow and use *Phytolacca*. We hope that, in another year, the communities will be able to control the disease themselves.

What goes on at your university's institute of traditional medicine?

At this institute, officially the "Swaziland Institute of Research in Traditional Medicine, Medicinal and Indigenous Food Plants," multidisciplinary teams study all aspects of traditional medicine. Traditional healers are essential team members because they know the healing plants and how to use them. We have had several workshops

with traditional healers, trying to convince them of the importance of sharing their knowledge with us—because they are going to die, like all of us, and the knowledge may soon be lost. However, the healers—even my relatives!—are reluctant to help. They think, "You with your white coats are going to make loads of money from my knowledge." Their belief system is another obstacle. The healers believe that they are given the power of healing by their ancestors, and they are supposed to pass on this knowledge only to their children. But mostly it is suspicion. You know, for a long time they were called witches, and quite a few of the older ones are still sore about that; they ask me, "When is that Witchcraft Act of yours going to be repealed?"—as if I had written it! But slowly we are managing to convince them. We want to involve them for the long term, not only to show us the plants and help us grow them but 10 come into the lab to teach us how they prepare the medicine, so that we can quantify everything. But it's not easy.

It is also important, I think, to study the spiritual beliefs of the healers because the whole system is based on those beliefs. They say they are shown the plants in a dream by their ancestors' spirits, and they make diagnoses by throwing bones and going into a trance, during which the spirits speak to them.

What is the state of the environment and biological diversity in Swaziland?

Not very good. I think the underlying problem is overreliance on the natural environment, es-

pecially plant resources, in many rural areas, people have chopped down trees for wood until the land is completely bare; they do not know how to replant. Their grazing animals, such as cattle, often eat whatever plants remain. And the healers may overharvest medicinal plants from the wild. Many plants are disappearing.

Preservation of diversity goes along with preservation of the environment. So, you find that, in parts of Swaziland, certain animals have disappeared because the plants they live on are no longer there. Even the climate is affected. For instance, in the forested highveld of Swaziland, there used to be lots of rain. But as the plants are removed, the rainfall lessens.

Another issue is damage that can result from projects associated with economic development, such as mining and dam construction. It is only recently that companies carrying out these big projects are being required to take care of the environment.

What are the challenges that science education faces in Africa?

We don't have enough resources to build proper science facilities, and we don't have enough science teachers. Another serious problem is the underrepresentation of women in science; this is particularly bad in Africa. Women are left behind. Science, especially physical science, is not considered a field for women. Many people think that if women go too far, they won't get a husband. But the situation is starting to change.

You are the President of the Third World Organization for Women in Science (TWOWS). What does this organization do?

We provide fellowships for postgraduate study, enlisting support from organizational benefactors. The fellowship recipients are usually sent to good universities in developing countries, such as South Africa or Pakistan, where the available money can go a long way. TWOWS also promotes collaboration among women from developing countries who are already established scientists.

But it's crucial to start at the earliest level, primary school. Researchers have learned that once girls get started in science, they do well. But they need to be encouraged by their teachers. If there is equipment available, it is used by the boys; the girls' role may be simply recording the results! So we are working hard to encourage the involvement of women scientists at all levels of education, to show the teachers that girls can be scientists.

"You can control schistosomiasis by killing the parasite with a drug or by killing the snail with a synthetic molluscicide—but both are too expensive in Africa.... *Phytolacca* berries are a better control method... because people can easily grow the plant."

2

The Chemical Context of Life

A. Figure 2.1 The bombardier beetle uses chemistry to defend itself.

Key Concepts

- 2.1 Matter consists of chemical elements in pure form and in combinations called compounds
- 2.2 An element's properties depend on the structure of its atoms
- 2.3 The formation and function of molecules depend on chemical bonding between atoms
- 2.4 Chemical reactions make and break chemical bonds

Overview

Chemical Foundations of Biology

Like other animals, beetles have evolved structures and mechanisms that defend them from attack. The soil-dwelling bombardier beetle has a particularly effective mechanism for dealing with the ants that plague it. Upon detecting an ant on its body, this beetle ejects a spray of boiling hot liquid from glands in its abdomen, aiming the spray directly at the ant. (In **Figure 2.1**, the beetle aims its spray at a scientist's forceps.) The spray contains irritating chemicals that are generated at the moment of ejection by the explosive reaction of two sets of chemicals stored separately in the glands. The reaction produces heat and an audible pop.

Research on the bombardier beetle has involved chemistry, physics, and engineering, as well as biology. This is not surprising, for unlike a college catalog of courses, nature is not neatly packaged into the individual natural sciences. Biologists specialize in the study of life, but organisms and the world they live in are natural systems to which basic concepts of chemistry and physics apply. Biology is a multidisciplinary science.

This unit of chapters introduces key concepts of chemistry that will apply throughout our study of life. We will make

many connections to the themes introduced in Chapter 1. One of those themes is the organization of life into a hierarchy of structural levels, with additional properties emerging at each successive level. In this unit, we will see how the theme of emergent properties applies to the lowest levels of biological organization—to the ordering of atoms into molecules and to the interactions of those molecules within cells. Somewhere in the transition from molecules to cells, we will cross the blurry boundary⁷ between nonlife and life. We begin by considering the chemical components that make up all matter. As Lydia Makhubu mentioned in the interview on pages 30 and 31, chemistry is an integral aspect of biology;

Concept & 2.1

Matter consists of chemical elements in pure form and in combinations called compounds

Elements and Compounds

Organisms are composed of matter, which is anything that takes up space and has mass.* Matter exists in many diverse forms, each with its own characteristics. Rocks, metals, oils, gases, and humans are just a few examples of what seems an endless assortment of matter.

* Sometimes we substitute the term weight for mass, although the two are not identical. Mass is the amount of matter in an object, whereas the weight of an object is how strongly that mass is pulled by gravity. The weight of an astronaut walking on the moon is approximately 1/6 that on Earth, but his or her mass is the same. However, as long as we are earthbound, the weight of an object is a measure of its mass; in everyday language, therefore, we tend to use the terms interchangeably.

A Figure 2.2 The emergent properties of a compound.

The metal sodium combines with the poisonous gas chlorine to form the edible compound sodium chloride, or table salt.

Matter is made up of elements. An **element** is a substance that cannot be broken down to other substances by chemical reactions. Today, chemists recognize 92 elements occurring in nature; gold, copper, carbon, and oxygen are examples. Each element has a symbol, usually the first letter or two of its name. Some of the symbols are derived from Latin or German names; for instance, the symbol for sodium is Na, from the Latin word *natrium*.

A **compound** is a substance consisting of two or more different elements combined in a fixed ratio. Table salt, for example, is sodium chloride (NaCl), a compound composed of the elements sodium (Na) and chlorine (Cl) in a 1:1 ratio. Pure sodium is a metal and pure chlorine is a poisonous gas. When chemically combined, however, sodium and chlorine form an edible compound. This is a simple example of organized matter having emergent properties: A compound has characteristics different from those of its elements (Figure 2.2).

Essential Elements of Life

About 25 of the 92 natural elements are known to be essential to life. Just four of these—carbon (C), oxygen (O), hydrogen (H), and nitrogen (N)—make up 96% of living matter. Phos-

Table 2.1 Naturally Occurring Elements in the Human Body

| Symbol | Element | Atomic Number (See p. 34) | Percentage of Human Body Weight |
|--------|------------|------------------------------|---------------------------------|
| O | Oxygen | 8 | 65.0 |
| C | Carbon | 6 | 18.5 |
| H | Hydrogen | 1 | 9.5 |
| N | Nitrogen | 7 | 3.3 |
| Ca | Calcium | 20 | 1.5 |
| P | Phosphorus | 15 | 1.0 |
| K | Potassium | 19 | 0.4 |
| S | Sulfur | 16 | 0.3 |
| Na | Sodium | 11 | 0.2 |
| Cl | Chlorine | 17 | 0.2 |
| Mg | Magnesium | 12 | 0.1 |

Trace elements (less than 0.01%): boron (B), chromium (Cr), cobalt (Co), copper (Cu), fluorine (F), iodine (I), iron (Fe), manganese (Mn), molybdenum (Mo), selenium (Se), silicon (Si), and vanadium (V).

phorus (P), sulfur (S), calcium (Ca), potassium (K), and a few other elements account for most of the remaining 4% of an organism's weight. Table 2.1 lists by percentage the elements that make up the human body; the percentages for other organisms are similar. Figure 2.3a illustrates the effect of a deficiency of nitrogen, an essential element, in a plant.

Trace elements are those required by an organism in only minute quantities. Some trace elements, such as iron (Fe), are needed by all forms of life; others are required only by certain species. For example, in vertebrates (animals with backbones), the element iodine (I) is an essential ingredient of a hormone produced by the thyroid gland. A daily intake of only 0.15 milligram (mg) of iodine is adequate for normal

(a) Nitrogen deficiency

(b) Iodine deficiency

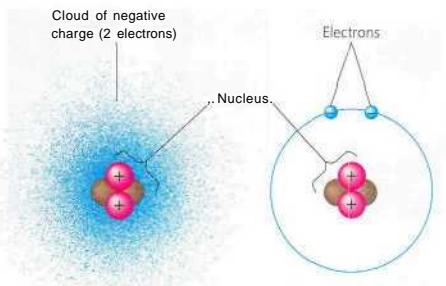

▲ Figure 2.3 The effects of essential-element deficiencies. (a) This photo shows the effect of nitrogen deficiency in corn. In this controlled experiment, the plants on the left are growing in soil that was fertilized with compounds containing nitrogen, while the soil on the right is deficient in nitrogen. (b) Goiter, an enlarged thyroid gland, is the result of a deficiency of the trace element iodine. The goiter of this Malaysian woman can probably be reversed by iodine supplements.

activity of the human thyroid. An iodine deficiency in the diet causes the thyroid gland to grow to abnormal size, a condition called goiter (**Figure 2.3b**). Where it is available, iodized salt has reduced the incidence of goiter.

Concept Check 2.1

- Explain why table salt is a compound, while the oxygen we breathe is not.
- What four chemical elements are most abundant in the food you ate yesterday?

For suggested answers, see Appendix A.

(a) This model represents the electrons as a cloud of negative charge, as if we had taken many snapshots of the 2 electrons over time, with each dot representing an electron's position at one point in time.

(b) In this even more simplified model, the electrons are shown as two small blue spheres on a circle around the nucleus.

A Figure 2.4 Simplified models of a helium (He) atom. The helium nucleus consists of 2 neutrons (brown) and 2 protons (pink). Two electrons (blue) move rapidly around the nucleus. These models are not to scale; they greatly overestimate the size of the nucleus in relation to the electron cloud.

Concept 2.2

An element's properties depend on the structure of its atoms

Each element consists of a certain kind of atom that is different from the atoms of any other element. An atom is the smallest unit of matter that still retains the properties of an element. Atoms are so small that it would take about a million of them to stretch across the period printed at the end of this sentence. We symbolize atoms with the same abbreviation used for the element made up of those atoms; thus, C stands for both the element carbon and a single carbon atom.

Subatomic Particles

Although the atom is the smallest unit having the properties of its element, these tiny bits of matter are composed of even smaller parts, called *subatomic particles*. Physicists have split the atom into more than a hundred types of particles, but only three kinds of particles are stable enough to be of relevance here: neutrons, protons, and electrons. Neutrons and protons are packed together tightly to form a dense core, or atomic nucleus, at the center of the atom. The electrons, moving at nearly the speed of light, form a cloud around the nucleus. **Figure 2.4** shows two models of the structure of the helium atom as an example.

Electrons and protons are electrically charged. Each electron has one unit of negative charge, and each proton has one unit of positive charge. A neutron, as its name implies, is electrically neutral. Protons give the nucleus a positive charge, and it is the attraction between opposite charges that keeps the rapidly moving electrons in the vicinity of the nucleus.

The neutron and proton are almost identical in mass, each about 1.7×10^{-24} gram (g). Grams and other conventional units are not very useful for describing the mass of objects so

minuscule. Thus, for atoms and subatomic particles (and for molecules as well), we use a unit of measurement called the dalton, in honor of John Dalton, the British scientist who helped develop atomic theory around 1800. (The dalton is the same as the *atomic mass unit*, or amu, a unit you may have encountered elsewhere.) Neutrons and protons have masses close to 1 dalton. Because the mass of an electron is only about $\frac{1}{200}$ that of a neutron or proton, we can ignore electrons when computing the total mass of an atom.

Atomic Number and Atomic Mass

Atoms of the various elements differ in their number of subatomic particles. All atoms of a particular element have the same number of protons in their nuclei. This number of protons, which is unique to that element, is called the atomic number and is written as a subscript to the left of the symbol for the element. The abbreviation $_2\text{He}$, for example, tells us that an atom of the element helium has 2 protons in its nucleus. Unless otherwise indicated, an atom is neutral in electrical charge, which means that its protons must be balanced by an equal number of electrons. Therefore, the atomic number tells us the number of protons and also the number of electrons in an electrically neutral atom.

We can deduce the number of neutrons from a second quantity, the mass number, which is the sum of protons plus neutrons in the nucleus of an atom. The mass number is written

as a superscript to the left of an element's symbol. For example, we can use this shorthand to write an atom of helium as ${}^2\text{He}$. Because the atomic number indicates how many protons there are, we can determine the number of neutrons by subtracting the atomic number from the mass number: A ${}^2\text{He}$ atom has 2 neutrons. An atom of sodium, ${}^{23}\text{Na}$, has 11 protons, 11 electrons, and 12 neutrons. The simplest atom is hydrogen ${}^1\text{H}$, which has no neutrons; it consists of a lone proton with a single electron moving around it.

Almost all of an atom's mass is concentrated in its nucleus, because, as mentioned earlier, the contribution of electrons to mass is negligible. Because neutrons and protons each have a mass very close to 1 dalton, the mass number is an approximation of the total mass of an atom, called its **atomic mass**. So we might say that the atomic mass of sodium (MgNa) is 23 daltons, although more precisely it is 22.9898 dakons.

Isotopes

All atoms of a given element have the same number of protons, but some atoms have more neutrons than other atoms of the same element and therefore have greater mass. These different atomic forms are called **isotopes** of the element. In nature, an element occurs as a mixture of its isotopes. For example, consider the three isotopes of the element carbon, which has the atomic number 6. The most common isotope is carbon-12, ${}^{12}\text{C}$, which accounts for about 99% of the carbon in nature. It has 6 neutrons. Most of the remaining 1% of carbon consists of atoms of the isotope ${}^{13}\text{C}$, with 7 neutrons. A third, even rarer isotope, ${}^{14}\text{C}$, has 8 neutrons. Notice that all three isotopes of carbon have 6 protons—otherwise, they would not be carbon. Although isotopes of an element have slightly different masses, they behave identically in chemical reactions. (The number usually given as the atomic mass of an element, such as 22.9898 daltons for sodium, is actually an average of the atomic masses of all the elements naturally occurring isotopes.)

Both ${}^{12}\text{C}$ and ${}^{13}\text{C}$ are stable isotopes, meaning that their nuclei do not have a tendency to lose particles. The isotope ${}^{14}\text{C}$, however, is unstable, or radioactive. A **radioactive isotope** is one in which the nucleus decays spontaneously, giving off particles and energy. When the decay leads to a change in the number of protons, it transforms the atom to an atom of a different element. For example, radioactive carbon decays to form nitrogen.

Radioactive isotopes have many useful applications in biology. In Chapter 26, you will learn how researchers use measurements of radioactivity in fossils to date those relics of past life. Radioactive isotopes are also useful as tracers to follow atoms through metabolism, the chemical processes of an organism. Cells use the radioactive atoms as they would nonradioactive isotopes of the same element, but the radioactive tracers can be readily detected. **Figure 2.5** presents an example of how biologists use radioactive tracers to monitor biological processes, in this case cells making copies of their DNA.

Figure 2.5
Research Method Radioactive Tracers

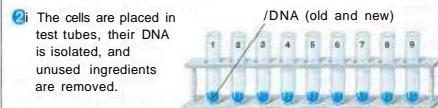

APPLICATION Scientists use radioactive isotopes to label certain chemical substances, creating tracers that can be used to follow a metabolic process or locate the substance within an organism. In this example, radioactive tracers are being used to determine the effect of temperature on the rate at which cells make copies of their DNA.

TECHNIQUE

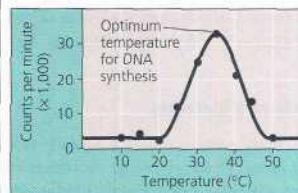

- ① Ingredients for making DNA are added to human cells. One ingredient is labeled with ${}^3\text{H}$, a radioactive isotope of hydrogen. Nine dishes of cells are incubated at different temperatures. The cells make new DNA, incorporating the radioactive tracer with ${}^3\text{H}$.

- ② The cells are placed in test tubes, their DNA is isolated, and unused ingredients are removed.

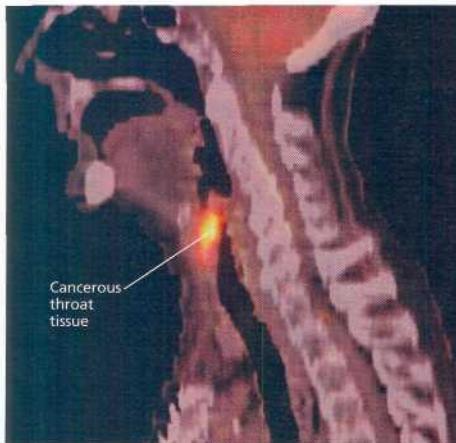

- ③ A solution called scintillation fluid is added to the test tubes and they are placed in a scintillation counter. As the ${}^3\text{H}$ in the newly made DNA decays, it emits radiation that excites chemicals in the scintillation fluid, causing them to give off light. Flashes of light are recorded by the scintillation counter.

U H 3 i 9 H The frequency of flashes, which is recorded as counts per minute, is proportional to the amount of the radioactive tracer present, indicating the amount of new DNA. In this

experiment, when the counts per minute are plotted against temperature, it is clear that temperature affects the rate of DNA synthesis—the most DNA was made at 35 °C.

A Figure 2.6 A PET scan, a medical use for radioactive isotopes. PET, an acronym for positron-emission tomography, detects locations of intense chemical activity in the body. The patient is first injected with a nutrient such as glucose labeled with a radioactive isotope that emits subatomic particles. These particles collide with electrons made available by chemical reactions in the body. A PET scanner detects the energy released in these collisions and maps "hot spots," the regions of an organ that are most chemically active at the time. The color of the image varies with the amount of the isotope present, with the bright yellow color here identifying a hot spot of cancerous throat tissue.

Radioactive tracers are important diagnostic tools in medicine. For example, certain kidney disorders can be diagnosed by injecting small doses of substances containing radioactive isotopes into the blood and then measuring the amount of tracer excreted in the urine. Radioactive tracers are also used in combination with sophisticated imaging instruments, such as PET scanners, which can monitor chemical processes, such as those involved in cancerous growth, as they actually occur in the body (**Figure 2.6**).

Although radioactive isotopes are very useful in biological research and medicine, radiation from decaying isotopes also poses a hazard to life by damaging cellular molecules. The severity of this damage depends on the type and amount of radiation an organism absorbs. One of the most serious environmental threats is radioactive fallout from nuclear accidents. The doses of most isotopes used in medical diagnosis, however, are relatively safe.

The Energy Levels of Electrons

The simplified models of the atom in Figure 2.4 greatly exaggerate the size of the nucleus relative to the volume of the whole atom. If an atom of helium were the size of Yankee Stadium, the nucleus would be only the size of a pencil eraser in

the center of the field. Moreover, the electrons would be like two tiny gnats buzzing around the stadium, in a space approximately a million times as large as the nucleus. Atoms are mostly empty space.

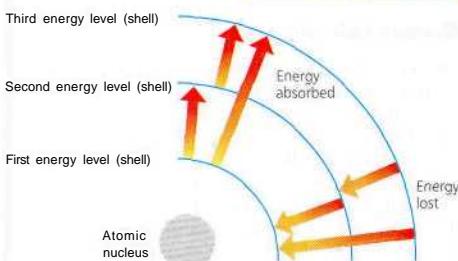

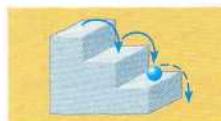

When two atoms approach each other during a chemical reaction, their nuclei do not come close enough to interact. Of the three kinds of subatomic particles we have discussed, only electrons are directly involved in the chemical reactions between atoms.

An atom's electrons vary in the amount of energy they possess. Energy is defined as the capacity to cause change, for instance by doing work. Potential energy is the energy that matter possesses because of its location or structure. For example, because of its altitude, water in a reservoir on a hill has potential energy. When the gates of the reservoir's dam are opened and the water runs downhill, the energy can be used to do work, such as turning generators. Because energy has been expended, the water has less energy at the bottom of the hill than it did in the reservoir. Matter has a natural tendency to move to the lowest possible state of potential energy; in this example, water runs downhill. To restore the potential energy of a reservoir, work must be done to elevate the water against gravity.

The electrons of an atom also have potential energy because of how they are arranged in relation to the nucleus. The negatively charged electrons are attracted to the positively charged nucleus. It takes work to move an electron farther away from the nucleus, so the more distant the electrons are from the nucleus, the greater their potential energy. Unlike the continuous flow of water downhill, changes in the potential energy of electrons can occur only in steps of fixed amounts. An electron having a certain discrete amount of energy is something like a ball on a staircase (**Figure 2.7a**). The ball can have different amounts of potential energy, depending on which step it is on, but it cannot spend much time between the steps. An electron cannot exist in between its fixed states of potential energy.

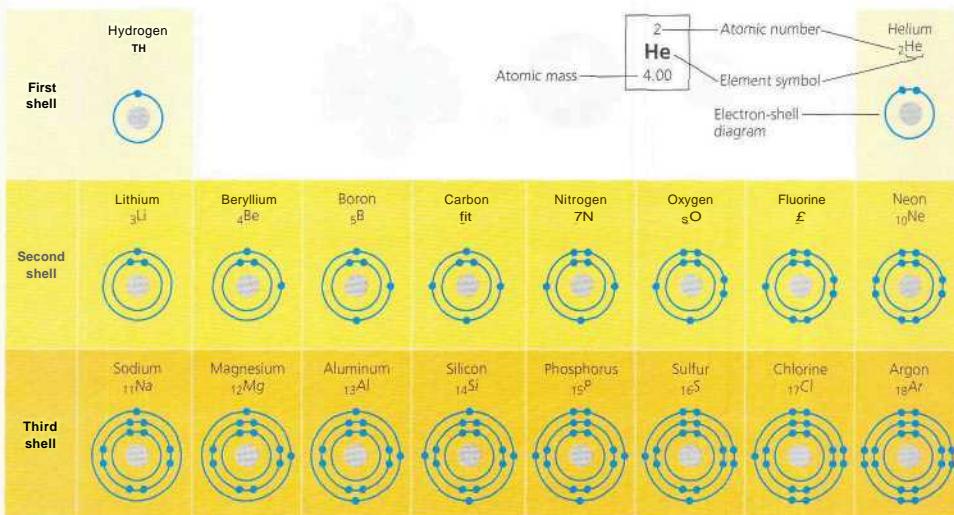

The different states of potential energy that electrons have in an atom are called energy levels. An electron's energy⁷ level is correlated with its average distance from the nucleus; these average distances are represented symbolically by electron shells (**Figure 2.7b**). The first shell is closest to the nucleus, and electrons in this shell have the lowest potential energy. Electrons in the second shell have more energy, electrons in the third shell more energy still, and so on. An electron can change the shell it occupies, but only by absorbing or losing an amount of energy equal to the difference in potential energy between its position in the old shell and that in the new shell. When an electron absorbs energy, it moves to a shell farther out from the nucleus. For example, light energy can excite an electron to a higher energy level. (Indeed, this is the first step taken when plants harness the energy of sunlight for photosynthesis, the process that produces food from carbon dioxide and water.) When an electron loses energy, it "falls back"¹ to a

(a) A ball bouncing down a flight of stairs provides an analogy for energy levels of electrons, because the ball can only rest on each step, not between steps.

(b) An electron can move from one level to another only if the energy it gains or loses is exactly equal to the difference in energy between the two levels. Arrows indicate some of the step-wise changes in potential energy that are possible.

A Figure 2.7 Energy levels of an atom's electrons. Electrons exist only at fixed levels of potential energy, which are also called electron shells.

A Figure 2.8 Electron-shell diagrams of the first 18 elements in the periodic table. In a standard periodic table, information for each element is presented as shown for helium in the inset. In the diagrams in this

modified table, electrons are shown as blue dots and electron shells (representing energy levels) as concentric rings. We are using these electron-shell diagrams as a convenient way to picture the distribution of an atom's electrons

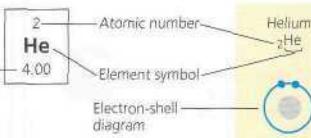

among its electron shells, but keep in mind that these are simplified models. The elements are arranged in rows, each representing the filling of an electron shell. As electrons are added, they occupy the lowest available shell.

shell closer to the nucleus, and the lost energy is usually released to the environment in the form of heat. For example, sunlight excites electrons in the paint of a dark car to higher energy levels. When the electrons fall back to their original levels, the surface of the car heats up. This thermal energy can be transferred to the air or to your hand if you touch the car.

Electron Configuration and Chemical Properties

The chemical behavior of an atom is determined by its electron configuration—that is, the distribution of electrons in the atom's electron shells. Beginning with hydrogen, the simplest atom, we can imagine building the atoms of the other elements by adding 1 proton and 1 electron at a time (along with an appropriate number of neutrons). **Figure 2.8**, an abbreviated version of what is called the *periodic table of the elements*, shows this distribution of electrons for the first 18 elements, from hydrogen (₁H) to argon (₁₈Ar). The elements are arranged in three rows, or periods, corresponding to the number of electron shells in their atoms. The left-to-right sequence of elements in each row corresponds to the sequential addition of electrons (and protons).

Hydrogen's 1 electron and helium's 2 electrons are located in the first shell. Electrons, like all matter, tend to exist in the

lowest available state of potential energy, which they have in the first shell. However, the first shell can hold no more than 2 electrons; thus, there are only two elements (hydrogen and helium) in the first row of the table. An atom with more than 2 electrons must use higher shells because the first shell is full. The next element, lithium, has 3 electrons. Two of these electrons fill the first shell while the third electron occupies the second shell. The second shell holds a maximum of 8 electrons. Neon, at the end of the second row, has 8 electrons in the second shell, giving it a total of 10 electrons.

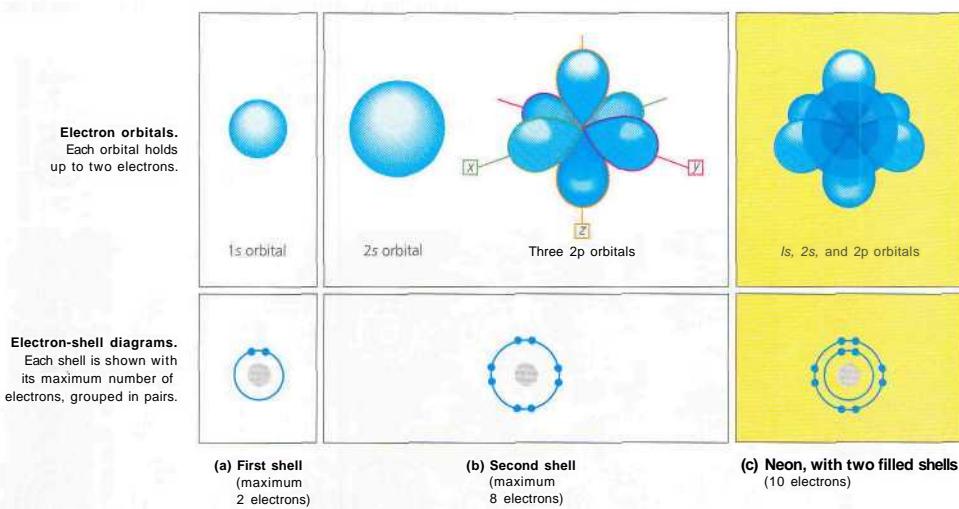

The chemical behavior of an atom depends mostly on the number of electrons in its *outermost* shell. We call those outer electrons **valence electrons** and the outermost electron shell the **valence shell**. In the case of lithium, there is only 1 valence electron, and the second shell is the valence shell. Atoms with the same number of electrons in their valence shells exhibit similar chemical behavior. For example, fluorine (F) and chlorine (Cl) both have 7 valence electrons, and both combine with the element sodium to form compounds (see Figure 2.2). An atom with a completed valence shell is unreactive; that is, it will not interact readily with other atoms it encounters. At the far right of the periodic table are helium, neon, and argon,

the only three elements shown in Figure 2.8 that have full valence shells. These elements are said to be *inert*, meaning chemically unreactive. All the other atoms in Figure 2.8 are chemically reactive because they have incomplete valence shells.

Electron Orbitals

Early in the 20th century, the electron shells of an atom were visualized as concentric paths of electrons orbiting the nucleus, somewhat like planets orbiting the sun. It is still convenient to use two-dimensional concentric-circle diagrams to symbolize electron shells, as in Figure 2.8, if we bear in mind that an electron shell represents the *average* distance of an electron from the nucleus. This is only a model, however, and it does not give a real picture of an atom. In reality, we can never know the exact path of an electron. What we can do instead is describe the space in which an electron spends most of its time. The three-dimensional space where an electron is found 90% of the time is called an orbital.

Each electron shell consists of a specific number of orbitals of distinctive shapes and orientations (Figure 2.9). You can

A Figure 2.9 Electron orbitals. The three-dimensional shapes in the top half of this figure represent electron orbitals—the volumes of space where the electrons of an atom are most likely to be found. Each orbital holds a maximum of 2 electrons. The bottom half of the figure shows the corresponding electron-

shell diagrams. (a) The first electron shell has one spherical (s) orbital, designated 1s. (b) The second and all higher shells each have one larger s orbital (designated 2s for the second shell) plus three dumbbell-shaped orbitals called p orbitals (2p for the second shell). The three 2p orbitals lie at right angles to one another

along imaginary x-, y-, and z-axes of the atom. Each 2p orbital is outlined here in a different color. (c) To symbolize the electron orbitals of the element neon, which has a total of 10 electrons, we superimpose the 1s orbital of the first shell and the 2s and three 2p orbitals of the second shell.

think of an orbital as a component of an electron shell. (Recall that an electron shell corresponds to a particular energy level.) The first electron shell has only one spherical *s* orbital (called 1s), but the second shell has four orbitals: one large spherical *s* orbital (called 2s) and three dumbbell-shaped *p* orbitals (called 2p orbitals). Each 1*p* orbital is oriented at right angles to the other two 2*p* orbitals (see Figure 2.9). (The third and higher electron shells also have *s* and *p* orbitals, as well as orbitals of more complex shapes.)

No more than 2 electrons can occupy a single orbital. The first electron shell can therefore accommodate a maximum of 2 electrons in its *s* orbital. The lone electron of a hydrogen atom occupies the 1*s* orbital, as do the 2 electrons of a helium atom. The four orbitals of the second electron shell can hold a maximum of 8 electrons. Electrons in each of the four orbitals have nearly the same energy but they move in different volumes of space.

The reactivity of atoms arises from the presence of unpaired electrons in one or more orbitals of their valence shells. Notice that the electron configurations in Figure 2.8 build up with the addition of 1 electron at a time. For simplicity, we place 1 electron on each side of the outer shell until the shell is half full, and then pair up electrons until the shell is full. When atoms interact to complete their valence shells, it is the *unpaired* electrons that are involved.

Concept 2.3

The formation and function of molecules depend on chemical bonding between atoms

Now that we have looked at the structure of atoms, we can move up the hierarchy of organization and see how atoms combine to form molecules and ionic compounds. Atoms with incomplete valence shells can interact with certain other atoms in such a way that each partner completes its valence shell: The atoms either share or transfer valence electrons. These interactions usually result in atoms staying close together, held by attractions called chemical bonds. The strongest kinds of chemical bonds are covalent bonds and ionic bonds.

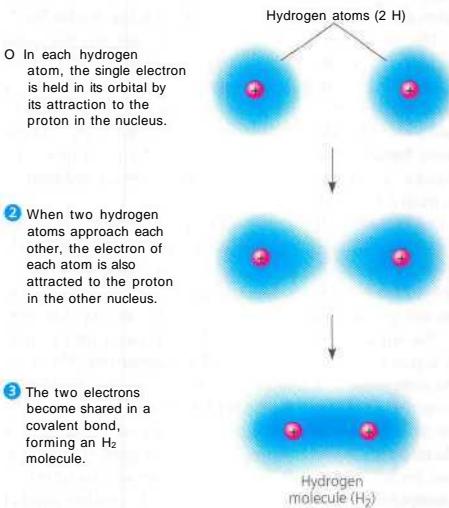

Covalent Bonds

A covalent bond is the sharing of a pair of valence electrons by two atoms. For example, let's consider what happens when two hydrogen atoms approach each other. Recall that hydrogen has 1 valence electron in the first shell, but the shell's capacity is 2 electrons. When the two hydrogen atoms come close enough for their 1*s* orbitals to overlap, they share their electrons (Figure 2.10). Each hydrogen atom now has 2 electrons associated with it in what amounts to a completed valence shell, shown in an electron-shell diagram in

Concept Check 2.2

1. A lithium atom has 3 protons and 4 neutrons. What is its atomic mass in daltons?
2. A nitrogen atom has 7 protons, and the most common isotope of nitrogen has 7 neutrons. A radioactive isotope of nitrogen has 8 neutrons. What is the atomic number and mass number of this radioactive nitrogen? Write as a chemical symbol with a subscript and superscript.
3. Look at Figure 2.8, and determine the atomic number of magnesium. How many protons and electrons does it have? How many electron shells? How many valence electrons are in the valence shell?
4. In an electron-shell diagram of phosphorus, in which shell do electrons have the most potential energy? In which shell do electrons have the least potential energy?
5. How many electrons does fluorine have? How many electron shells? Name the orbitals that are occupied. How many unpaired electrons does fluorine have?

For suggested answers, see Appendix A.

A Figure 2.10 Formation of a covalent bond.

Figure 2.11a. Two or more atoms held together by covalent bonds constitute a molecule. In this case, we have formed a hydrogen molecule. We can abbreviate the structure of this molecule as H=H, where the line represents a single covalent bond, or simply a single bond—that is, a pair of shared electrons. This notation, which represents both atoms and bonding, is called a structural formula. We can abbreviate even further by writing H₂, a molecular formula indicating simply that the molecule consists of two atoms of hydrogen.

With 6 electrons in its second electron shell, oxygen needs 2 more electrons to complete its valence shell. Two oxygen atoms form a molecule by sharing *two* pairs of valence electrons (Figure 2.11b). The atoms are thus joined by what is called a double covalent bond, or simply a double bond.

Each atom that can share valence electrons has a bonding capacity corresponding to the number of covalent bonds the atom can form. When the bonds form, they give the atom a full complement of electrons in the valence shell. The bonding capacity of oxygen, for example, is 2. This bonding capacity is called the atom's valence and usually equals the number of unpaired electrons in the atom's outermost (valence) shell. See if you can determine the valences of hydrogen, oxygen, nitrogen, and carbon by studying the electron configurations in Figure 2.8. By counting the unpaired electrons, you can see that the valence of hydrogen is 1; oxygen, 2; nitrogen, 3; and carbon, 4. A more complicated case is phosphorus (P), another element important to life. Phosphorus can have a valence of 3, as we would predict from its 3 unpaired electrons. In biologically important molecules, however, we can consider it to have a valence of 5, forming three single bonds and one double bond.

The molecules H₂ and O₂ are pure elements, not compounds. (Recall that a compound is a combination of two or more *different* elements.) An example of a molecule that is a compound is water, with the molecular formula H₂O. It takes two atoms of hydrogen to satisfy the valence of one oxygen atom. Figure 2.11c shows the structure of a water molecule. Water is so important to life that Chapter 3 is devoted entirely to its structure and behavior.

Another molecule that is a compound is methane, the main component of natural gas, with the molecular formula CH₄ (Figure 2.11d). It takes four hydrogen atoms, each with a valence of 1, to complement one atom of carbon, with its valence of 4. We will look at many other compounds of carbon in Chapter 4.

The attraction of a particular kind of atom for the electrons of a covalent bond is called its electronegativity. The more electronegative an atom, the more strongly it pulls shared electrons toward itself. In a covalent bond between two atoms of the same element, the outcome of the tug-of-war for common electrons is a standoff; the two atoms are equally electronegative. Such a bond, in which the electrons are shared equally, is a nonpolar covalent bond. For example, the covalent bond of H₂ is nonpolar, as is the double bond of O₂. In other compounds, however, where one atom is bonded to a more de-

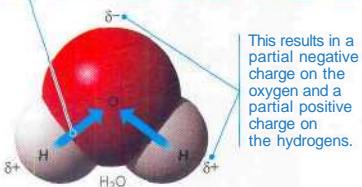

| Name (molecular formula) | Electron- shell diagram | Structural formula | Space- filling model |
|---|---|-----------------------|--|
| (a) Hydrogen (H₂). Two hydrogen atoms can form a single bond. | (lip) | H—H |  |
| (b) Oxygen (O₂). Two oxygen atoms share two pairs of electrons to form a double bond. |  | O=O |  |
| (c) Water (H₂O). Two hydrogen atoms and one oxygen atom are joined by covalent bonds to produce a molecule of water. |  | O—H H |  |
| (d) Methane (CH₄). Four hydrogen atoms can satisfy the valence of one carbon atom, forming methane. |  | H—C—H H |  |

A Figure 2.11 Covalent bonding in four molecules. A single covalent bond consists of a pair of shared electrons. The number of electrons required to complete an atom's valence shell generally determines how many bonds that atom will form. Three ways of indicating bonds are shown; the space-filling model comes closest to representing the actual shape of the molecule (see also Figure 2.16).

tronegative atom, the electrons of the bond are not shared equally. This sort of bond is called a polar covalent bond. Such bonds vary in their polarity, depending on the relative electronegativity of the two atoms. For example, the individual bonds of methane (CH₄) are slightly polar because carbon and hydrogen differ slightly in electronegativity. In a more extreme example, the bonds between the oxygen and hydrogen atoms of a water molecule are quite polar (Figure 2.12). Oxygen is one of the most electronegative of the 92 elements, attracting shared electrons much more strongly than hydrogen does. In a covalent bond between oxygen and hydrogen, the electrons spend more time near the oxygen nucleus than they do near the hydrogen nucleus. Because electrons have a negative charge, the unequal sharing of electrons in water causes the oxygen atom to have a partial negative charge (indicated by the Greek letter 8 before a minus sign, 8⁻, or "delta minus") and each hydrogen atom a partial positive charge (8⁺, or "delta plus").

4

Because oxygen (O) is more electronegative than hydrogen (H), shared electrons are pulled more toward oxygen.

A Figure 2.12 Polar covalent bonds in a water molecule.

Ionic Bonds

In some cases, two atoms are so unequal in their attraction for valence electrons that the more electronegative atom strips an electron completely away from its partner. This is what happens when an atom of sodium (${}_1\text{Na}$) encounters an atom of chlorine (${}-7\text{Cl}$) (Figure 2.13). A sodium atom has a total of 11 electrons, with its single valence electron in the third electron shell. A chlorine atom has a total of 17 electrons, with 7 electrons in its valence shell. When these two atoms meet, the lone valence electron of sodium is transferred to the chlorine atom, and both atoms end up with their valence shells complete. (Because sodium no longer has an electron in the third shell, the second shell is now the valence shell.)

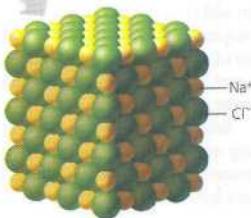

The electron transfer between the two atoms moves one unit of negative charge from sodium to chlorine. Sodium, now with 11 protons but only 10 electrons, has a net electrical charge of $1+$. A charged atom (or molecule) is called an ion. When the charge is positive, the ion is specifically called a cation; the sodium atom has become a cation. Conversely, the chlorine atom, having gained an extra electron, now has 17 protons and 18 electrons, giving it a net electrical charge of $1-$; it has become a chloride ion—an anion, or negatively

charged ion. Because of their opposite charges, cations and anions attract each other; this attraction is called an ionic bond. The transfer of an electron is not the formation of a bond; rather, it allows a bond to form because it results in two ions. Any two ions of opposite charge can form an ionic bond. The ions need not have acquired their charge by an electron transfer with each other.

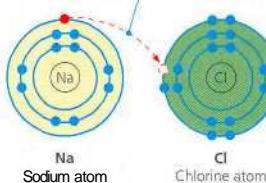

Compounds formed by ionic bonds are called ionic compounds, or salts. We know the ionic compound sodium chloride (NaCl) as table salt (Figure 2.14). Salts are often found in nature as crystals of various sizes and shapes, each an aggregate of vast numbers of cations and anions bonded by their electrical attraction and arranged in a three-dimensional lattice. A salt crystal does not consist of molecules in the sense that a covalently bonded molecule has a definite size and number of atoms. The formula for an ionic compound, such as NaCl , indicates only the ratio of elements in a crystal of the salt. " NaCl " is not a molecule.

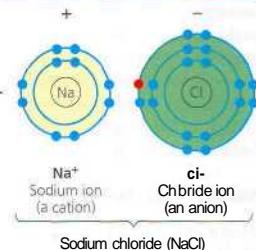

< Figure 2.14 A sodium chloride crystal. The sodium ions (Na^+) and chloride ions (Cl^-) are held together by ionic bonds. The formula NaCl tells us that the ratio of Na^+ to Cl^- is 1:1.

O The lone valence electron of a sodium atom is transferred to join the 7 valence electrons of a chlorine atom.

Q Each resulting ion has a completed valence shell. An ionic bond can form between the oppositely charged ions.

> Figure 2.13 Electron transfer and ionic bonding. The attraction between oppositely charged atoms, or ions, is an ionic bond. An ionic bond can form between any two oppositely charged ions, even if they have not been formed by transfer of an electron from one to the other.

Not all salts have equal numbers of cations and anions. For example, the ionic compound magnesium chloride ($MgCl_2$) has two chloride ions for each magnesium ion. Magnesium (Mg) must lose 2 outer electrons if the atom is to have a complete valence shell, so it tends to become a cation with a net charge of $2+$ (Mg^{2+}). One magnesium cation can therefore form ionic bonds with two chloride anions.

The term ion also applies to entire molecules that are electrically charged. In the salt ammonium chloride (NH_4Cl), for instance, the anion is a single chloride ion (Cl^-), but the cation is ammonium (NH_4^+), a nitrogen atom with four covalently bonded hydrogen atoms. The whole ammonium ion has an electrical charge of $1+$ because it is 1 electron short.

Environment affects the strength of ionic bonds. In a dry salt crystal the bonds are so strong that it takes a hammer and chisel to break enough of them to crack the crystal in two. Place the same salt crystal in water, however, and the salt dissolves as the attractions between its ions decrease. In the next chapter, you will learn how water dissolves salts.

Weak Chemical Bonds

In living organisms, most of the strongest chemical bonds are covalent ones, which link atoms to form a cell's molecules. But weaker bonding within and between molecules is also indispensable in the cell, where the properties of life emerge from such interactions. The most important large biological molecules are held in their functional form by weak bonds. In addition, when two molecules in the cell make contact, they may adhere temporarily by weak bonds. The reversibility of weak bonding can be an advantage: Two molecules can come together, respond to one another in some way, and then separate.

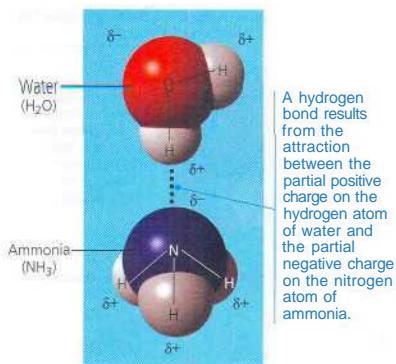

Several types of weak chemical bonds are important in living organisms. One is the ionic bond, which we just discussed. Another type of weak bond, crucial to life, is known as a hydrogen bond.

Hydrogen Bonds

Among the various kinds of weak chemical bonds, hydrogen bonds are so important in the chemistry of life that they deserve special attention. A hydrogen bond forms when a hydrogen atom covalently bonded to one electronegative atom is also attracted to another electronegative atom. In living cells, the electronegative partners involved are usually oxygen or nitrogen atoms. Refer to **Figure 2.15** to examine the simple case of hydrogen bonding between water (H_2O) and ammonia (NH_3). In the next chapter, we'll see how hydrogen bonds between water molecules allow some insects to walk on water.

Van der Waals Interactions

Even a molecule with nonpolar covalent bonds may have positively and negatively charged regions. Because electrons are in

• **Figure 2.15 A hydrogen bond.**

constant motion, they are not always symmetrically distributed in the molecule; at any instant, they may accumulate by chance in one part of the molecule or another. The results are ever-changing "hot spots" of positive and negative charge that enable all atoms and molecules to stick to one another.

These van der Waals interactions are weak and occur only when atoms and molecules are very close together. In spite of their weakness, van der Waals interactions were recently shown to be responsible for the ability of a gecko lizard (right) to walk up a wall. Each gecko toe has hundreds of thousands of tiny hairs, with multiple projections at the hair's tip that increase surface area. Apparently, the van der Waals interactions between the hair tip molecules and the molecules of the wall's surface are so numerous that in spite of their individual weakness, together they can support the gecko's body weight.

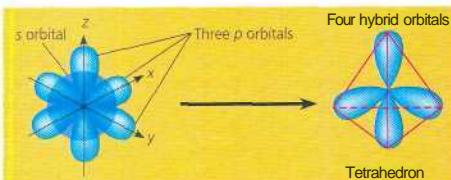

Van der Waals interactions, hydrogen bonds, ionic bonds, and other weak bonds may form not only between molecules but also between different regions of a single large molecule, such as a protein. Although these bonds are individually weak, their cumulative effect is to reinforce the three-dimensional shape of a large molecule. You will learn more about the very important biological roles of weak bonds in Chapter 5.

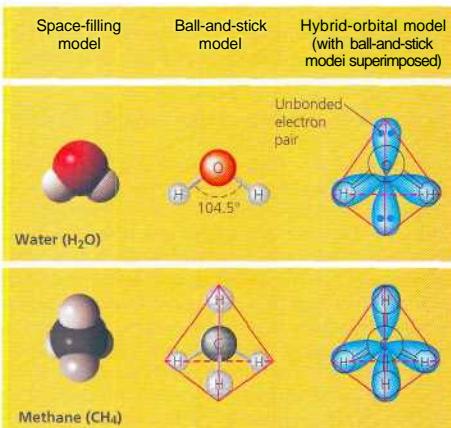

Molecular Shape and Function

A molecule has a characteristic size and shape. The precise shape of a molecule is usually very important to its function in the living cell.

A molecule consisting of two atoms, such as H_2 or O_2 , is always linear, but molecules with more than two atoms have

(a) Hybridization of orbitals. The single s and three p orbitals of a valence shell involved in covalent bonding combine to form four teardrop-shaped hybrid orbitals. These orbitals extend to the four corners of an imaginary tetrahedron (outlined in pink).

(b) Molecular shape models. Three models representing molecular shape are shown for two examples: water and methane. The positions of the hybrid orbitals determine the shapes of the molecules.

A Figure 2.16 Molecular shapes due to hybrid orbitals.

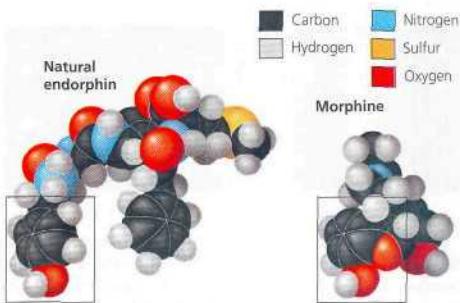

more complicated shapes. These shapes are determined by the positions of the atoms' orbitals. When an atom forms covalent bonds, the orbitals in its valence shell rearrange. For atoms with valence electrons in both s and p orbitals (review Figure 2.9), the single s and three p orbitals hybridize to form four new hybrid orbitals shaped like identical teardrops extending from the region of the atomic nucleus (Figure 2.16a). If we connect the larger ends of the teardrops with lines, we have the outline of a geometric shape called a tetrahedron, similar to a pyramid.

For the water molecule (H_2O), two of the hybrid orbitals in the oxygen atom's valence shell are shared with hydrogen atoms (Figure 2.16b). The result is a molecule shaped roughly like a Y its two covalent bonds spread apart at an angle of 104.5° .

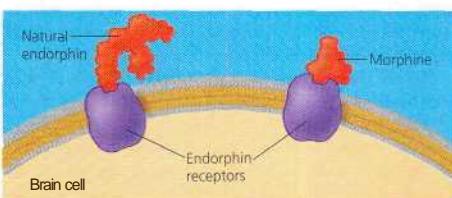

The methane molecule (CH_4) has the shape of a completed tetrahedron because all four hybrid orbitals of carbon are shared with hydrogen atoms (see Figure 2.16b). The nucleus

of the carbon is at the center, with its four covalent bonds radiating to hydrogen nuclei at the corners of the tetrahedron. Larger molecules containing multiple carbon atoms, including many of the molecules that make up living matter, have more complex overall shapes. However, the tetrahedral shape of a carbon atom bonded to four other atoms is often a repeating motif within such molecules.

Molecular shape is crucial in biology because it determines how biological molecules recognize and respond to one another with specificity. Only molecules with complementary shapes are able to bind to each other by weak bonds. An example of this specificity is provided by a mechanism of pain control. Natural signal molecules called endorphins bind to specific molecules, called receptors, on the surface of brain cells, producing euphoria and relieving pain. It turns out that molecules with shapes similar to endorphins have similar effects. Morphine, heroin, and other opiate drugs, for example, mimic endorphins by binding to endorphin receptors in the brain (Figure 2.17). The role of molecular shape in brain chemistry illustrates the relationship between structure and function, one of biology's unifying themes.

(a) Structures of endorphin and morphine. The boxed portion of the endorphin molecule (left) binds to receptor molecules on target cells in the brain. The boxed portion of the morphine molecule (right) is a close match.

(b) Binding to endorphin receptors. Endorphin receptors on the surface of a brain cell can bind to both endorphin and morphine.

A Figure 2.17 A molecular mimic. Morphine affects pain perception and emotional state by mimicking the brain's natural endorphins.

Concept Check

1. Why does the following structure fail to make sense chemically?

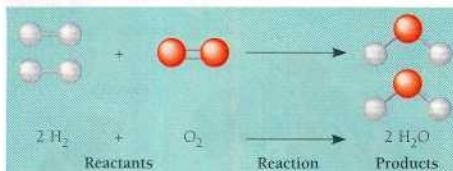

2. Explain what holds together the atoms in a crystal of magnesium chloride (MgCl_2).

For suggested answers, see Appendix A.

Concept 2.4

Chemical reactions make and break chemical bonds

The making and breaking of chemical bonds, leading to changes in the composition of matter, are called **chemical reactions**. An example is the reaction between hydrogen and oxygen to form water:

This reaction breaks the covalent bonds of H_2 and O_2 and forms the new bonds of H_2O . When we write a chemical reaction, we use an arrow to indicate the conversion of the starting materials, called the **reactants**, to the **products**. The coefficients indicate the number of molecules involved; for example, the coefficient 2 in front of the H_2 means that the reaction starts with two molecules of hydrogen. Notice that all atoms of the reactants must be accounted for in the products. Matter is conserved in a chemical reaction: Reactions cannot create or destroy matter but can only rearrange it.

Photosynthesis, which takes place within the cells of green plant tissues, is a particularly important example of how chemical reactions rearrange matter. Humans and other animals ultimately depend on photosynthesis for food and oxygen, and this process is at the foundation of almost all ecosystems. The following chemical shorthand summarizes the process of photosynthesis:

The raw materials of photosynthesis are carbon dioxide (CO_2), which is taken from the air, and water (H_2O), which is

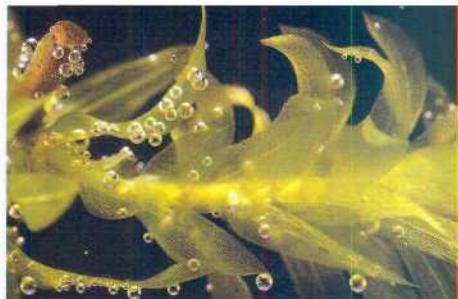

absorbed from the soil. Within the plant cells, sunlight powers the conversion of these ingredients to a sugar called glucose ($\text{C}_6\text{H}_{12}\text{O}_6$) and oxygen molecules (O_2), a by-product that the plant releases into the surroundings (Figure 2.18). Although photosynthesis is actually a sequence of many chemical reactions, we still end up with the same number and kinds of atoms we had when we started—Matter has simply been rearranged, with an **input** of energy provided by sunlight.

Some chemical reactions go to completion; that is, all the reactants are converted to products. But most reactions are reversible, the products of the forward reaction becoming the reactants for the reverse reaction. For example, hydrogen and nitrogen molecules can combine to form ammonia, but ammonia can also decompose to regenerate hydrogen and nitrogen:

The opposite-headed arrows indicate that the reaction is reversible.

One of the factors affecting the rate of a reaction is the concentration of reactants. The greater the concentration of reactant molecules, the more frequently they collide with one another and have an opportunity to react to form products. The same holds true for the products. As products accumulate, collisions resulting in the reverse reaction become increasingly frequent. Eventually, the forward and reverse reactions occur at the same rate, and the relative concentrations of products and reactants stop changing. The point at which the reactions offset one another exactly is called **chemical equilibrium**. This is a dynamic equilibrium; reactions are still going on, but with no net effect on the concentrations of reactants and products. Equilibrium does *not* mean that the reactants and products are

A **Figure 2.18** Photosynthesis: a solar-powered rearrangement of matter. *Elodea*, a freshwater plant, produces sugar by rearranging the atoms of carbon dioxide and water in the chemical process known as photosynthesis, which is powered by sunlight. Much of the sugar is then converted to other food molecules. Oxygen gas (O_2) is a by-product of photosynthesis; notice the bubbles of oxygen escaping from the leaves in the photo.

equal in concentration, but only that their concentrations have stabilized at a particular ratio. The reaction involving ammonia reaches equilibrium when ammonia decomposes as rapidly as it forms. In this case, there is far more ammonia than hydrogen and nitrogen at equilibrium.

We will return to the subject of chemical reactions after more detailed study of the various types of molecules that are important to life. In the next chapter, we focus on water, the substance in which all the chemical processes of living organisms occur.

Concept Check 2.4

- Refer to the reaction between hydrogen and oxygen to form water, shown as a ball-and-stick model on page 44. Draw the electron-shell diagram representing this reaction.
- Which occurs faster at equilibrium, the formation of products from reactants, or reactants from products?

For suggested answers, see Appendix A.

Chapter *J Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 2.1

Matter consists of chemical elements in pure form and in combinations called compounds

I* **Elements and Compounds** (pp. 32–33) Elements cannot be broken down chemically to other substances. A compound contains two or more elements in a fixed ratio.

II* **Essential Elements of Life** (pp. 33–34) Carbon, oxygen, hydrogen, and nitrogen make up approximately 96% of living matter.

Investigation How Are Space Rocks Analyzed for Signs of Life?

Concept 2.2

An element's properties depend on the structure of its atoms

• **Subatomic Particles** (p. 34) An atom is the smallest unit of an element. An atom has a nucleus made up of positively charged protons and uncharged neutrons, as well as a surrounding cloud of negatively charged electrons.

Activity Structure of the Atomic Nucleus

• **Atomic Number and Atomic Mass** (pp. 34–35) The number of electrons in an electrically neutral atom equals the number of protons.

• **Isotopes** (pp. 35–36) Most elements have two or more isotopes, different in neutron number and therefore mass. Some isotopes are unstable and give off particles and energy as radioactivity. Radioactive tracers help biologists monitor biological processes.

• **The Energy Levels of Electrons** (pp. 36–37) In an atom, electrons occupy specific energy levels, each of which can be represented by an electron shell of that atom.

• **Electron Configuration and Chemical Properties** (pp. 37–38) Electron configuration determines the chemical behavior of an atom. Chemical behavior depends on the number of valence electrons—electrons in the outermost shell. An atom with an incomplete valence shell is reactive.

Activity Electron Arrangement

• **Electron Orbitals** (pp. 38–39) Electrons move within orbitals, three-dimensional spaces with specific shapes located within each successive shell.

Activity Build an Atom

Concept 2.3

The formation and function of molecules depend on chemical bonding between atoms

• **Covalent Bonds** (pp. 39–41) Chemical bonds form when atoms interact and complete their valence shells. A single covalent bond is the sharing of a pair of valence electrons by two atoms; double bonds are the sharing of two pairs of electrons. Molecules consist of two or more covalently bonded atoms. Electrons of a polar covalent bond are pulled closer to the more electronegative atom. A covalent bond is nonpolar if both atoms are the same and therefore equally electronegative.

Activity Covalent Bonds

Activity Nonpolar and Polar Molecules

• **Ionic Bonds** (pp. 41–42) Two atoms may differ so much in electronegativity that one or more electrons are actually transferred from one atom to the other. The result is a negatively charged ion (anion) and a positively charged ion (cation). The attraction between two ions of opposite charge is called an ionic bond.

Activity Ionic Bonds

• **Weak Chemical Bonds** (p. 42) A hydrogen bond is a weak attraction between one electronegative atom and a hydrogen atom that is covalently linked to another electronegative atom. Van der Waals interactions occur when transiently positive and negative regions of molecules attract each other. Weak bonds reinforce the shapes of large molecules and help molecules adhere to each other.

Activity Hydrogen Bonds

• **Molecular Shape and Function** (pp. 42–44) A molecule's shape is determined by the positions of its atoms' valence orbitals. When covalent bonds form, the s and p orbitals in the valence shell of an atom may combine to form four hybrid orbitals that extend to the corners of an imaginary tetrahedron; such orbitals are responsible for the shapes of H₂O, CH₄, and many more complex biological molecules. Shape is usually the basis for the recognition of one biological molecule by another.

Concept 2.4

Chemical reactions make and break chemical bonds

• Chemical reactions change reactants into products while conserving matter. Most chemical reactions are reversible. Chemical equilibrium is reached when the forward and reverse reaction rates are equal (pp. 44–45).

TESTING YOUR KNOWLEDGE

Evolution Connection

The text states that the percentages of naturally occurring elements making up the human body (see Table 2.1) are similar to the percentages of these elements found in other organisms. How could you account for this similarity among organisms?

Scientific Inquiry

Female silkworm moths (*Bombyx mori*) attract males by emitting chemical signals that spread through the air. A male hundreds of meters away can detect these molecules and fly toward their source. The sensory organs responsible for this behavior are the comblike antennae visible in the photograph here. Each filament of an antenna is equipped with thousands of receptor cells that detect the sex attractant. Based on what you learned in this chapter, propose a hypothesis to account for the ability of the male moth to detect a specific molecule in the presence of many other molecules in the air. What predictions does your hypothesis make? Design an experiment to test one of these predictions.

investigation How Are Space Rocks Analyzed for Signs of Life?

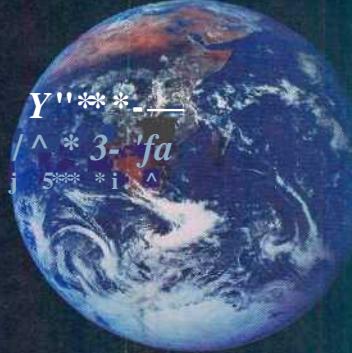

Science, Technology, and Society

While waiting at an airport, Neil Campbell once overheard this claim: "It's paranoid and ignorant to worry about industry or agriculture contaminating the environment with their chemical wastes. After all, this stuff is just made of the same atoms that were already present in our environment." How would you counter this argument?

Water and the Fitness of the Environment

• Figure 3.1 A view of Earth from space, showing our planet's abundance of water.

Key Concepts

- 3.1 The polarity of water molecules results in hydrogen bonding
- 3.2 Four emergent properties of water contribute to Earth's fitness for life
- 3.3 Dissociation of water molecules leads to acidic and basic conditions that affect living organisms

Overview

The Molecule That Supports All of Life

As astronomers study newly discovered planets orbiting distant stars, they hope to find evidence of water on these far-off celestial bodies, for water is the substance that makes possible life as we know it here on Earth. All organisms familiar to us are made mostly of water and live in an environment dominated by water. Water is the biological medium here on Earth, and possibly on other planets as well.

Life on Earth began in water and evolved there for 3 billion years before spreading onto land. Modern life, even terrestrial (land-dwelling) life, remains tied to water. All living organisms require water more than any other substance. Human beings, for example, can survive for quite a few weeks without food, but only a week or so without water. Molecules of water participate in many chemical reactions necessary to sustain life. Most cells are surrounded by water, and cells themselves are about 70–95% water. Three-quarters of Earth's surface is submerged in water (Figure 3.1). Although most of this water is in liquid form, water is also present on Earth as ice and vapor. Water is the only common substance to exist in the natural environment in all three physical states of matter: solid, liquid, and gas.

The abundance of water is a major reason Earth is habitable. In a classic book called *The Fitness of the Environment*, ecologist Lawrence Henderson highlights the importance of water to life. While acknowledging that life adapts to its environment through natural selection, Henderson emphasizes that for life to exist at all, the environment must first be a suitable abode. In this chapter, you will learn how the structure of a water molecule allows it to form weak chemical bonds with other molecules, including other water molecules. This ability leads to unique properties that support and maintain living systems on our planet. Your objective in this chapter is to develop a conceptual understanding of how water contributes to the fitness of Earth for life.

Concept 3.1

The polarity of water molecules results in hydrogen bonding

Water is so common that it is easy to overlook the fact that it is an exceptional substance with many extraordinary qualities. Following the theme of emergent properties, we can trace water's unique behavior to the structure and interactions of its molecules.

Studied in isolation, the water molecule is deceptively simple. Its two hydrogen atoms are joined to the oxygen atom by single covalent bonds. Because oxygen is more electronegative than hydrogen, the electrons of the polar bonds spend more time closer to the oxygen atom. In other words, the bonds that hold together the atoms in a water molecule are polar covalent bonds. The water molecule, shaped something like a wide Y is a polar molecule, meaning that opposite ends of the molecule have opposite charges: The oxygen region of the molecule has

Concept 3.2

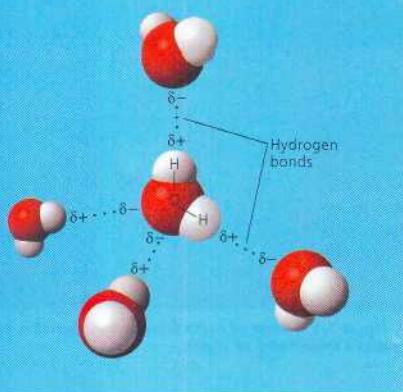

Four emergent properties of water contribute to Earth's fitness for life

We will examine four of water's properties that contribute to the suitability of Earth as an environment for life. These are water's cohesive behavior, its ability to moderate temperature, its expansion upon freezing, and its versatility as a solvent.

Cohesion

Water molecules stay close to each other as a result of hydrogen bonding. When water is in its liquid form, its hydrogen bonds are very fragile, about one-twentieth as strong as covalent bonds. They form, break, and re-form with great frequency. Each hydrogen bond lasts only a few trillionths of a second, but the molecules are constantly forming new bonds with a succession of partners. Thus, at any instant, a substantial percentage of all the water molecules are bonded to their neighbors, making water more structured than most other liquids. Collectively, the hydrogen bonds hold the substance together, a phenomenon called cohesion.

Cohesion due to hydrogen bonding contributes to the transport of water and dissolved nutrients against gravity in plants (**Figure 3.3**). Water from the roots reaches the leaves through

A **Figure 3.2** Hydrogen bonds between water molecules.

The charged regions of a polar water molecule are attracted to oppositely charged parts of neighboring molecules. Each molecule can hydrogen-bond to multiple partners, and these associations are constantly changing. At any instant in liquid water at 37°C (human body temperature), about 15% of the molecules are bonded to four partners in short-lived clusters.

a partial negative charge (5—), and the hydrogens have a partial positive charge (6+) (see Figure 2.12).

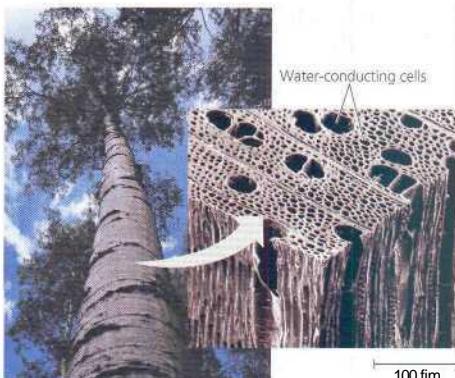

The anomalous properties of water arise from attractions between these polar molecules. The attraction is electrical; the slightly positive hydrogen of one molecule is attracted to the slightly negative oxygen of a nearby molecule. The two molecules are thus held together by a hydrogen bond (**Figure 3.2**). Although the arrangement of molecules in a sample of liquid water is constantly changing, at any given moment, many of the molecules are linked by multiple hydrogen bonds. The extraordinary qualities of water are emergent properties resulting from the hydrogen bonding that orders molecules into a higher level of structural organization.

Concept Check 3.1

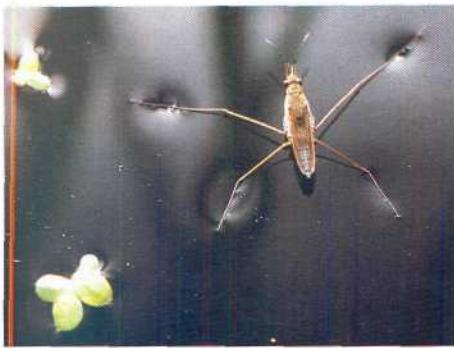

- What is electronegativity and how does it affect interactions between water molecules?
- Why is it unlikely that two neighboring water molecules would be arranged like this?

For suggested answers, see Appendix A.

A Figure 3.3 Water transport in plants. Evaporation from leaves pulls water upward from the roots through water-conducting cells, in this case located in the trunk of a tree. Cohesion due to hydrogen bonding helps hold together the column of water within the cells. Adhesion of the water to cell walls helps resist the downward pull of gravity. Because of these properties, the tallest trees can transport water more than 100 meters (m) upward—approximately one-quarter the height of the Empire State Building in New York City.

A Figure 3.4 Walking on water. The high surface tension of water, resulting from the collective strength of its hydrogen bonds, allows the water strider to walk on the surface of a pond.

& network of water-conducting cells. As water evaporates from a leaf, hydrogen bonds cause water molecules leaving the veins to tug on molecules farther down, and the upward pull is transmitted through the water-conducting cells all the way down to the roots. **Adhesion**, the clinging of one substance to another, also plays a role. Adhesion of water to the walls of the cells helps counter the downward pull of gravity.

Related to cohesion is **surface tension**, a measure of how difficult it is to stretch or break the surface of a liquid. Water has a greater surface tension than most other liquids. At the interface between water and air is an ordered arrangement of water molecules, hydrogen-bonded to one another and to the water below. This makes the water behave as though coated with an invisible film. You can observe the surface tension of water by slightly overfilling a drinking glass; the water will stand above the rim. In a more biological example, some animals can stand, walk, or run on water without breaking the surface (**Figure 3.4**).

Moderation of Temperature

Water moderates air temperature by absorbing heat from air that is warmer and releasing the stored heat to air that is cooler. Water is effective as a heat bank because it can absorb or release a relatively large amount of heat with only a slight change in its own temperature. To understand this capability of water, we must first look briefly at heat and temperature.

Heat and Temperature

Anything that moves has **kinetic energy**, the energy of motion. Atoms and molecules have kinetic energy because they are always moving, although not necessarily in any particular direction. The faster a molecule moves, the greater its kinetic

energy. **Heat** is a measure of the *total* amount of kinetic energy due to molecular motion in a body of matter. **Temperature** measures the intensity of heat due to the *average* kinetic energy of the molecules. When the average speed of the molecules increases, a thermometer records this as a rise in temperature. Heat and temperature are related, but they are not the same. A swimmer crossing the English Channel has a higher temperature than the water, but the ocean contains far more heat because of its volume.

Whenever two objects of different temperature are brought together, heat passes from the warmer to the cooler object until the two are the same temperature. Molecules in the cooler object speed up at the expense of the kinetic energy of the warmer object. An ice cube cools a drink not by adding coldness to the liquid, but by absorbing heat from the liquid as the ice itself melts.

Throughout this book, we will use the **Celsius scale** to indicate temperature (Celsius degrees are abbreviated as $^{\circ}\text{C}$). At sea level, water freezes at 0°C and boils at 100°C . The temperature of the human body averages 37°C , and comfortable room temperature is about $20\text{--}25^{\circ}\text{C}$.

One convenient unit of heat used in this book is the **calorie** (cal). A calorie is the amount of heat it takes to raise the temperature of 1 g of water by 1°C . Conversely a calorie is also the amount of heat that 1 g of water releases when it cools by 1°C . **Akilocalorie (kcal)**, 1,000 cal, is the quantity of heat required to raise the temperature of 1 kilogram (kg) of water by 1°C . (The "calories" on food packages are actually kilocalories.) Another energy unit used in this book is the **joule (J)**. One joule equals 0.239 cal; one calorie equals **4.184 J**.

Water's High Specific Heat

The ability of water to stabilize temperature stems from its relatively high specific heat. The **specific heat** of a substance is defined as the amount of heat that must be absorbed or lost for 1 g of that substance to change its temperature by 1°C . We already know water's specific heat because we have defined a calorie as the amount of heat that causes 1 g of water to change its temperature by 1°C . Therefore, the specific heat of water is 1 calorie per gram per degree Celsius, abbreviated as $1 \text{ cal/g}^{\circ}\text{C}$. Compared with most other substances, water has an unusually high specific heat. For example, ethyl alcohol, the type of alcohol in alcoholic beverages, has a specific heat of $0.6 \text{ cal/g}^{\circ}\text{C}$ —that is, only 0.6 cal is required to raise the temperature of 1 g of ethyl alcohol 1°C .

Because of the high specific heat of water relative to other materials, water will change its temperature less when it absorbs or loses a given amount of heat. The reason you can burn your fingers by touching the metal handle of a pot on the stove when the water in the pot is still lukewarm is that the specific heat of water is ten times greater than that of iron. In other words, it will take only 0.1 cal to raise the temperature of 1 g

of iron 1°C. Specific heat can be thought of as a measure of how well a substance resists changing its temperature when it absorbs or releases heat. Water resists changing its temperature; when it does change its temperature, it absorbs or loses a relatively large quantity of heat for each degree of change.

We can trace water's high specific heat, like many of its other properties, to hydrogen bonding. Heat must be absorbed in order to break hydrogen bonds, and heat is released when hydrogen bonds form. A calorie of heat causes a relatively small change in the temperature of water because much of the heat is used to disrupt hydrogen bonds before the water molecules can begin moving faster. And when the temperature of water drops slightly many additional hydrogen bonds form, releasing a considerable amount of energy in the form of heat.

What is the relevance of water's high specific heat to life on Earth? A large body of water can absorb and store a huge amount of heat from the sun in the daytime and during summer while warming up only a few degrees. And at night and during winter, the gradually cooling water can warm the air. This is the reason coastal areas generally have milder climates than inland regions. The high specific heat of water also tends to stabilize ocean temperatures, creating a favorable environment for marine life. Thus, because of its high specific heat, the water that covers most of Earth keeps temperature fluctuations on land and in water within limits that permit life. Also, because organisms are made primarily of water, they are more able to resist changes in their own temperature than if they were made of a liquid with a lower specific heat.

Evaporative Cooling

Molecules of any liquid stay close together because they are attracted to one another. Molecules moving fast enough to overcome these attractions can depart the liquid and enter the air as gas. This transformation from a liquid to a gas is called vaporization, or *evaporation*. Recall that the speed of molecular movement varies and that temperature is the *average* kinetic energy of molecules. Even at low temperatures, the speediest molecules can escape into the air. Some evaporation occurs at any temperature; a glass of water at room temperature, for example, will eventually evaporate. If a liquid is heated, the average kinetic energy of molecules increases and the liquid evaporates more rapidly.

Heat of vaporization is the quantity of heat a liquid must absorb for 1 g of it to be converted from the liquid to the gaseous state. For the same reason that water has a high specific heat, it also has a high heat of vaporization relative to most other liquids. To evaporate 1 g of water at 25°C, about 580 cal of heat is needed—nearly double the amount needed to vaporize a gram of alcohol or ammonia. Water's high heat of vaporization is another emergent property caused by hydrogen bonds, which must be broken before the molecules can make their exodus from the liquid.

Water's high heat of vaporization helps moderate Earth's climate. A considerable amount of solar heat absorbed by tropical seas is consumed during the evaporation of surface water. Then, as moist tropical air circulates poleward, it releases heat as it condenses to form rain.

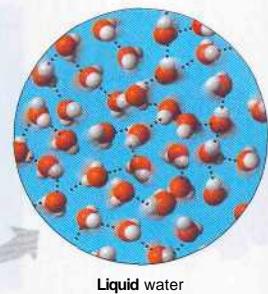

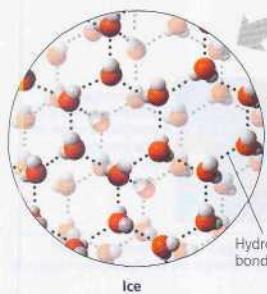

As a liquid evaporates, the surface of the liquid that remains behind cools down. This evaporative cooling occurs because the "hottest" molecules, those with the greatest kinetic energy, are the most likely to leave as gas. It is as if the hundred fastest runners at a college transferred to another school; the average speed of the remaining students would decline.

Evaporative cooling of water contributes to the stability of temperature in lakes and ponds and also provides a mechanism that prevents terrestrial organisms from overheating. For example, evaporation of water from the leaves of a plant helps keep the tissues in the leaves from becoming too warm in the sunlight. Evaporation of sweat from human skin dissipates body heat and helps prevent overheating on a hot day or when excess heat is generated by strenuous activity. High humidity on a hot day increases discomfort because the high concentration of water vapor in the air inhibits the evaporation of sweat from the body.

Insulation of Bodies of Water by Floating Ice

Water is one of the few substances that are less dense as a solid than as a liquid. In other words, ice floats in liquid water. While other materials contract when they solidify, water expands. The cause of this exotic behavior is, once again, hydrogen bonding. At temperatures above 4°C, water behaves like other liquids, expanding as it warms and contracting as it cools. Water begins to freeze when its molecules are no longer moving vigorously enough to break their hydrogen bonds. As the temperature falls to 0°C, the water becomes locked into a crystalline lattice, each water molecule bonded to four partners (Figure 3.5). The hydrogen bonds keep the molecules at "arm's length," far enough apart to make ice about 10% less dense (10% fewer molecules for the same volume) than liquid water at 4°C. When ice absorbs enough heat for its temperature to rise above 0°C, hydrogen bonds between molecules are disrupted. As the crystal collapses, the ice melts, and molecules are free to slip closer together. Water reaches its greatest density at 4°C and then begins to expand as the molecules move faster. Keep in mind, however, that even in liquid water, many of the molecules are connected by hydrogen bonds, though only transiently: The hydrogen bonds are constantly breaking and re-forming.

The ability of ice to float because of the expansion of water as it solidifies is an important factor in the fitness of the environment. If ice sank, then eventually all ponds, lakes, and even oceans would freeze solid, making life as we know it impossible on Earth. During summer, only the upper few inches of the ocean would thaw. Instead, when a deep body of

i Figure 3.5 Ice: crystalline structure and floating barrier. In ice, each molecule is hydrogen-bonded to four neighbors in a three-dimensional crystal. Because the crystal is

spacious, ice has fewer molecules than an equal volume of liquid water. In other words, ice is less dense than liquid water. Floating ice becomes a barrier that protects the liquid

water below from the colder air. The marine organism shown here is called a euphausiid shrimp; it was photographed beneath the antarctic ice.

water cools, the floating ice insulates the liquid water below, preventing it from freezing and allowing life to exist under the frozen surface, as shown in the photo in Figure 3.5.

The Solvent of Life

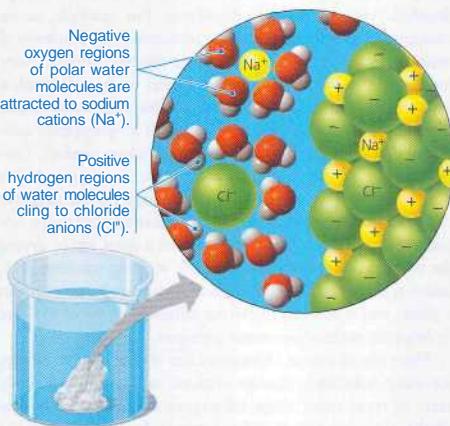

A sugar cube placed in a glass of water will dissolve. The glass will then contain a uniform **mixture** of sugar and water; the concentration of dissolved sugar will be the same everywhere in the mixture. A liquid that is a completely homogeneous mixture of two or more substances is called a **solution**. The **dissolving** agent of a solution is the **solvent**, and the substance that is dissolved is the **solute**. In this case, water is the solvent and sugar is the solute. An **aqueous solution** is one in which water is the solvent.

The medieval alchemists tried to find a universal solvent, one that would dissolve anything. They learned that nothing works better than water. However, water is not a universal solvent; if it were, it would dissolve any container in which it was stored, including our cells. But water is a very versatile solvent, a quality we can trace to the polarity of the water molecule.

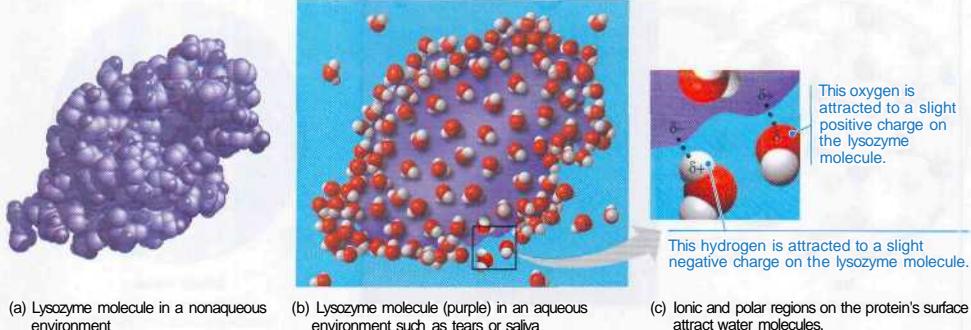

Suppose, for example, that a crystal of the ionic compound sodium chloride (NaCl) is placed in water (Figure 3.6). At the surface of the crystal, the sodium and chloride ions are exposed to the solvent. These ions and the water molecules have *i*: mutual affinity through electrical attraction. The oxygen regions of the water molecules are negatively charged and cling to sodium cations. The hydrogen regions of the water molecules are positively charged and are attracted to chloride anions. As a result, water molecules surround the individual sodium and chloride ions, separating and shielding them from one another. The sphere of water molecules around each dissolved ion

is called a **hydration shell**. Working inward from the surface of the salt crystal, water eventually dissolves all the ions. The result is a solution of two solutes, sodium cations and chloride anions, homogeneously mixed with water, the solvent. Other ionic compounds also dissolve in water. Seawater, for instance, contains a great variety of dissolved ions, as do living cells.

A compound does not need to be ionic to dissolve in water; compounds made up of nonionic polar molecules, such as

& Figure 3.6 A crystal of table salt dissolving in water. A sphere of water molecules, called a hydration shell, surrounds each solute ion.

A Figure 3.7 A water-soluble protein. This figure shows human lysozyme, a protein found in tears and saliva that has antibacterial action.

sugars, are also water-soluble. Such compounds dissolve when water molecules surround each of the solute molecules. Even molecules as large as proteins can dissolve in water if they have ionic and polar regions on their surface (**Figure 3.7**). Many different kinds of polar compounds are dissolved (along with ions) in the water of such biological fluids as blood, the sap of plants, and the liquid within all cells. Water is the solvent of life.

Hydrophilic and Hydrophobic Substances

Whether ionic or polar, any substance that has an affinity for water is said to be hydrophilic (from the Greek *hydro*, water, and *philios*, loving). In some cases, substances can be hydrophilic without actually dissolving. For example, some components in cells are such large molecules (or complexes of multiple molecules) that they do not dissolve. Instead, they remain suspended in the aqueous liquid of the cell. Such a mixture is an example of a colloid, a stable suspension of fine particles in a liquid. Another example of a hydrophilic substance that does not dissolve is cotton, a plant product. Cotton consists of giant molecules of cellulose, a compound with numerous regions of partial positive and partial negative charges associated with polar bonds. Water adheres to the cellulose fibers. Thus, a cotton towel does a great job of drying the body, yet does not dissolve in the washing machine. Cellulose is also present in the walls of water-conducting cells in a plant; you read earlier how the adhesion of water to these hydrophilic walls allows water transport to occur.

There are, of course, substances that do not have an affinity for water. Substances that are nonionic and nonpolar actually seem to repel water; these substances are said to be hydrophobic (from the Greek *phobos*, fearing). An example from the kitchen is vegetable oil, which, as you know, does not mix stably with water-based substances such as vinegar. The hydrophobic behavior of the oil molecules results from a preva-

lence of relatively nonpolar bonds, in this case bonds between carbon and hydrogen, which share electrons almost equally. Hydrophobic molecules related to oils are major ingredients of cell membranes. (Imagine what would happen to a cell if its membrane dissolved.)

Solute Concentration in Aqueous Solutions

Biological chemistry is "wet" chemistry. Most of the chemical reactions in organisms involve solutes dissolved in water. To understand chemical reactions, we need to know how many atoms and molecules are involved. Thus, it is important to learn how to calculate the concentration of solutes in an aqueous solution (the number of solute molecules in a volume of solution).

When carrying out experiments, we use mass to calculate the number of molecules. We know the mass of each atom in a given molecule, so we can calculate its molecular mass, which is simply the sum of the masses of all the atoms in a molecule. As an example, let's calculate the molecular mass of table sugar (sucrose), which has the molecular formula $C_{12}H_{22}O_{11}$. In round numbers of daltons, the mass of a carbon atom is 12, the mass of a hydrogen atom is 1, and the mass of an oxygen atom is 16. Thus, sucrose has a molecular mass of 342 daltons. Of course, weighing out small numbers of molecules is not practical. For this reason, we usually measure substances in units called moles, just as a dozen always means 12 objects, a mole (mol) represents an exact number of objects— 6.02×10^{23} , which is called Avogadro's number. Because of the way in which Avogadro's number and the unit *dalton* were originally defined, there are 6.02×10^{23} daltons in 1 gram. This is significant because once we determine the molecular mass of a molecule such as sucrose, we can use the same number (342), but with the unit *gram*, to represent the mass of 6.02×10^{23} molecules of sucrose, or one mole of sucrose (this is sometimes called the *molar mass*).

To obtain one mole of sucrose in the lab, therefore, we weigh out 342 g.

The practical advantage of measuring a quantity of chemicals in moles is that a mole of one substance has exactly the same number of molecules as a mole of any other substance. If the molecular mass of substance A is 342 daltons and that of substance B is 10 daltons, then 342 g of A will have the same number of molecules as 10 g of B. A mole of ethyl alcohol (C_2H_5O) also contains 6.02×10^{23} molecules, but its mass is only 46 g because the mass of a molecule of ethyl alcohol is less than that of a molecule of sucrose. Measuring in moles makes it convenient for scientists working in the laboratory to combine substances in fixed ratios of molecules.

How would we make a liter (L) of solution consisting of 1 mol of sucrose dissolved in water? We would measure out 342 g of sucrose and then gradually add water, while stirring, until the sugar was completely dissolved. We would then add enough water to bring the total volume of the solution up to 1 L. At that point, we would have a 1-molar (1 M) solution of sucrose. **Molarity**—the number of moles of solute per liter of solution—is the unit of concentration most often used by biologists for aqueous solutions.

Concept Check 3.2

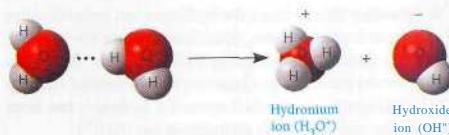

- Describe how properties of water contribute to the upward movement of water in a tree.
- Explain the popular adage, "It's not the heat, it's the humidity."
- How can the freezing of water crack boulders?
- How would you make a 0.5-molar (0.5 M) solution of sodium chloride (NaCl)? (The atomic mass of Na is 23 daltons and that of Cl is 35.5 daltons.)

For suggested answers, see Appendix A.

Concept 3.3

Dissociation of water molecules Heads to acidic and basic conditions that affect living organisms

Occasionally, a hydrogen atom participating in a hydrogen bond between two water molecules shifts from one molecule to the other. When this happens, the hydrogen atom leaves its electron behind, and what is actually transferred is a hydrogen **ion**, a single proton with a charge of $+1$. The water molecule that lost a proton is now a hydroxide ion (OH^-), which has a charge of -1 . The proton binds to the other water molecule, making that molecule a hydronium ion (H_3O^+). We can picture the chemical reaction this way:

Although this is what actually happens, we can think of the process in a simplified way, as the dissociation (separation) of a water molecule into a hydrogen ion and a hydroxide ion:

As the double arrows indicate, this is a reversible reaction that will reach a state of dynamic equilibrium when water dissociates at the same rate that it is being re-formed from H^+ and OH^- . At this equilibrium point, the concentration of water molecules greatly exceeds the concentrations of H^+ and OH^- . In fact, in pure water, only one water molecule in every 554 million is dissociated. The concentration of each ion in pure water is $10^{-7} M$ (at $25^\circ C$). This means that there is only one ten-millionth of a mole of hydrogen ions per liter of pure water and an equal number of hydroxide ions.

Although the dissociation of water is reversible and statistically rare, it is exceedingly important in the chemistry of life. Hydrogen and hydroxide ions are very reactive. Changes in their concentrations can drastically affect a cell's proteins and other complex molecules. As we have seen, the concentrations of H^+ and OH^- are equal in pure water, but adding certain kinds of solutes, called acids and bases, disrupts this balance. Biologists use something called the pH scale to describe how acidic or basic (the opposite of acidic) a solution is. In the remainder of this chapter, you will learn about acids, bases, and pH and why changes in pH can adversely affect organisms.

Effects of Changes in pH

Before discussing the pH scale, let's see what acids and bases are and how they interact with water.

Adds and Bases

What would cause an aqueous solution to have an imbalance in its H^+ and OH^- concentrations? When the substances called acids dissolve in water, they donate additional H^+ to the solution. An acid, according to the definition often used by biologists, is a substance that increases the hydrogen ion concentration of a solution. For example, when hydrochloric acid (HCl) is added to water, hydrogen ions dissociate from chloride ions:

This additional source of H^+ (dissociation of water is the other source) results in the solution having more H^+ than OH^- . Such a solution is known as an acidic solution.

A substance that reduces the hydrogen ion concentration of a solution is called a base. Some bases reduce the H^+ concentration directly by accepting hydrogen ions. Ammonia (NH_3), for instance, acts as a base when the unshared electron pair in nitrogen's valence shell attracts a hydrogen ion from the solution, resulting in an ammonium ion (NH_4^+):

Other bases reduce the H^+ concentration indirectly by dissociating to form hydroxide ions, which then combine with hydrogen ions in the solution to form water. One base that acts this way is sodium hydroxide (NaOH), which in water dissociates into its ions:

In either case, the base reduces the H^+ concentration. Solutions with a higher concentration of OH^- than H^+ are known as basic solutions. A solution in which the H^+ and OH^- concentrations are equal is said to be neutral.

Notice that single arrows were used in the reactions for HCl and NaOH . These compounds dissociate completely when mixed with water, and so hydrochloric acid is called a strong acid and sodium hydroxide a strong base. In contrast, ammonia is a relatively weak base. The double arrows in the reaction for ammonia indicate that the binding and release of hydrogen ions are reversible reactions, although at equilibrium there will be a fixed ratio of NH_4^+ to NH_3 .

There are also weak acids, which reversibly release and accept back hydrogen ions. An example is carbonic acid, which has essential functions in many organisms:

Here the equilibrium so favors the reaction in the left direction that when carbonic acid is added to water, only 1% of the molecules are dissociated at any particular time. Still, that is enough to shift the balance of H^+ and OH^- from neutrality.

The pH Scale

In any aqueous solution at 25°C , the product of the H^+ and OH^- concentrations is constant at 10^{-14} . This can be written

$$[\text{H}^+] [\text{OH}^-] = 10^{-14}$$

In such an equation, brackets indicate molar concentration for the substance enclosed within them. In a neutral solution at room temperature (25°C), $[\text{H}^+] = 10^{-7}$ and $[\text{OH}^-] = 10^{-7}$, so in this case, 10^{-14} is the product of $10^{-7} \times 10^{-7}$. If enough acid is added to a solution to increase $[\text{H}^+]$ to 10^{-5} M, then $[\text{OH}^-]$ will decline by an equivalent amount (to 10^{-9} M (note that $10^{-5} \times 10^{-9} = 10^{-14}$). This constant relationship expresses the behavior of acids and bases in an aqueous solution. An acid not only adds hydrogen ions to a solution, but

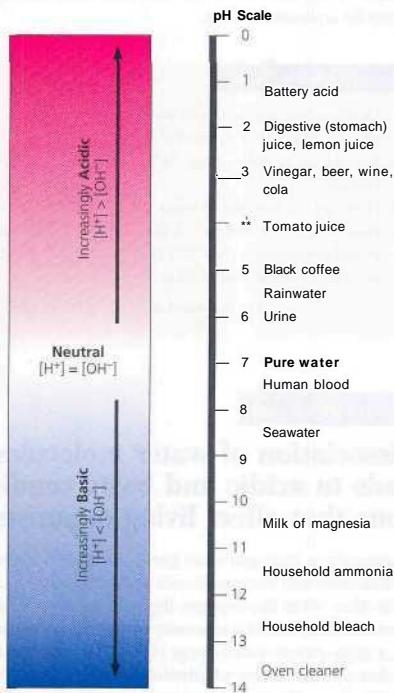

also removes hydroxide ions because of the tendency for H^+ to combine with OH^- to form water. A base has the opposite effect, increasing OH^- concentration but also reducing H^+ concentration by the formation of water. If enough of a base is added to raise the OH^- concentration to 10^{-4} M, it will cause the H^+ concentration to drop to 10^{-10} M. Whenever we know the concentration of either H^+ or OH^- in an aqueous solution, we can deduce the concentration of the other ion.

Because the H^+ and OH^- concentrations of solutions can vary by a factor of 100 trillion or more, scientists have developed a way to express this variation more conveniently than in moles per liter. The pH scale (Figure 3.8) compresses the range of H^+ and OH^- concentrations by employing logarithms. The pH of a solution is defined as the negative logarithm (base 10) of the hydrogen ion concentration:

$$\text{pH} = -\log [\text{H}^+]$$

For a neutral aqueous solution, $[\text{H}^+]$ is 10^{-7} M, giving us

$$-\log(10^{-7}) = -(-7) = 7$$

& Figure 3.8 The pH scale and pH values of some aqueous solutions.

Notice that pH *declines* as H⁺ concentration *increases*. Notice, too, that although the pH scale is based on H⁺ concentration, it also implies OH⁻ concentration. A solution of pH 10 has a hydrogen ion concentration of 1(T¹⁰ M and a hydroxide ion concentration of 10⁻⁴ M.

The pH of a neutral aqueous solution is 7, the midpoint of the scale. A pH value less than 7 denotes an acidic solution; the lower the number, the more acidic the solution. The pH for basic solutions is above 7. Most biological fluids are within the range pH 6-8. There are a few exceptions, however, including the strongly acidic digestive juice of the human stomach, which has a pH of about 2.

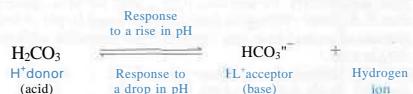

Remember that each pH unit represents a tenfold difference in H⁺ and OH⁻ concentrations. It is this mathematical feature that makes the pH scale so compact. A solution of pH 3 is not twice as acidic as a solution of pH 6, but a thousand times more acidic. When the pH of a solution changes slightly, the actual concentrations of H⁺ and OH⁻ in the solution change substantially.

Buffers

The internal pH of most living cells is close to 7. Even a slight change in pH can be harmful, because the chemical processes of the cell are very sensitive to the concentrations of hydrogen and hydroxide ions.

The presence of buffers in biological fluids allows for a relatively constant pH despite the addition of acids or bases. **Buffers** are substances that minimize changes in the concentrations of H⁺ and OH⁻ in a solution. For example, buffers normally maintain the pH of human blood very close to 7.4, which is slightly basic. A person cannot survive for more than a few minutes if the blood pH drops to 7 (neutral) or rises to 7.8. Under normal circumstances, the buffering capacity of the blood prevents such swings in pH.

A buffer works by accepting hydrogen ions from the solution when they are in excess and donating hydrogen ions to the solution when they have been depleted. Most buffer solutions contain a weak acid and its corresponding base, which combine reversibly with hydrogen ions. There are several buffers that contribute to pH stability in human blood and many other biological solutions. One of these is carbonic acid (H₂CO₃), which, as already mentioned, dissociates to yield a bicarbonate ion (HCO₃⁻) and a hydrogen ion (H⁺):

The chemical equilibrium between carbonic acid and bicarbonate acts as a pH regulator, the reaction shifting left or right as other processes in the solution add or remove hydrogen ions. If the H⁺ concentration in blood begins to fall (that is, if pH rises), the reaction proceeds to the right and more carbonic acid disso-

ciates, replenishing hydrogen ions. But when H⁺ concentration in blood begins to rise (when pH drops), the reaction proceeds to the left, with HCO₃⁻ (the base) removing the hydrogen ions from the solution to form H₂CO₃. Thus, the carbonic acid-bicarbonate buffering system consists of an acid and a base in equilibrium with each other. Most other buffers are also acid-base pairs.

The Threat of Acid Precipitation

Considering the dependence of all life on water, contamination of rivers, lakes, and seas is a dire environmental problem. One of the most serious assaults on water quality is acid precipitation. Uncontaminated rain has a pH of about 5.6, slightly acidic, owing to the formation of carbonic acid from carbon dioxide and water. **Acid precipitation** refers to rain, snow, or fog with a pH lower or more acidic than pH 5.6.

Acid precipitation is caused primarily by the presence in the atmosphere of sulfur oxides and nitrogen oxides, gaseous compounds that react with water in the air to form strong acids, which fall to earth with rain or snow. A major source of these oxides is the burning of fossil fuels (coal, oil, and gas) in factories and automobiles. "Electrical power plants that burn coal produce more of these pollutants than any other single source. Winds carry the pollutants away, and acid rain may fall hundreds of kilometers away from industrial centers. In certain sites in Pennsylvania and New York, the pH of rainfall in December 2001 averaged 4.3, about 20 times more acidic than normal rain. Acid precipitation falls on many other regions, including eastern Canada, the Cascade Mountains of the Pacific Northwest, and certain parts of Europe and Asia (Figure 3.9).

Acid precipitation can damage life in lakes and streams. In addition, acid precipitation falling on land washes away certain mineral ions, such as calcium and magnesium ions, that

A Figure 3.9 Acid precipitation and its effects on a forest.
Acid rain is thought to be responsible for killing trees in many forests, including the fir forest shown here in the Czech Republic.

ordinarily help buffer the soil solution and are essential nutrients for plant growth. At the same time, other minerals, such as aluminum, reach toxic concentrations when acidification increases their solubility. The effects of acid precipitation on soil chemistry have taken a toll on some North American forests and are contributing to the decline of European forests (see Figure 3.9). Nevertheless, studies indicate that the majority of North American forests are not currently suffering substantially from acid precipitation.

If there is reason for optimism about the future quality of water resources, it is that we have made progress in reducing acid precipitation (see Chapter 54). Continued progress can come only from the actions of people who are concerned about environmental quality. This requires understanding the

crucial role that water plays in the environment's fitness for continued life on Earth.

Concept Check 3.3

- Compared to a basic solution at pH 9, the same volume of an acidic solution at pH 4 has _____ times more hydrogen ions (H^+).
- HCl is a strong acid that dissociates completely in water: $HCl \rightarrow H^+ + Cl^-$. What is the pH of 0.01 MHO?

For suggested answers, see Appendix A.

Chapter 3 | Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 3.1

The polarity of water molecules results in hydrogen bonding

- A hydrogen bond forms when the oxygen of one water molecule is electrically attracted to the hydrogen of a nearby molecule. Hydrogen bonding between water molecules is the basis for water's unusual properties (pp. 47–48).

Activity *The Polarity of Water*

Concept 3.2

Four emergent properties of water contribute to Earth's fitness for life

- Cohesion** (pp. 48–49) Hydrogen bonding keeps water molecules close to each other, and this cohesion helps pull water upward in the microscopic vessels of plants. Hydrogen bonding is also responsible for water's surface tension.

Activity *Cohesion of Water*

- Moderation of Temperature** (pp. 49–50) Hydrogen bonding gives water a high specific heat. Heat is absorbed when hydrogen bonds break and is released when hydrogen bonds form, helping minimize temperature fluctuations to within limits that permit life. Evaporative cooling is based on water's high heat of vaporization. Water molecules must have a relatively high kinetic energy to break hydrogen bonds. The evaporative loss of these energetic water molecules cools a surface.

• Insulation of Bodies of Water by Floating Ice

(pp. 50–51) Ice is less dense than liquid water because its more organized hydrogen bonding causes expansion into a crystal formation. The lower density causes ice to float, which allows life to exist under the frozen surfaces of lakes and polar seas.

- The Solvent of Life** (pp. 51–53) Water is an unusually versatile solvent because its polar molecules are attracted to charged and polar substances. Ions or polar substances surrounded by water molecules dissolve and are called solutes. Hydrophilic substances have an affinity for water; hydrophobic substances do not. Molarity, the number of moles of solute per liter of solution, is used as a measure of solute concentration in solutions. A mole is a certain number of molecules of a substance. The mass of a mole of the substance in grams is the same as the molecular mass in daltons.

Concept 3.3

Dissociation of water molecules leads to acidic and basic conditions that affect living organisms

- Effects of Changes in pH (pp. 53–55) Water can dissociate into H^+ and OH^- . The concentration of H^+ is expressed as pH, where $pH = -\log [H^+]$. Acids donate additional H^+ in aqueous solutions; bases donate OH^- or accept H^+ . In a neutral solution at 25°C, $[H^+] = [OH^-] = 10^{-7}$, and the pH is less than 7. In an acidic solution, $[H^{+}]$ is greater than $[OH^-]$, and the pH is less than 7. In a basic solution, $[H^+]$ is less than $[OH^-]$, and the pH is greater than 7. Buffers in biological fluids resist changes in pH. A buffer consists of an acid-base pair that combines reversibly with hydrogen ions.

Activity *Dissociation of Water Molecules*
Activity *Acids, Bases, and pH*

- The Threat of Acid Precipitation** (pp. 55–56) Acid precipitation is rain, snow, or fog with a pH below 5.6. It often results from a reaction in the air between water vapor and sulfur oxides and nitrogen oxides produced by the combustion of fossil fuels.

Investigation *How Does Acid Precipitation Affect Trees?*

TESTING YOUR KNOWLEDGE

Evolution Connection

The surface of the planet Mars has many landscape features reminiscent of those formed by flowing water on Earth, including what appear to be meandering channels and outwash areas. Recent probes sent to Mars have revealed strong evidence that liquid water was once present on its surface. Ice exists at the Martian poles today, and some scientists suspect a great deal more water may be present beneath the Martian surface. Why has there been so much interest in the presence of water on Mars? Does the presence of water make it more likely that life had evolved there? What other physical factors might also be important?

Scientific Inquiry

1. Design a controlled experiment to test the hypothesis that acid precipitation inhibits the growth of *Bodea*, a common freshwater plant.
2. In agricultural areas, farmers pay close attention to the weather forecast. Right before a predicted overnight freeze, farmers spray water on crops to protect the plants. Use the properties of water to explain how this works. Be sure to mention why hydrogen bonds are responsible for this phenomenon.

Investigation *How Does Acid Precipitation Affect Trees?*

Science, Technology, and Society

Agriculture, industry, and the growing populations of cities all compete, through political influence, for water. If you were in charge of water resources in an arid region, what would your priorities be for allocating the limited water supply for various uses? How would you try to build consensus among the different special-interest groups?

Carbon and the Molecular Diversity of Life

• Figure 4.1 Life is based on carbon.

Key Concepts

- 4.1 Organic chemistry is the study of carbon compounds
- 4.2 Carbon atoms can form diverse molecules by bonding to four other atoms
- 4.3 Functional groups are the parts of molecules involved in chemical reactions

Overview

Carbon—The Backbone of Biological Molecules

Although water is the universal medium for life on Earth, living organisms, including all the plants **and** the snail you see in **Figure 4.1**, are made up of chemicals based mostly on the element carbon. Carbon enters the biosphere through the action of plants, which use the sun's energy to transform CO₂ in the atmosphere into the molecules of life. These molecules are then passed along to animals that feed on plants, such as the snail in the photo. Of all chemical elements, carbon is unparalleled in its ability to form molecules that are large, complex, and diverse, and this molecular diversity has made possible the diversity of organisms that have evolved on Earth. Proteins, DNA, carbohydrates, and other molecules that distinguish living matter from inanimate material are all composed of carbon atoms bonded to one another and to atoms of other elements. Hydrogen (H), oxygen (O), nitrogen (N), sulfur (S), and phosphorus (P) are other common ingredients of these compounds, but it is carbon (C) that accounts for the large diversity of biological molecules.

Proteins and other very large molecules are the main focus of Chapter 5. In this chapter, we investigate the properties of smaller molecules, using them to illustrate a few concepts

of molecular architecture that highlight carbon's importance to life and the theme that emergent properties arise from the organization of the matter of living organisms.

Concept 4.1

Organic chemistry is the study of carbon compounds

Compounds containing carbon are said to be organic, and the branch of chemistry that specializes in the study of carbon compounds is called **organic chemistry**. Organic compounds range from simple molecules, such as methane (CH₄), to colossal ones, such as proteins, with thousands of atoms and molecular masses **in excess of 100,000 daltons**. Most organic compounds contain hydrogen atoms in addition to carbon atoms.

The overall percentages of the major elements of life—C, H, O, N, 5, and P—are quite uniform from one organism to another. Because of carbons versatility, however, this limited assortment of atomic building blocks, taken in roughly the same proportions, can be used to build an inexhaustible variety of organic molecules. Different species of organisms, and different individuals within a species, are distinguished by variations in their organic molecules.

Since the dawn of human history, people have used other organisms as sources of valued substances—from foods to medicines and fabrics. The science of organic chemistry originated in attempts to purify and improve the yield of such products. By the early 19th century, chemists had learned to make many simple compounds in the laboratory by combining elements under the right conditions. Artificial synthesis of the complex molecules extracted from living matter seemed impossible, however. At that time, the Swedish chemist Jons

Jakob Berzelius made the distinction between organic compounds, those that seemingly could arise only within living organisms, and inorganic compounds, those that were found in the nonliving world. The new discipline of organic chemistry was first built on a foundation of *vitalism*, the belief in a life force outside the jurisdiction of physical and chemical laws.

Chemists began to chip away at the foundation of vitalism when they learned to synthesize organic compounds in their laboratories. In 1828, Friedrich Wöhler, a German chemist who had studied with Berzelius, attempted to make an "inorganic" salt, ammonium cyanate, by mixing solutions of ammonium ions (NH_4^+) and cyanate ions (CNO^-). Wöhler was astonished to find that instead of the expected product, he had made urea, an organic compound present in the urine of animals. Wöhler challenged the vitalists when he wrote, "I must tell you that I can prepare urea without requiring a kidney or an animal, either man or dog." However, one of the ingredients used in the synthesis, the cyanate, had been extracted from animal blood, and the vitalists were not swayed by Wöhler's discovery. A few years later, however, Hermann Kolbe, a student of Wöhler's, made the organic compound acetic acid from inorganic substances that could themselves be prepared directly from pure elements.

The foundation of vitalism finally crumbled after several more decades of laboratory synthesis of increasingly complex organic compounds. In 1953, Stanley Miller, then a graduate student at the University of Chicago, helped bring this abiotic (nonliving) synthesis of organic compounds into the context of evolution. Miller used a laboratory simulation of chemical conditions on the primitive Earth to demonstrate that the spontaneous synthesis of organic compounds could have been an early stage in the origin of life (Figure 4.2).

The pioneers of organic chemistry helped shift the mainstream of biological thought from vitalism to *mechanism*, the view that all natural phenomena, including the processes of life, are governed by physical and chemical laws. Organic chemistry was redefined as the study of carbon compounds, regardless of their origin. Most naturally occurring organic compounds are produced by organisms, and these molecules represent a diversity and range of complexity unrivaled by inorganic compounds. However, the same rules of chemistry apply to inorganic and organic molecules alike. The foundation of organic chemistry is not some intangible life force, but the unique chemical versatility of the element carbon.

Concept Check 4.1

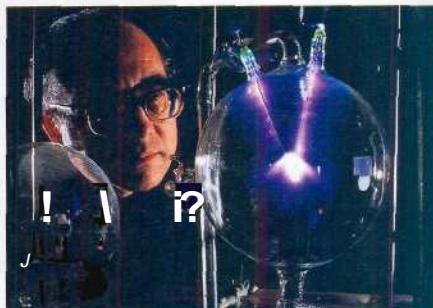

- In Stanley Miller's experiment, what conclusion could be drawn from the presence of urea in the products?

For suggested answers, see Appendix A.

Figure 4.2 **Could organic compounds have been synthesized abiotically on the early Earth?**

EXPERIMENT

In 1953, Stanley Miller simulated what were thought to be environmental conditions on the lifeless, primordial Earth. As shown in this recreation, Miller used electrical discharges (simulated lightning) to trigger reactions in a primitive "atmosphere" of H_2O , H_2 , NH_3 (ammonia), and CH_4 (methane)—some of the gases released by volcanoes.

RESULTS

A variety of organic compounds that play key roles in living cells were synthesized in Miller's apparatus.

CONCLUSION

Organic compounds may have been synthesized abiotically on the early Earth, setting the stage for the origin of life. (We will explore this hypothesis in more detail in Chapter 26.)

Concept 4.2

Carbon atoms can form diverse molecules by bonding to four other atoms

The key to the chemical characteristics of an atom, as you learned in Chapter 2, is in its configuration of electrons. Electron configuration determines the kinds and number of bonds an atom will form with other atoms.

The Formation of Bonds with Carbon

Carbon has a total of 6 electrons, with 2 in the first electron shell and 4 in the second shell. Having 4 valence electrons in a shell that holds 8, carbon would have to donate or accept 4 electrons to complete its valence shell and become an ion. Instead, a carbon atom usually completes its valence shell by sharing its 4 electrons with other atoms in covalent bonds so that 8 electrons are present. Each carbon atom thus acts as an intersection point from which a molecule can branch off in up to

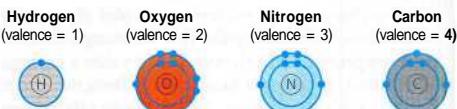

| Name and Comment | Molecular Formula | Structural Formula | Bali-and-Stik Model | Space-Filling Model |
|---|-------------------------------|---|---------------------|---------------------|
| (a) Methane. When a carbon atom has four single bonds to other atoms, the molecule is tetrahedral. | CH ₄ | H H—C—H H | | |
| (b) Ethane. A molecule may have more than one tetrahedral group of single-bonded atoms. (Ethane consists of two such groups ² .) | C ₂ H ₆ | H— H—C—C—H H— H | | |
| (c) Ethene (ethylene). When two carbon atoms are joined by a double bond, all atoms attached to those carbons are in the same plane; the molecule is flat. | C ₂ H ₄ | H— H=C=H H | | |

A Figure 4.3 The shapes of three simple organic molecules.

four directions. This *tetravalence* is one facet of carbon's versatility that makes large, complex molecules possible.

In Chapter 2, you also learned that when a carbon atom forms single covalent bonds, the arrangement of its four hybrid orbitals causes the bonds to angle toward the corners of an imaginary tetrahedron (see Figure 2.16b). The bond angles in methane (CH₄) are 109.5° (Figure 4.3a), and they are approximately the same in any group of atoms where carbon has four single bonds. For example, ethane (C₂H₆) is shaped like two tetrahedrons overlapping at their apexes (Figure 4.3b). In molecules with still more carbons, every grouping of a carbon bonded to four other atoms has a tetrahedral shape. But when two carbon atoms are joined by a double bond, all bonds around those carbons are in the same plane. For example, ethene (C₂H₄) is a flat molecule; its atoms all lie in the same plane (Figure 4.3c). We find it convenient to write all structural formulas as though the molecules represented were flat, but keep in mind that molecules are three-dimensional and that the shape of a molecule often determines its function.

The electron configuration of carbon gives it covalent compatibility with many different elements. Figure 4.4 shows electron-shell diagrams of the four major atomic components of organic molecules. As you may recall from Chapter 2, these models allow us to see the valences of carbon and its most frequent partners—oxygen, hydrogen, and nitrogen. We can think of these valences as the basis for the rules of covalent bonding in organic chemistry—the building code that governs the architecture of organic molecules.

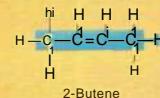

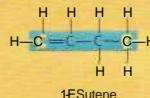

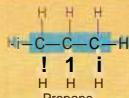

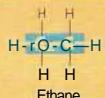

A Figure 4.4 Electron-shell diagrams showing valences for the major elements of organic molecules. Valence is the number of covalent bonds an atom can form. It is generally equal to the number of electrons required to complete the atom's outermost (valence) electron shell (see Figure 2.8).

A couple of additional examples will show how the rules of covalent bonding apply to carbon atoms with partners other than hydrogen. In the carbon dioxide molecule (CO₂), a single carbon atom is joined to two atoms of oxygen by double covalent bonds. The structural formula for CO₂ is shown here:

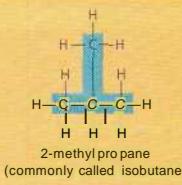

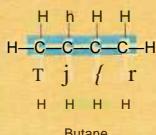

Each line in a structural formula represents a pair of shared electrons. Notice that the carbon atom in CO₂ is involved in two double bonds, the equivalent of four single covalent bonds. The arrangement completes the valence shells of all atoms in the molecule. Because carbon dioxide is a very simple molecule and lacks hydrogen, it is often considered inorganic, even though it contains carbon. Whether we call CO₂ organic or inorganic, there is no question about its importance to the living world. As previously mentioned, CO₂ is the source of carbon for all the organic molecules found in organisms.

Another relatively simple molecule is urea, CO(NH₂)₂. This is the organic compound found in urine that Wöhler

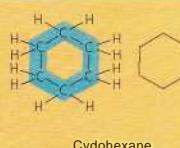

(a) Length. Carbon skeletons vary in length.

(b) Branching. Skeletons may be unbranched or branched.

(c) Double bonds. The skeleton may have double bonds, which can vary in location,

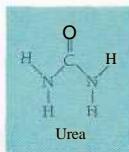

(d) Rings. Some carbon skeletons are arranged in rings, in the abbreviated structural formula for each compound (at the right), each corner represents a carbon and its attached hydrogens.

A Figure 4.5 Variations in carbon skeletons. Hydrocarbons, organic molecules consisting only of carbon and hydrogen, illustrate the diversity of the carbon skeletons of organic molecules.

learned to synthesize in the early 19th century. The structural formula for urea is shown at the right.

Again, each atom has the required number of covalent bonds. In this case, one carbon atom is involved in both single and double bonds.

Both urea and carbon dioxide are molecules with only one carbon atom. But as Figure 4.3 shows, a carbon atom can also use one or more of its valence electrons to form covalent bonds to other carbon atoms, making it possible to link the atoms into chains of seemingly infinite variety.

Molecular Diversity Arising from Carbon Skeleton Variation

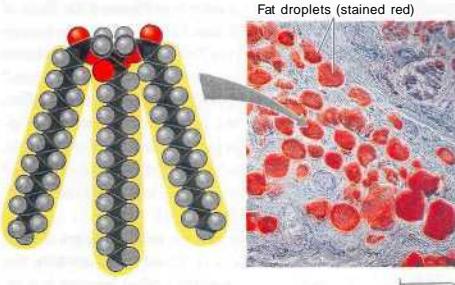

Carbon chains form the skeletons of most organic molecules (**Figure 4.5**). The skeletons vary in length and may be straight, branched, or arranged in closed rings. Some carbon skeletons have double bonds, which vary in number and location. Such variation in carbon skeletons is one important source of the molecular complexity and diversity that characterize living matter. In addition, atoms of other elements can be bonded to the skeletons at available sites.

Hydrocarbons

All the molecules shown in Figures 4.3 and 4.5 are hydrocarbons, organic molecules consisting only of carbon and hydrogen. Atoms of hydrogen are attached to the carbon skeleton wherever electrons are available for covalent bonding. Hydrocarbons are the major components of petroleum, which

is called a fossil fuel because it consists of the partially decomposed remains of organisms that lived millions of years ago.

Although hydrocarbons are not prevalent in living organisms, many of a cell's organic molecules have regions consisting of only carbon and hydrogen. For example, the molecules known as fats have long hydrocarbon tails attached to a non-hydrocarbon component (**Figure 4.6**). Neither petroleum nor fat dissolves in water; both are hydrophobic compounds

(a) A fat molecule

(b) Mammalian adipose cells

A Figure 4.6 The role of hydrocarbons in fats. (a) A fat molecule consists of a small, non-hydrocarbon component joined to three hydrocarbon tails. The tails can be broken down to provide energy. They also account for the hydrophobic behavior of fats. (Black = carbon; gray = hydrogen; red = oxygen.) (b) Mammalian adipose cells stockpile fat molecules as a fuel reserve. Each adipose cell in this micrograph is almost filled by a large fat droplet, which contains a huge number of fat molecules.

because the great majority of their bonds are nonpolar carbon-to-hydrogen linkages. Another characteristic of hydrocarbons is that they can undergo reactions that release a relatively large amount of energy. The gasoline that fuels a car consists of hydrocarbons, and the hydrocarbon tails of fat molecules serve as stored fuel for animal bodies.

Isomers

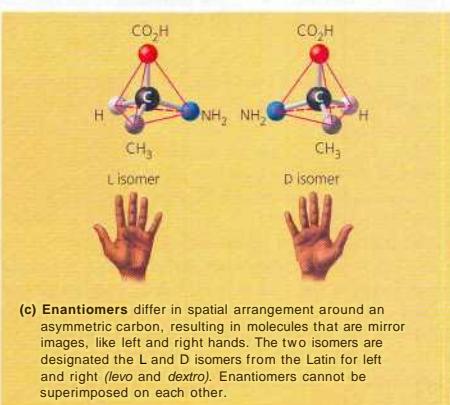

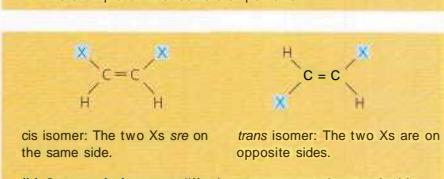

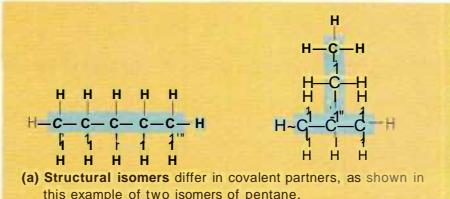

Variation in the architecture of organic molecules can be seen in isomers, compounds that have the same numbers of atoms of the same elements but different structures and hence different properties. Compare, for example, the two pentanes in **Figure 4.7a**. Both have the molecular formula C_5H_{12} , but they differ in the covalent arrangement of their carbon skeletons. The skeleton is straight in one form of pentane but branched in the other. We will examine three types of isomers: structural isomers, geometric isomers, and enantiomers.

Structural isomers differ in the covalent arrangements of their atoms. The number of possible isomers increases tremendously as carbon skeletons increase in size. There are only three pentanes (two are shown in Figure 4.7a), but there are 18 variations of C_8H_{18} and 366,319 possible structural isomers of $C_{20}H_{42}$. Structural isomers may also differ in the location of double bonds.

Geometric isomers have the same covalent partnerships, but they differ in their spatial arrangements. Geometric isomers arise from the inflexibility of double bonds, which, unlike single bonds, will not allow the atoms they join to rotate freely about the bond axis. If a double bond joins two carbon atoms, and each C also has two different atoms (or groups of atoms) attached to it, then two distinct geometric isomers are possible. Consider the simple example in **Figure 4.7b**. Each of the carbons has an H and an X attached to it, but one isomer has a "cis" arrangement, with two Xs on the same side relative to the double bond, and the other isomer has a "trans" arrangement, with the Xs on opposite sides. The subtle difference in shape between geometric isomers can dramatically affect the biological activities of organic molecules. For example, the biochemistry of vision involves a light-induced change of rhodopsin, a chemical compound in the eye, from the *cis* isomer to the *trans* isomer (see Chapter 49).

Enantiomers are molecules that are mirror images of each other. In the ball-and-stick models shown in **Figure 4.7c**, the middle carbon is called an *asymmetric carbon* because it is attached to four different atoms or groups of atoms. The four groups can be arranged in space about the asymmetric carbon in two different ways that are mirror images. They are, in a way, left-handed and right-handed versions of the molecule. A cell can distinguish these isomers based on their different shapes. Usually, one isomer is biologically active and the other is inactive.

The concept of enantiomers is important in the pharmaceutical industry because the two enantiomers of a drug

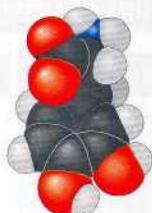

A Figure 4.7 Three types of isomers. Compounds with the same molecular formula but different structures, isomers are a source of diversity in organic molecules.

may not be equally effective. For example, L-dopa is effective against Parkinson's disease, while its enantiomer, D-dopa, is not (**Figure 4.8**). In some cases, one of the isomers may even produce harmful effects. This was the case with thalidomide, a drug prescribed for thousands of pregnant women in the late 1950s and early 1960s. The drug was a mixture of two enantiomers. One enantiomer reduced morning sickness, the desired effect, but the other caused severe birth defects. (Unfortunately, even if the "good" thalidomide enantiomer is used in purified form, some of it soon converts to the "bad" enantiomer in the patient's body) The differing effects of enantiomers in the body demonstrate that organisms are sensitive to even

the most subtle variations in molecular architecture. Once again, we see that molecules have emergent properties that depend on the specific arrangement of their atoms.

Concept Check 4.2

1. Draw a structural formula for C_2H_4 .
2. Look at Figure 4.5, and determine which pair(s) of molecules is (are) isomers of each other, identifying the type(s) of isomer.
3. What is the chemical similarity between gasoline and fat?

For suggested answers, see Appendix A.

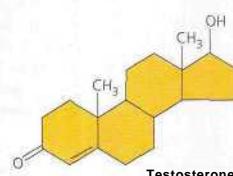

Female lion

Estradiol

Male lion

Testosterone

A Figure 4.9 A comparison of functional groups of female (estradiol) and male (testosterone) sex hormones. The two molecules differ only in the functional groups attached to a common carbon skeleton of four fused rings, which is shown here in abbreviated form. These subtle variations in molecular architecture influence the development of the anatomical and physiological differences between female and male vertebrates.

replace one or more of the hydrogens bonded to the carbon skeleton of the hydrocarbon. (However, some functional groups include atoms of the carbon skeleton, as we will see.)

Each functional group behaves consistently from one organic molecule to another, and the number and arrangement of the groups help give each molecule its unique properties. Consider the differences between testosterone and estradiol (a type of estrogen). These compounds are male and female sex hormones, respectively, in humans and other vertebrates (**Figure 4.9**). Both are steroids, organic molecules with a common carbon skeleton in the form of four fused rings. These sex hormones differ only in the functional groups attached to the rings. The different actions of these two molecules on many targets throughout the body help produce the contrasting features of females and males. Thus, even our sexuality has its biological basis in variations of molecular architecture.

The six functional groups most important in the chemistry of life are the hydroxyl, carbonyl, carboxyl, amino, sulphydryl, and phosphate groups. These groups are hydrophilic and thus increase the solubility of organic compounds in water. Before reading further, take time to familiarize yourself with the functional groups in **Figure 4.10** on the next two pages.

Concept 4.3

Functional groups are the parts of molecules involved in chemical reactions

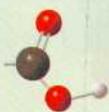

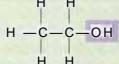

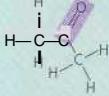

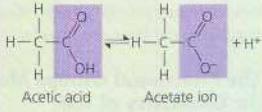

The distinctive properties of an organic molecule depend not only on the arrangement of its carbon skeleton, but also on the molecular components attached to that skeleton. We will now examine certain groups of atoms that are frequently attached to the skeletons of organic molecules.

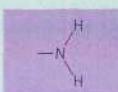

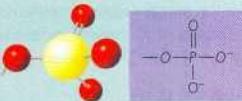

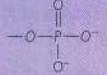

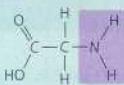

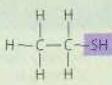

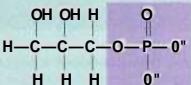

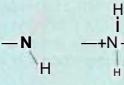

The Functional Groups Most Important in the Chemistry of Life

The components of organic molecules that are most commonly involved in chemical reactions are known as functional groups. If we think of hydrocarbons as the simplest organic molecules, we can view functional groups as attachments that

ATP: An Important Source of Energy for Cellular Processes

The "Phosphate" column in Figure 4.10 shows a simple example of an organic phosphate molecule. A more complicated organic phosphate, adenosine triphosphate, or ATP, is worth mentioning because it is the primary energy-transferring molecule in the cell. ATP consists of an organic molecule called adenosine attached to a string of three phosphate groups:

Where three phosphates are present in series, as in ATP, one phosphate may split off as an inorganic phosphate ion. This ion, HOPO₃²⁻, is often abbreviated Pi in this book. Losing one phosphate, ATP becomes adenosine diphosphate, or ADP. The reaction releases energy that can be used by the cell, as you will learn in more detail in Chapter 8.

SUMMARY OF KEY CONCEPTS

Concept 4.1

Organic chemistry is the study of carbon compounds

- Organic compounds were once thought to arise only within living organisms, but this idea (vitalism) was disproved when chemists were able to synthesize organic compounds in the laboratory (pp. 58-59).

Concept 4.2

Carbon atoms can form diverse molecules by bonding to four other atoms

- The Formation of Bonds with Carbon (pp. 59-61)** A covalent-bonding capacity of four contributes to carbon's ability to form diverse molecules. Carbon can bond to a variety of atoms, including O, H, and N. Carbon atoms can also bond to other carbons, forming the carbon skeletons of organic compounds.
- Molecular Diversity Arising from Carbon Skeleton Variation** (pp. 61-63) The carbon skeletons of organic molecules vary in length and shape and have bonding sites for atoms of other elements. Hydrocarbons consist only of carbon and hydrogen. Isomers are molecules with the same molecular formula but different structures and properties. Three types of isomers are structural isomers, geometric isomers, and enantiomers.

Activity *Diversity of Carbon-Based Molecules*

Concept Check 4.3

- What does the term "amino acid" signify about the structure of such a molecule?
- What change usually occurs in ATP when it releases energy?

For suggested answers, see Appendix A.

The Chemical Elements of Life: A Review

Living matter, as you have learned, consists mainly of carbon, oxygen, hydrogen, and nitrogen, with smaller amounts of sulfur and phosphorus. These elements share the characteristic of forming strong covalent bonds, a quality that is essential in the architecture of complex organic molecules. Of all these elements, carbon is the virtuoso of the covalent bond. The versatility of carbon makes possible the great diversity of organic molecules, each with particular properties that emerge from the unique arrangement of its carbon skeleton and the functional groups appended to that skeleton. At the foundation of all biological diversity lies this variation at the molecular level.

Chapter & Review

Activity Isomers

investigation *What Factors Determine the Effectiveness of Drugs?*

Concept 4.3

Functional groups are the parts of molecules involved in chemical reactions

- The Functional Groups Most Important in the Chemistry of Life** (pp. 63-65) Functional groups are chemically reactive groups of atoms within an organic molecule that give the molecule distinctive chemical properties. The hydroxyl group (—OH) is polar, thus helping compounds dissolve in water. The carbonyl group (—CO) can be either at the end of a carbon skeleton (aldehyde) or within the skeleton (ketone). The carboxyl group (—COOH) is found in carboxylic acids. The hydrogen of this group can dissociate, making such molecules weak acids. The amino group (—NH₂) can accept a proton (H⁺), thereby acting as a base. The sulphydryl group (—SH) helps stabilize the structure of some proteins. The phosphate group (—PO₃²⁻) has an important role in the transfer of energy.

Activity *Functional Groups*

- ATP: An Important Source of Energy for Cellular Processes** (p. 66) When a phosphate group splits off from ATP, energy is released that can be used by the cell.

- The Chemical Elements of Life: A Review** (p. 66) Living matter is made mostly of carbon, oxygen, hydrogen, and nitrogen, with some sulfur and phosphorus. Biological diversity has its molecular basis in carbon's ability to form a huge number of molecules with particular shapes and chemical properties.

TESTING YOUR KNOWLEDGE

Science, Technology, and Society

Evolution Connection

Some scientists believe that life elsewhere in the universe might be based on the element silicon, rather than on carbon, as on Earth. What properties does silicon share with carbon that would make silicon-based life more likely than, say neon-based life or aluminum-based life? (See Figure 2.8.)

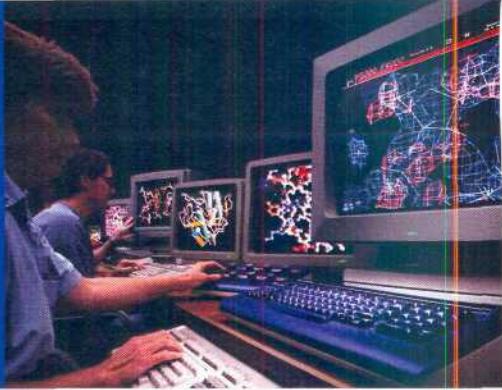

Scientific Inquiry

In 1918, an epidemic of sleeping sickness caused an unusual rigid paralysis in some survivors, similar to symptoms of advanced Parkinson's disease. Years later, L-dopa, a chemical used to treat Parkinson's disease (see Figure 4.8), was given to some of these patients, as dramatized in the movie *Awakenings*. L-Dopa was remarkably effective at eliminating the paralysis, at least temporarily. However, its enantiomer, D-dopa, was subsequently shown to have no effect at all, as is the case for Parkinson's disease. Suggest a hypothesis to explain why, for both diseases, one enantiomer is effective and the other is not.

investigation *What Factors Determine the Effectiveness of Drugs?*

Thalidomide achieved notoriety 50 years ago because of a wave of birth defects among children born to women who took thalidomide during pregnancy as a treatment for morning sickness. However, in 1998 the U.S. Food and Drug Administration (FDA) approved this drug for the treatment of certain conditions associated with Hansen's disease (leprosy). In clinical trials, thalidomide also shows promise for use in treating patients suffering from AIDS, tuberculosis, and some types of cancer. Do you think approval of this drug is appropriate? If so, under what conditions? What criteria do you think the FDA should use in weighing a drug's benefits against its dangers?

5 Tie Structure and Function of Macromolecules

Key Concepts

- 5.1 Most macromolecules are polymers, built from monomers
- 5.2 Carbohydrates serve as fuel and building material
- 5.3 Lipids are a diverse group of hydrophobic molecules
- 5.4 Proteins have many structures, resulting in a wide range of functions
- 5.5 Nucleic acids store and transmit hereditary information

Overview

The Molecules of life

We have seen how the concept of emergent properties applies to water and relatively simple organic molecules. Each type of small molecule has unique properties arising from the orderly arrangement of its atoms. Another level in the hierarchy of biological organization is reached when small organic molecules are joined inside cells, forming larger molecules. The four main classes of large biological molecules are carbohydrates, lipids, proteins, and nucleic acids. Many of these cellular molecules are, on the molecular scale, huge. For example, a protein may consist of thousands of covalently connected atoms that form a molecular colossus with a mass of over 100,000 daltons. Biologists use the term macromolecule for such giant molecules.

Considering the size and complexity of macromolecules, it is remarkable that biochemists have determined the detailed structures of so many of them (Figure 5.1). The architecture of a macromolecule helps explain how that molecule works. Life's large molecules are the main subject of this chapter. For

these molecules, as at all levels in the biological hierarchy, form and function are inseparable.

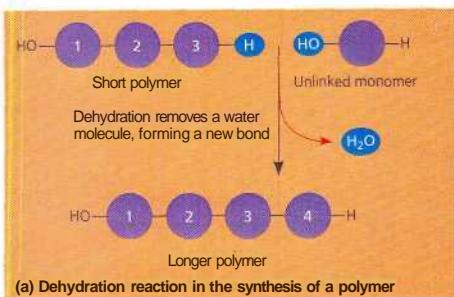

Concept 5.1

Most macromolecules are polymers, built from monomers

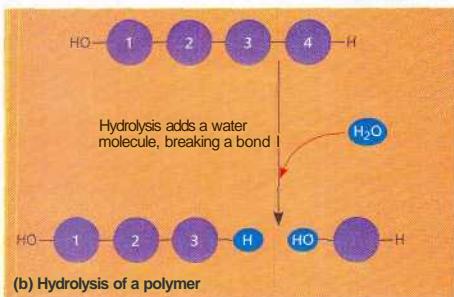

The large molecules in three of the four classes of life's organic compounds—carbohydrates, proteins, and nucleic acids—are chain-like molecules called polymers (from the Greek *polys*, many, and *metis*, part). A polymer is a long molecule consisting of many similar or identical building blocks linked by covalent bonds, much as a train consists of a chain of cars. The repeating units that serve as the building blocks of a polymer are small molecules called monomers. Some of the molecules that serve as monomers also have other functions of their own.

The Synthesis and Breakdown of Polymers

The classes of polymeric macromolecules differ in the nature of their monomers, but the chemical mechanisms by which cells make and break polymers are basically the same in all cases (Figure 5.2). Monomers are connected by a reaction in which two molecules are covalently bonded to each other through loss of a water molecule; this is called a condensation reaction, specifically a dehydration reaction, because the molecule lost is water (Figure 5.2a). When a bond forms between two monomers, each monomer contributes part of the water molecule that is lost. One molecule provides a hydroxyl group ($-\text{OH}$), while the other provides a hydrogen ($-\text{H}$). In making a polymer, this reaction is repeated as monomers are added to the chain one by one. The cell must expend energy to carry out these dehydration reactions, and the process oc-

(a) Dehydration reaction in the synthesis of a polymer

(b) Hydrolysis of a polymer

A Figure 5.2 The synthesis and breakdown of polymers.

curs only with the help of enzymes, specialized proteins that speed up chemical reactions in cells.

Polymers are disassembled to "monomers by hydrolysis, a process that is essentially the reverse of the dehydration reaction (Figure 5.2b). Hydrolysis means to break with water (from the Greek *hydro*, water, and *lysis*, break). Bonds between monomers are broken by the addition of water molecules, a hydrogen from the water attaching to one monomer and a hydroxyl group attaching to the adjacent monomer. An example of hydrolysis working in our bodies is the process of digestion. The bulk of the organic material in our food is in the form of polymers that are much too large to enter our cells. Within the digestive tract, various enzymes attack the polymers, speeding up hydrolysis. The released monomers are then absorbed into the bloodstream for distribution to all body cells. Those cells can then use dehydration reactions to assemble the monomers into new polymers that differ from the ones that were digested. The new polymers perform specific functions required by the cell.

The Diversity of Polymers

Each cell has thousands of different kinds of macromolecules; the collection varies from one type of cell to another even in the same organism. The inherent differences between human

siblings reflect variations in polymers, particularly DNA and proteins. Molecular differences between unrelated individuals are more extensive and between species greater still. The diversity of macromolecules in the living world is vast, and the possible variety is effectively limitless.

What is the basis for such diversity in life's polymers? These molecules are constructed from only 40 to 50 common monomers and some others that occur rarely. Building an enormous variety of polymers from such a limited list of monomers is analogous to constructing hundreds of thousands of words from only 26 letters of the alphabet. The key is arrangement—variation in the linear sequence that the units follow. However, this analogy falls far short of describing the great diversity of macromolecules, because most biological polymers are much longer than the longest word. Proteins, for example, are built from 20 kinds of amino acids arranged in chains that are typically hundreds of amino acids long. The molecular logic of life is simple but elegant: Small molecules common to all organisms are ordered into unique macromolecules.

We are now ready to investigate the specific structures and functions of the four major classes of organic compounds found in cells. For each class, we will see that the large molecules have emergent properties not found in their individual building blocks.

Concept Check 5.1

1. What are the four main classes of large biological molecules?
2. How many molecules of water are needed to completely hydrolyze a polymer that is 10 monomers long?
3. After you eat a slice of apple, which reactions must occur for the amino acid monomers in the protein of the apple to be converted into proteins in your body?

For suggested answers, see Appendix A.

Concept 5.2

Carbohydrates serve as fuel and building material

Carbohydrates include both sugars and the polymers of sugars. The simplest carbohydrates are the monosaccharides, or single sugars, also known as simple sugars. Disaccharides are double sugars, consisting of two monosaccharides joined by a condensation reaction. The carbohydrates that are macromolecules are polysaccharides, polymers composed of many sugar building blocks.

Sugars

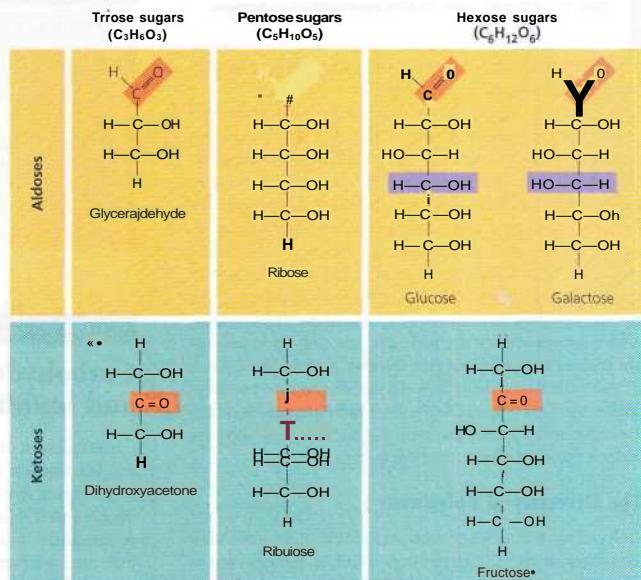

Monosaccharides (from the Greek *mows*, single, and *sacchar*, sugar) generally have molecular formulas that are some multiple of the unit CH_2O (**Figure 5.3**). Glucose ($\text{C}_6\text{H}_{12}\text{O}_6$), the most common monosaccharide, is of central importance in the chemistry of life. In the structure of glucose, we can see the trademarks of a sugar: The molecule has a carbonyl group (C=O) and multiple hydroxyl groups ($-\text{OH}$). Depending on the location of the carbonyl group, a sugar is either an aldose (aldehyde sugar) or a ketose (ketone sugar). Glucose, for example, is an aldose; fructose, a structural isomer of glucose, is a ketose. (Most names for sugars end in *-ose*.) Another criterion for classifying sugars is the size of the carbon skeleton, which ranges from three to seven carbons long. Glucose, fructose, and other sugars that have six carbons are called hexoses. Trioses (three-carbon sugars) and pentoses (five-carbon sugars) are also common.

Still another source of diversity for simple sugars is in the spatial arrangement of their parts around asymmetric carbons. (Recall from Chapter 4 that an asymmetric carbon is a carbon attached to four different kinds of partners.) Glucose and galactose, for example, differ only in the placement of parts around one asymmetric carbon (see the purple boxes in Figure 5.3). What seems like a small difference is significant enough to give the two sugars distinctive shapes and behaviors.

Although it is convenient to draw glucose with a linear carbon skeleton, this representation is not completely accurate. In aqueous solutions, glucose molecules, as well as most other sugars, form rings (**Figure 5.4**).

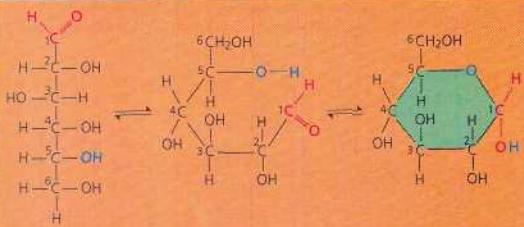

Monosaccharides, particularly glucose, are major nutrients for cells. In the process known as cellular respiration, cells extract the energy stored in glucose molecules. Not only are simple sugar molecules a major fuel for cellular work, but their carbon skeletons serve as raw material for the synthesis of other types of small organic molecules, such as amino acids and fatty acids. Sugar molecules that are not immediately used in these ways are generally incorporated as monomers into disaccharides or polysaccharides.

A disaccharide consists of two monosaccharides joined by a glycosidic linkage, a covalent bond formed between two monosaccharides by a dehydration reaction. For example, maltose is a disaccharide formed by the linking of two molecules of glucose (**Figure 5.5a**). Also known as malt sugar, maltose is an ingredient used in brewing beer. The most prevalent disaccharide is sucrose, which is table sugar. Its two monomers are glucose and fructose (**Figure 5.5b**). Plants generally transport carbohydrates from leaves to roots and other nonphotosynthetic organs in the form of sucrose. Lactose, the sugar present in milk, is another disaccharide, in this case a glucose molecule joined to a galactose molecule.

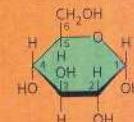

• **Figure 5.3** The structure and classification of some monosaccharides.

Sugars may be aldoses (aldehyde sugars, top row) or ketoses (ketone sugars, bottom row), depending on the location of the carbonyl group (dark orange). Sugars are also classified according to the length of their carbon skeletons. A third point of variation is the spatial arrangement around asymmetric carbons (compare, for example, the purple portions of glucose and galactose).

(a) Linear and ring forms. Chemical equilibrium between the linear and ring structures greatly favors the formation of rings. To form the glucose ring, carbon 1 bonds to the oxygen attached to carbon 5.

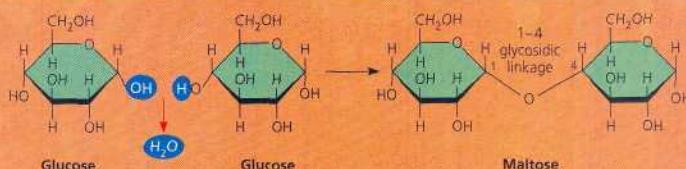

(b) Abbreviated ring structure. Each corner represents a carbon. The ring's thicker edge indicates that you are looking at the ring edge-on; the components attached to the ring lie above or below the plane of the ring.

A Figure 5.4 Linear and ring forms of glucose.

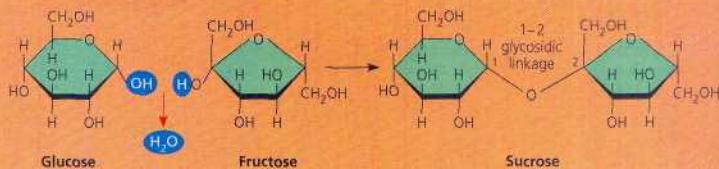

(a) Dehydration reaction in the synthesis of maltose.

The bonding of two glucose units forms maltose. The glycosidic link joins the number 1 carbon of one glucose to the number 4 carbon of the second glucose. Joining the glucose monomers in a different way would result in a different disaccharide.

(b) Dehydration reaction in the synthesis of sucrose.

Sucrose is a disaccharide formed from glucose and fructose. Notice that fructose, though a hexose like glucose, forms a five-sided ring.

A Figure 5.5 Examples of disaccharide synthesis.

Polysaccharides

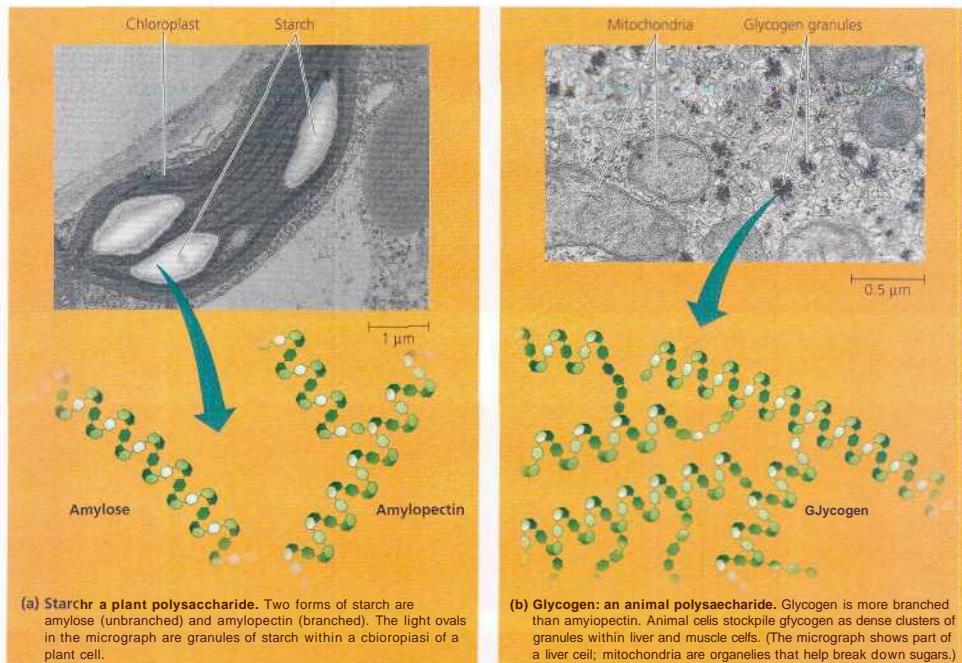

Polysaccharides are macromolecules, polymers with a few hundred to a few thousand monosaccharides joined by glycosidic linkages. Some polysaccharides serve as storage material, hydrolyzed as needed to provide sugar for cells. Other polysaccharides serve as building material for structures that protect the cell or the whole organism. The architecture and function of a polysaccharide are determined by its sugar monomers and by the positions of its glycosidic linkages.

Storage Polysaccharides

Starch, a storage polysaccharide of plants, is a polymer consisting entirely of glucose monomers. Most of these monomers are

joined by 1-4 linkages (number 1 carbon to number 4 carbon), like the glucose units in maltose (see Figure 5.5a). The angle of these bonds makes the polymer helical. The simplest form of starch, amylose, is unbranched. Amylopectin, a more complex form of starch, is a branched polymer with 1-6 linkages at the branch points.

Plants store starch as granules within cellular structures called plastids, which include chloroplasts (Figure 5.6a). Synthesizing starch enables the plant to stockpile surplus glucose. Because glucose is a major cellular fuel, starch represents stored energy. The sugar can later be withdrawn from this carbohydrate "bank" by hydrolysis, which breaks the bonds between the glucose monomers. Most animals, including humans, also have enzymes that can hydrolyze plant starch, making glucose

(a) Starch: a plant polysaccharide. Two forms of starch are amylose (unbranched) and amylopectin (branched). The light ovals in the micrograph are granules of starch within a chloroplast of a plant cell.

(b) Glycogen: an animal polysaccharide. Glycogen is more branched than amylopectin. Animal cells stockpile glycogen as dense clusters of granules within liver and muscle cells. (The micrograph shows part of a liver cell; mitochondria are organelles that help break down sugars.)

A Figure 5.6 Storage polysaccharides of plants and animals. These examples, starch and glycogen, are composed entirely of glucose monomers, represented here by hexagons. Due to their molecular structure, the polymer chains tend to form helices.

available as a nutrient for cells. Potato tubers and grains—the fruits of wheat, corn, rice, and other grasses—are the major sources of starch in the human diet.

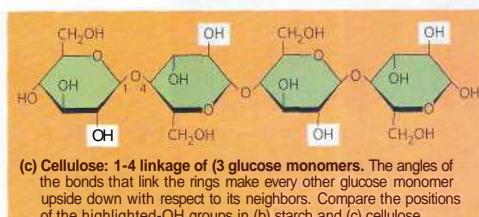

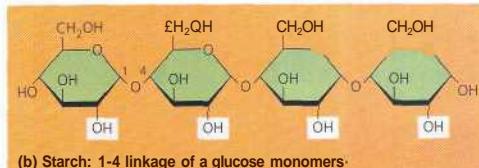

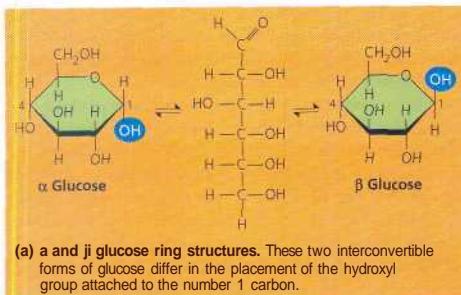

Animals store a polysaccharide called glycogen, a polymer of glucose that is like amylopectin but more extensively branched (**Figure 5.6b**). Humans and other vertebrates store glycogen mainly in liver and muscle cells. Hydrolysis of glycogen in these cells releases glucose when the demand for sugar increases. This stored fuel cannot sustain an animal for long, however. In humans, for example, glycogen stores are depleted in about a day unless they are replenished by consumption of food.

Structural Polysaccharides

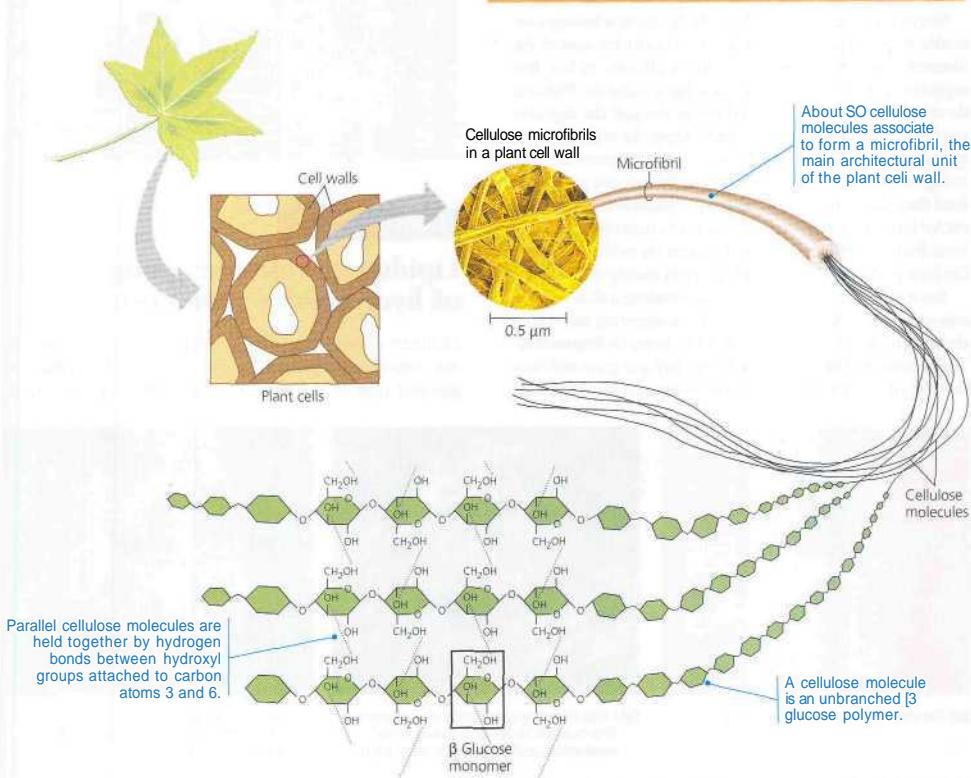

Organisms build strong materials from structural polysaccharides. For example, the polysaccharide called cellulose is a major component of the tough walls that enclose plant cells. On a global scale, plants produce almost 10^{11} (100 billion) tons of cellulose per year; it is the most abundant organic compound on Earth. Like starch, cellulose is a polymer of

glucose, but the glycosidic linkages in these two polymers differ. The difference is based on the fact that there are actually two slightly different ring structures for glucose (**Figure 5.7a**). When glucose forms a ring, the hydroxyl group attached to the number 1 carbon is positioned either below or above the plane of the ring. These two ring forms for glucose are called alpha (α) and beta (β), respectively. In starch, all the glucose monomers are in the α configuration (**Figure 5.7b**), the arrangement we saw in Figures 5.4 and 5.5. In contrast, the glucose monomers of cellulose are all in the β configuration, making every other glucose monomer upside down with respect to its neighbors (**Figure 5.7c**).

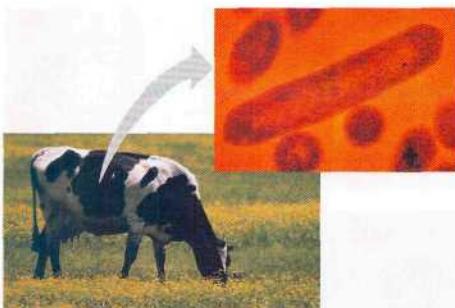

The differing glycosidic links in starch and cellulose give the two molecules distinct three-dimensional shapes. Whereas a starch molecule is mostly helical, a cellulose molecule is straight (and never branched), and its hydroxyl groups are free to hydrogen-bond with the hydroxyls of other cellulose molecules lying parallel to it. In plant cell walls, parallel cellulose molecules held together in this way are grouped into units called microfibrils (**Figure 5.8**). These cable-like microfibrils

A Figure 5.7 Starch and cellulose structures.

A Figure 5.8 The arrangement of cellulose in plant cell walls.

• **Figure 5.9** Cellulose-digesting bacteria are found in grazing animals such as this cow.

are a strong building material for plants as well as for humans, who use wood, which is rich in cellulose, for lumber.

Enzymes that digest starch by hydrolyzing its *a* linkages are unable to hydrolyze the (3 linkages of cellulose because of the distinctly different shapes of these two molecules. In fact, few organisms possess enzymes that can digest cellulose. Humans do not; the cellulose in our food passes through the digestive tract and is eliminated with the feces. Along the way, the cellulose abrades the wall of the digestive tract and stimulates the lining to secrete mucus, which aids in the smooth passage of food through the tract. Thus, although cellulose is not a nutrient for humans, it is an important part of a healthful diet. Most fresh fruits, vegetables, and whole grains are rich in cellulose. On food packages, "insoluble fiber" refers mainly to cellulose.

Some microbes can digest cellulose, breaking it down to glucose monomers. A cow harbors cellulose-digesting bacteria in the rumen, the first compartment in its stomach (Figure 5.9). The bacteria hydrolyze the cellulose of hay and grass and convert the glucose to other nutrients that nourish the cow. Simi-

larly, a termite, which is unable to digest cellulose by itself, has microbes living in its gut that can make a meal of wood. Some fungi can also digest cellulose, thereby helping recycle chemical elements within Earth's ecosystems,

Another important structural polysaccharide is chitin, the carbohydrate used by arthropods (insects, spiders, crustaceans, and related animals) to build their exoskeletons (Figure 5.10). An exoskeleton is a hard case that surrounds the soft parts of an animal. Pure chitin is leathery, but it becomes hardened when encrusted with calcium carbonate, a salt. Chitin is also found in many fungi, which use this polysaccharide rather than cellulose as the building material for their cell walls. Chitin is similar to cellulose, except that the glucose monomer of chitin has a nitrogen-containing appendage (see Figure 5.10a).

Concept Check 5.2

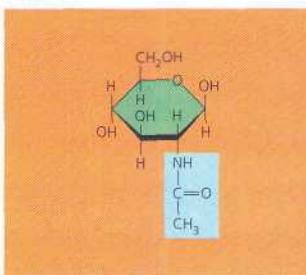

1. Write the formula for a monosaccharide that has three carbons.
2. A dehydration reaction joins two glucose molecules to form maltose. The formula for glucose is $C_6H_{12}O_6$. What is the formula for maltose?
3. Compare and contrast starch and cellulose.

For suggested answers, see Appendix A.

Concept 5.3

Lipids are a diverse group of hydrophobic molecules

Lipids are the one class of large biological molecules that does not consist of polymers. The compounds called lipids are grouped together because they share one important trait:

(a) The structure of the chitin monomer.

(b) Chitin forms the exoskeleton of arthropods. This cicada is molting, shedding its old exoskeleton and emerging in adult form.

(c) Chitin is used to make a strong and flexible surgical thread that decomposes after the wound or incision heals.

A **Figure 5.10** Chitin, a structural polysaccharide.

They have little or no affinity for water. The hydrophobic behavior of lipids is based on their molecular structure. Although they may have some polar bonds associated with oxygen, lipids consist mostly of hydrocarbons. Smaller than true (polymeric) macromolecules, lipids are a highly varied group in both form and function. Lipids include waxes and certain pigments, but we will focus on the most biologically important types of lipids: fats, phospholipids, and steroids.

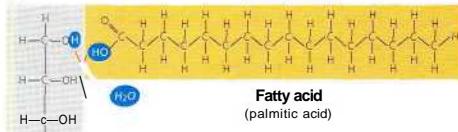

Fats

Although fats are not polymers, they are large molecules, and they are assembled from smaller molecules by dehydration reactions. A **fat** is constructed from two kinds of smaller molecules: glycerol and fatty acids (**Figure 5.11a**). Glycerol is an alcohol with three carbons, each bearing a hydroxyl group. A **fatty acid** has a long carbon skeleton, usually 16 or 18 carbon atoms in length. At one end of the fatty acid is a carboxyl group, the functional group that gives these molecules the name **fatty acid**. Attached to the carboxyl group is a long hydrocarbon chain. The nonpolar C—H bonds in the hydrocarbon chains of fatty acids are the reason fats are hydrophobic. Fats separate from water because the water molecules hydrogen-bond to one

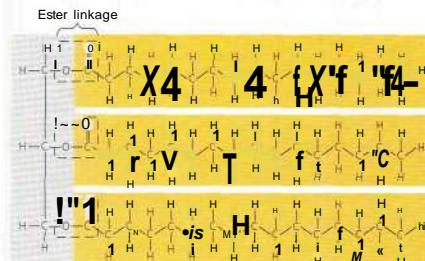

another and exclude the fats. A common example of this phenomenon is the separation of vegetable oil (a liquid fat) from the aqueous vinegar solution in a bottle of salad dressing.

In making a fat, three fatty acid molecules each join to glycerol by an ester linkage, a bond between a hydroxyl group and a carboxyl group. The resulting fat, also called a **triacylglycerol**, thus consists of three fatty acids linked to one glycerol molecule. (Still another name for a fat is *triglyceride*, a word often found in the list of ingredients on packaged foods.) The fatty acids in a fat can be the same, as in **Figure 5.11b**, or they can be of two or three different kinds.

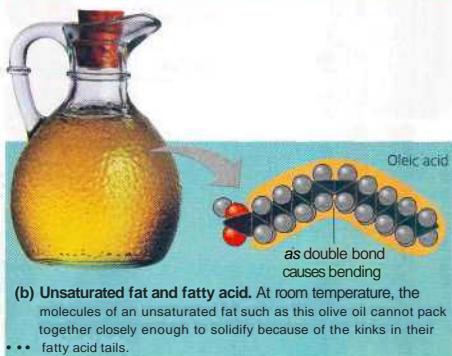

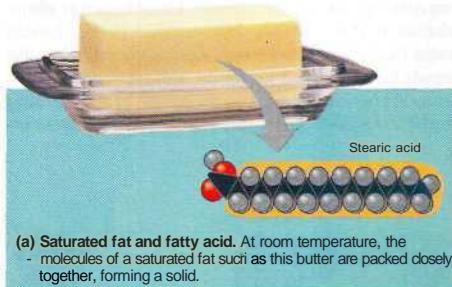

Fatty acids vary in length and in the number and locations of double bonds. The terms **saturated fats** and **unsaturated fats** are commonly used in the context of nutrition (**Figure 5.12**). These terms refer to the structure of the hydrocarbon chains of the fatty acids. If there are no double bonds between carbon atoms composing the chain, then as many hydrogen atoms as possible are bonded to the carbon skeleton. Such a structure is described as being **saturated** with hydrogen, so the resulting fatty acid is called a **saturated fatty acid** (**Figure 5.12a**). An **unsaturated**

(a) Dehydration reaction in the synthesis of a fat

A Figure 5.11 The synthesis and structure of a fat, or triacylglycerol. The molecular building blocks of a fat are one molecule of glycerol and three molecules of fatty acids. (a) One water molecule is removed for each fatty acid joined to the glycerol. (b) A fat molecule with three identical fatty acid units. The carbons of the fatty acids are arranged zig-zag to suggest the actual orientations of the four single bonds extending from each carbon (see Figure 43a).

A Figure 5.12 Examples of saturated and unsaturated fats and fatty acids.

fatty acid has one or more double bonds, formed by the removal of hydrogen atoms from the carbon skeleton. The fatty acid will have a kink in its hydrocarbon chain wherever a *cis* double bond occurs (Figure 5.12b).

A fat made from saturated fatty acids is called a saturated fat. Most animal fats are saturated: The hydrocarbon chains of their fatty acids—the “tails” of the fat molecules—lack double bonds, and the molecules can pack tightly side by side. Saturated animal fats—such as lard and butter—are solid at room temperature. In contrast, the fats of plants and fishes are generally unsaturated, meaning that they are built of one or more types of unsaturated fatty acids. Usually liquid at room temperature, plant and fish fats are referred to as oils—olive oil and cod liver oil are examples. The kinks where the *cis* double bonds are located prevent the molecules from packing together closely enough to solidify at room temperature. The phrase “hydrogenated vegetable oils” on food labels means that unsaturated fats have been synthetically converted to saturated fats by adding hydrogen. Peanut butter, margarine, and many other products are hydrogenated to prevent lipids from separating out in liquid (oil) form.

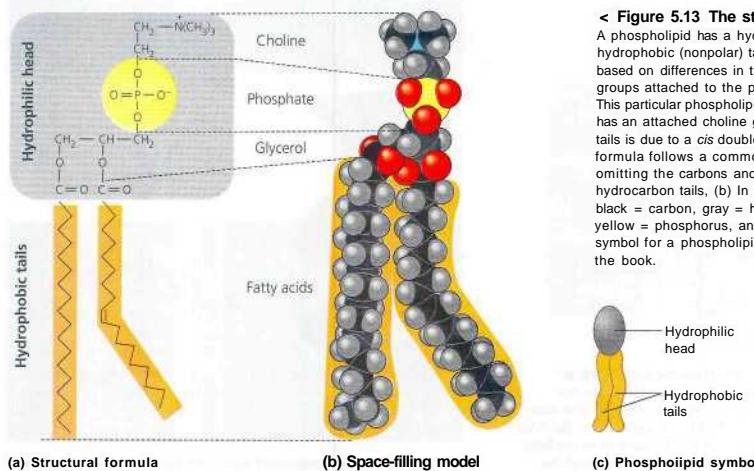

A diet rich in saturated fats is one of several factors that may contribute to the cardiovascular disease known as atherosclerosis. In this condition, deposits called plaques develop within the walls of blood vessels, causing inward bulges that impede blood flow and reduce the resilience of the vessels. Recent studies have shown that the process of hydrogenating vegetable oils produces not only saturated fats but also unsat-

urated fats with *trans* double bonds. These *trans* fat molecules may contribute more than saturated fats to atherosclerosis (see Chapter 42) and other problems.

Fat has come to have such a negative connotation in our culture that you might wonder whether fats serve any useful purpose. The major function of fats is energy storage. The hydrocarbon chains of fats are similar to gasoline molecules and just as rich in energy. A gram of fat stores more than twice as much energy as a gram of a polysaccharide, such as starch. Because plants are relatively immobile, they can function with bulky energy storage in the form of starch. (Vegetable oils are generally obtained from seeds, where more compact storage is an asset to the plant.) Animals, however, must carry their energy stores with them, so there is an advantage to having a more compact reservoir of fuel—fat. Humans and other mammals stock their long-term food reserves in adipose cells (see Figure 4.6b), which swell and shrink as fat is deposited and withdrawn from storage. In addition to storing energy, adipose tissue also cushions such **vital** organs as the kidneys, and a layer of fat beneath the skin insulates the body. This subcutaneous layer is especially thick in whales, seals, and most other marine mammals, protecting them from cold ocean water.

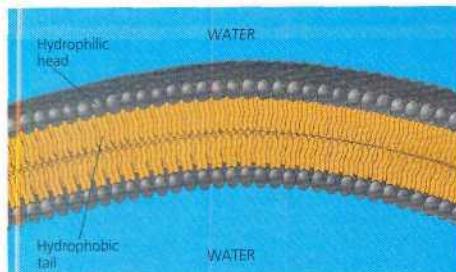

Phospholipids

A **phospholipid**, as shown in Figure 5.13, is similar to a fat, but has only two fatty acids attached to glycerol rather than three. The third hydroxyl group of glycerol is joined to a phosphate

◀ Figure 5.13 The structure of a phospholipid.

A phospholipid has a hydrophilic (polar) head and two hydrophobic (nonpolar) tails. Phospholipid diversity is based on differences in the two fatty acids and in the groups attached to the phosphate group of the head. This particular phospholipid, called a phosphatidylcholine, has an attached choline group. The kink in one of its tails is due to a *cis* double bond, (a) The structural formula follows a common chemical convention of omitting the carbons and attached hydrogens of the hydrocarbon tails, (b) In the space-filling model, black = carbon, gray = hydrogen, red = oxygen, yellow = phosphorus, and blue = nitrogen, (c) This symbol for a phospholipid will appear throughout the book.

A Figure 5.14 Bilayer structure formed by self-assembly of phospholipids in an aqueous environment. The phospholipid bilayer shown here is the main fabric of biological membranes. Note that the hydrophilic heads of the phospholipids are in contact with water in this structure, whereas the hydrophobic tails are in contact with each other and remote from water.

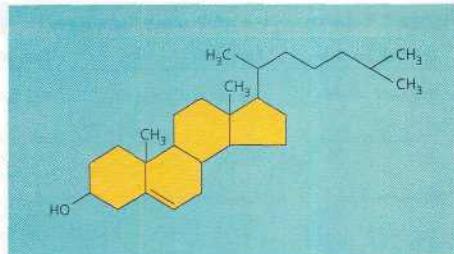

group, which has a negative electrical charge. Additional small molecules, usually charged or polar, can be linked to the phosphate group to form a variety of phospholipids.

Phospholipids show ambivalent behavior toward water. Their hydrocarbon tails are hydrophobic and are excluded from water. However, the phosphate group and its attachments form a hydrophilic head that has an affinity for water. When phospholipids are added to water, they self-assemble into double-layered aggregates—bilayers—that shield their hydrophobic portions from water (**Figure 5.14**).

At the surface of a cell, phospholipids are arranged in a similar bilayer. The hydrophilic heads of the molecules are on the outside of the bilayer, in contact with the aqueous solutions inside and outside the cell. The hydrophobic tails point toward the interior of the bilayer, away from the water. The phospholipid bilayer forms a boundary between the cell and its external environment; in fact, phospholipids are major components of all cell membranes. This behavior provides another example of how form fits function at the molecular level.

Steroids

Steroids are lipids characterized by a carbon skeleton consisting of four fused rings (**Figure 5.15**). Different steroids vary in the functional groups attached to this ensemble of rings. One steroid, cholesterol, is a common component of animal cell membranes and is also the precursor from which other steroids are synthesized. Many hormones, including vertebrate sex hormones, are steroids produced from cholesterol (see Figure 4.9). Thus, cholesterol is a crucial molecule in animals, although a high level of it in the blood may contribute to atherosclerosis. Both saturated fats

A Figure 5.15 Cholesterol, a steroid. Cholesterol is the molecule from which other steroids, including the sex hormones, are synthesized. Steroids vary in the functional groups attached to their four interconnected rings (shown in gold).

and *trans* fats exert their negative impact on health by affecting cholesterol levels.

Concept Check 5.3

1. Compare the structure of a fat (triglyceride) with that of a phospholipid.
2. How do saturated fats differ from unsaturated fats, both in structure and in behavior?
3. Why are human sex hormones considered to be lipids?

for suggested answers, see Appendix A.

Concept 5.4

Proteins have many structures, resulting in a wide range of functions

The importance of proteins is implied by their name, which comes from the Greek word *proteios*, meaning "first place." Proteins account for more than 50% of the dry mass of most cells, and they are instrumental in almost everything organisms do. Some proteins speed up chemical reactions, while others play a role in structural support, storage, transport, cellular communications, movement, and defense against foreign substances (**Table 5.1**, on the next page).

The most important type of protein may be enzymes. Enzymatic proteins regulate metabolism by acting as catalysts, chemical agents that selectively speed up chemical reactions in

Table 5.1 An Overview of Protein Functions

| Type of Protein | Function | Examples |
|--------------------------------|--|--|
| Enzymatic proteins | Selective acceleration of chemical reactions | Digestive enzymes catalyze the hydrolysis of the polymers in food. |
| Structural proteins | Support | Insects and spiders use silk fibers to make their cocoons and webs, respectively. Collagen and elastin provide a fibrous framework in animal connective tissues. Keratin is the protein of hair, horns, feathers, and other skin appendages. |
| Storage proteins | Storage of amino acids | Ovalbumin is the protein of egg white, used as an amino acid source for the developing embryo. Casein, the protein of milk, is the major source of amino acids for baby mammals. Plants have storage proteins in their seeds. |
| Transport proteins | Transport of other substances | Hemoglobin, the iron-containing protein of vertebrate blood, transports oxygen from the lungs to other parts of the body. Other proteins transport molecules across cell membranes. |
| Hormonal proteins | Coordination of an organism's activities | Insulin, a hormone secreted by the pancreas, helps regulate the concentration of sugar in the blood of vertebrates. |
| Receptor proteins | Response of cell to chemical stimuli | Receptors built into the membrane of a nerve cell detect chemical signals released by other nerve cells. |
| Contractile and motor proteins | Movement | Actin and myosin are responsible for the movement of muscles. Other proteins are responsible for the undulations of the organelles called cilia and flagella. |
| Defensive proteins | Protection against disease | Antibodies combat bacteria and viruses. |

the cell without being consumed by the reaction (**Figure 5.16**). Because an enzyme can perform its function over and over again, these molecules can be thought of as workhorses that keep cells running by carrying out the processes of life.

A human has tens of thousands of different proteins, each with a specific structure and function; proteins, in fact, are the most structurally sophisticated molecules known. Consistent with their diverse functions, they vary extensively in structure, each type of protein having a unique three-dimensional shape, or conformation.

Polypeptides

Diverse as proteins are, they are all polymers constructed from the same set of 20 amino acids. Polymers of amino acids are called **polypeptides**. A **protein** consists of one or more polypeptides folded and coiled into specific conformations.

Amino Acid Monomers

Amino acids are organic molecules possessing both carboxyl and amino groups (see Chapter 4). The illustration at the right shows the general formula for an amino acid. At the center of the amino acid is an asymmetric carbon atom called the *alpha (α) carbon*. Its four different partners are an amino group, a carboxyl group, a hydrogen atom, and a variable group symbolized by R. The R group, also called the side chain, differs with each amino acid. **Figure 5.17** shows the 20 amino acids that cells use to

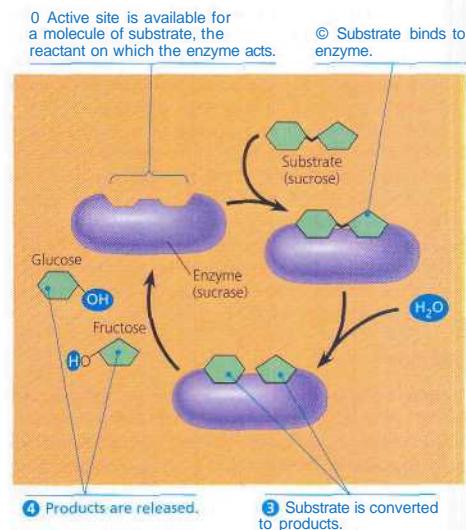

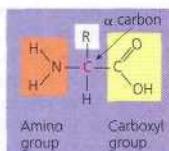

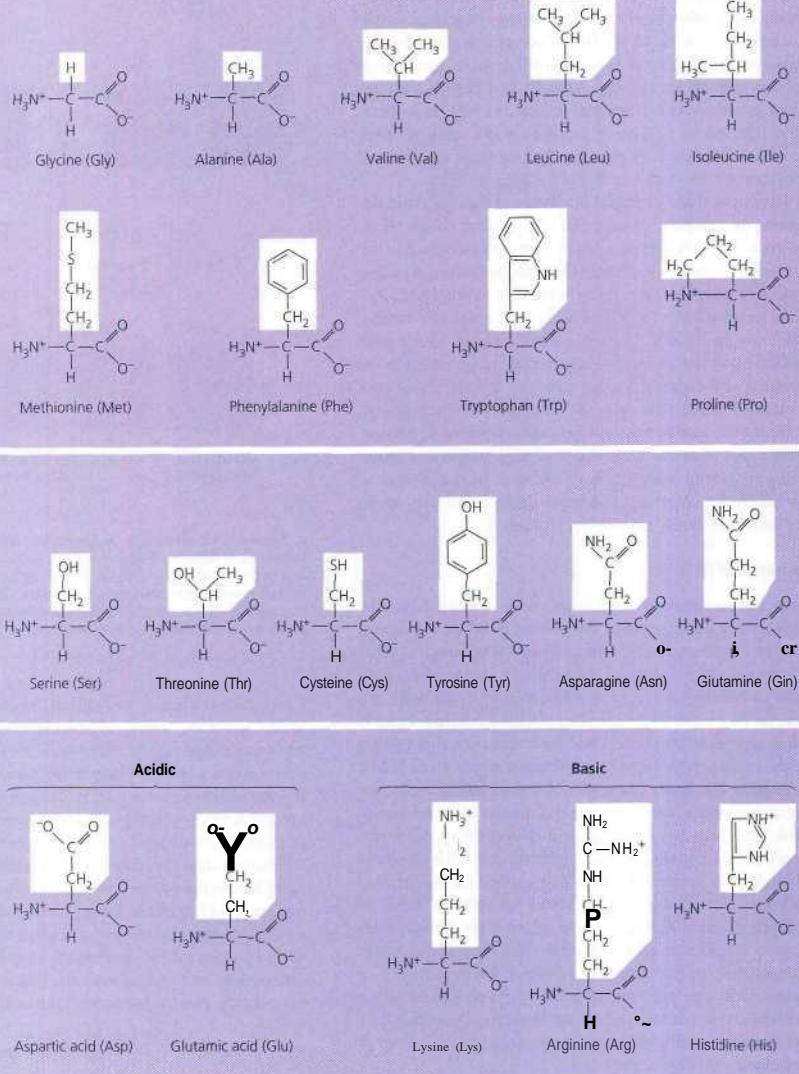

Figure 5.16 The catalytic cycle of an enzyme. The enzyme sucrase accelerates hydrolysis of sucrose into glucose and fructose. Acting as a catalyst, the sucrase protein is not consumed during the cycle, but is available for further catalysis.

4 Figure 5.17 The 20 amino acids of proteins. The amino acids are grouped here according to the properties of their side chains (R groups), highlighted in white. The amino

acids are shown in their prevailing ionic forms at pH 7.2, the pH within a cell. The three-letter abbreviations for the amino acids are in

parentheses. All the amino acids used in proteins are the same enantiomer, called the L form, as shown here (see Figure 4.7).

build their thousands of proteins. Here the amino and carboxyl groups are all depicted in ionized form, the way they usually exist at the pH in a cell. The R group may be as simple as a hydrogen atom, as in the amino acid glycine (the one amino acid lacking an asymmetric carbon, since two of its *a* carbons' partners are hydrogen atoms), or it may be a carbon skeleton with various functional groups attached, as in glutamine. (Organisms do have other amino acids, some of which are occasionally found in proteins. Because these are relatively rare, they are not shown in Figure 5.17.)

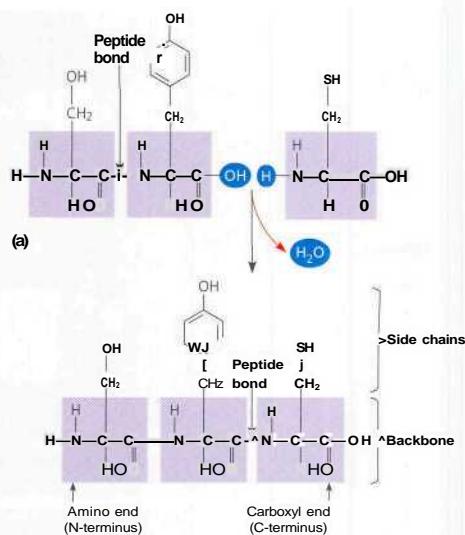

The physical and chemical properties of the side chain determine the unique characteristics of a particular amino acid. In Figure 5.17, the amino acids are grouped according to the properties of their side chains. One group consists of amino acids with nonpolar side chains, which are hydrophobic. Another group consists of amino acids with polar side chains, which are hydrophilic. Acidic amino acids are those with side chains that are generally negative in charge owing to the presence of a carboxyl group, which is usually dissociated (ionized) at cellular pH. Basic amino acids have amino groups in their side chains that are generally positive in charge. (Notice that *all* amino acids have carboxyl groups and amino groups; the terms *acidic* and *basic* in this context refer only to groups on the side chains.) Because they are charged, acidic and basic side chains are also hydrophilic.

Amino Acid Polymers

Now that we have examined amino acids, let's see how they are linked to form polymers (**Figure 5.18**). When two amino acids are positioned so that the carboxyl group of one is adjacent to the amino group of the other, an enzyme can cause them to join by catalyzing a dehydration reaction, with the removal of a water molecule. The resulting covalent bond is called a peptide bond. Repeated over and over, this process yields a polypeptide, a polymer of many amino acids linked by peptide bonds. At one end of the polypeptide chain is a free amino group; at the opposite end is a free carboxyl group. Thus, the chain has an amino end (N-terminus) and a carboxyl end (C-terminus). The repeating sequence of atoms highlighted in purple in Figure 5.18b is called the polypeptide backbone. Attached to this backbone are different kinds of appendages, the side chains of the amino acids. Polypeptides range in length from a few monomers to a thousand or more. Each specific polypeptide has a unique linear sequence of amino acids. The immense variety of polypeptides in nature illustrates an important concept introduced earlier—that cells can make many different polymers by linking a limited set of monomers into diverse sequences.

Determining the Amino Acid Sequence of a Polypeptide

The pioneer in determining the amino acid sequence of proteins was Frederick Sanger, who, with his colleagues at

A Figure 5.18 Making a polypeptide chain. (a) Peptide bonds formed by dehydration reactions link the carboxyl group of one amino acid to the amino group of the next. (b) The peptide bonds are formed one at a time, starting with the amino acid at the amino end (N-terminus). The polypeptide has a repetitive backbone (purple) to which the amino acid side chains are attached.

Cambridge University in England, worked on the hormone insulin in the late 1940s and early 1950s. His approach was to use protein-digesting enzymes and other catalysts that break polypeptides at specific places rather than completely hydrolyzing the chains to amino acids. Treatment with one of these agents cleaves a polypeptide into fragments (each consisting of multiple amino acid subunits) that can be separated by a technique called chromatography. Hydrolysis with a different agent breaks the polypeptide at different sites, yielding a second group of fragments. Sanger used chemical methods to determine the sequence of amino acids in these small fragments. Then he searched for overlapping regions among the pieces obtained by hydrolyzing with the different agents. Consider, for instance, two fragments with the following sequences:

Cys-Ser-Leu-Tyr-Gln-Leu
Iys-Gln-Leu-Glu-Asn

We can deduce from the overlapping regions that the intact polypeptide contains in its primary structure the following segment:

Cys-Ser-Leu-Iys-Gln-Leu-Glu-Asn

Just as we could reconstruct this sentence from a collection of fragments with overlapping sequences of letters, Sanger and his co-workers were able, after years of effort, to reconstruct the complete primary structure of insulin. Since then, most of the steps involved in sequencing a polypeptide have been automated.

Protein Conformation and Function

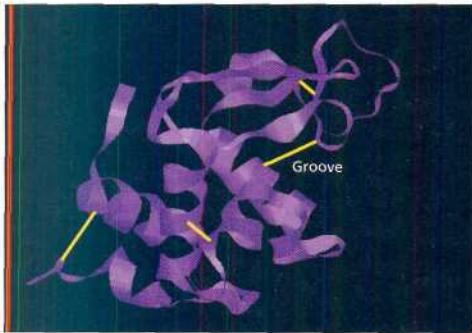

Once we have learned the amino acid sequence of a polypeptide, what can it tell us about protein conformation and function? The term *polypeptide* is not quite synonymous with the term *protein*. Even for a protein consisting of a single polypeptide, the relationship is somewhat analogous to that between a long strand of yarn and a sweater of particular size and shape that one can knit from the yarn. A functional protein is not *just* a polypeptide chain, but one or more polypeptides precisely twisted, folded, and coiled into a molecule of unique shape (**Figure 5.19**). It is the amino acid sequence of a polypeptide that determines what three-dimensional conformation the protein will take.

When a cell synthesizes a polypeptide, the chain generally folds spontaneously, assuming the functional conformation for that protein. This folding is driven and reinforced by the formation of a variety of bonds between parts of the chain, which in turn depends on the sequence of amino acids. Many proteins are globular (roughly spherical), while others are fibrous in shape. Even within these broad categories, countless variations are possible.

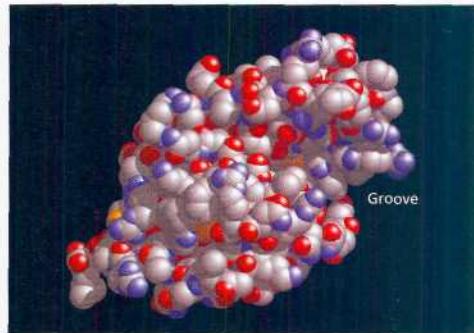

A protein's specific conformation determines how it works. In almost every case, the function of a protein depends on its ability to recognize and bind to some other molecule. For instance, an antibody (a protein) binds to a particular foreign substance that has invaded the body, and an enzyme (another type of protein) recognizes and binds to its substrate, the substance the enzyme works on. In Chapter 2, you learned that natural signal molecules called endorphins bind to specific receptor proteins on the surface of brain cells in humans, producing euphoria and relieving pain. Morphine, heroin, and other opiate drugs are able to mimic endorphins because they all share a similar shape with endorphins and can thus fit into and bind to endorphin receptors in the brain. This fit is very specific, something like a lock and key (see Figure 2.17). Thus, the function of a protein—for instance, the ability of a receptor protein to identify and associate with a particular pain-relieving signal molecule—is an emergent property resulting from exquisite molecular order.

Four Levels of Protein Structure

In the complex architecture of a protein, we can recognize three superimposed levels of structure, known as primary, secondary, and tertiary structure. A fourth level, quaternary structure, arises when a protein consists of two or more polypeptide chains. **Figure 5.20**, on the following two pages, describes these four levels of protein structure. Be sure to study this figure thoroughly before going on to the next section.

(a) A ribbon model shows how the single polypeptide chain folds and coils to form the functional protein. (The yellow lines represent one type of chemical bond that stabilizes the protein's shape.)

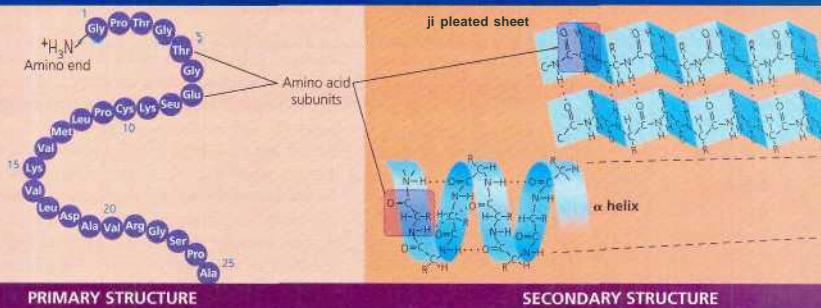

(b) A space-filling model shows more clearly the globular shape seen in many proteins, as well as the specific conformation unique to lysozyme.

4 Figure 5.19 Conformation of a protein, the enzyme lysozyme. Present in our sweat, tears, and saliva, lysozyme is an enzyme that helps prevent infection by binding to and destroying specific molecules on the surface of many kinds of bacteria. The groove is the part of the protein that recognizes and binds to the target molecules on bacterial walls.

Figure 5.20

Exploring Levels of Protein Structure

The **primary structure** of a protein is its unique sequence of amino acids. As an example, let's consider transthyretin, a globular protein found in the blood that transports vitamin A and a particular thyroid hormone throughout the body. Each of the four identical polypeptide chains that, together, make up transthyretin is composed of 127 amino acids. Shown here is one of these chains unraveled for a closer look at its primary structure. A specific¹ one of the 20 amino acids, indicated here by its three-letter abbreviation, occupies each of the 127 positions along the chain. The primary structure is like the order of letters in a very long word. If left to chance, there would be 20^{127} different ways of making a polypeptide chain 127 amino acids long. However, the precise primary structure of a protein is determined not by the random linking of amino acids, but by inherited genetic information.

Most proteins have segments of their polypeptide chains repeatedly coiled or folded in patterns that contribute to the protein's overall conformation. These coils and folds, collectively referred to as **secondary structure**, are the result of hydrogen bonds between the repeating constituents of the polypeptide backbone (not the amino acid side chains). Both the oxygen and the nitrogen atoms of the backbone are electronegative, with partial negative charges (see Figure 2.15). The weakly positive hydrogen atom attached to the nitrogen atom has an affinity for the oxygen atom of a nearby peptide bond. Individually, these hydrogen bonds are weak, but because they are repeated many times over a relatively long region of the polypeptide chain, they can support a particular shape for that part of the protein.

One such secondary structure is the α **helix**, a delicate coil held together by hydrogen bonding between every fourth amino acid, shown above for transthyretin. Although transthyretin has only one α helix region (see tertiary structure), other globular proteins have multiple stretches of a helix separated by nonhelical regions. Some fibrous proteins, such as α -keratin, the structural protein of hair, have the α helix formation over most of their length.

The other main type of secondary structure is the (3) **pleated sheet**. As shown above, in this structure two or more regions of the polypeptide chain lying side by side are connected by hydrogen bonds between parts of the two parallel polypeptide backbones. Pleated sheets make up the core of many globular proteins, as is the case for transthyretin, and dominate some fibrous proteins, including the silk protein of a spider's web. The teamwork of so many hydrogen bonds makes each spider silk fiber stronger than a steel strand of the same weight.

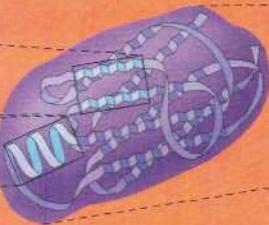

Abdominal glands of the spider secrete silk fibers that form the web.

The radiating strands, made of dry silk fibers, maintain the shape of the web.

The spiral strands (capture strands) are elastic, stretching in response to wind, rain, and the touch of insects.

Spider silk: a structural protein containing β pleated sheets

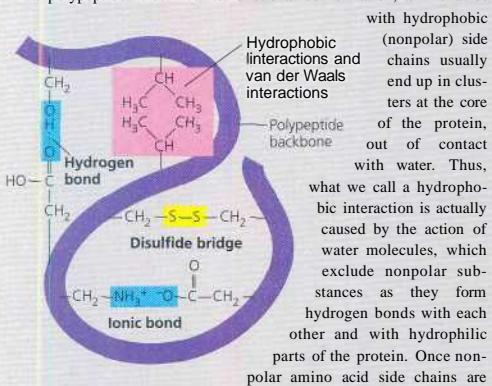

TERTIARY STRUCTURE

QUATERNARY STRUCTURE

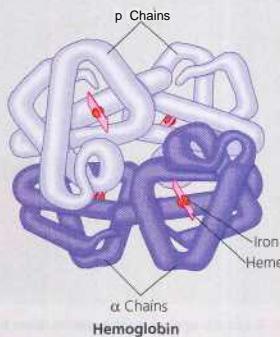

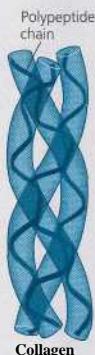

Superimposed on the patterns of secondary structure is a protein's tertiary structure, shown above for the transthyretin polypeptide. Rather than involving interactions between backbone constituents, tertiary structure is the overall shape of a polypeptide resulting from interactions between the side chains (R groups) of the various amino acids. One type of interaction that contributes to tertiary structure is—somewhat misleadingly—called a hydrophobic interaction. As a polypeptide folds into its functional conformation, amino acids

close together, van der Waals interactions help hold them together. Meanwhile, hydrogen bonds between polar side chains and ionic bonds between positively and negatively charged side chains also help stabilize tertiary structure. These are all weak interactions, but their cumulative effect helps give the protein a unique shape.

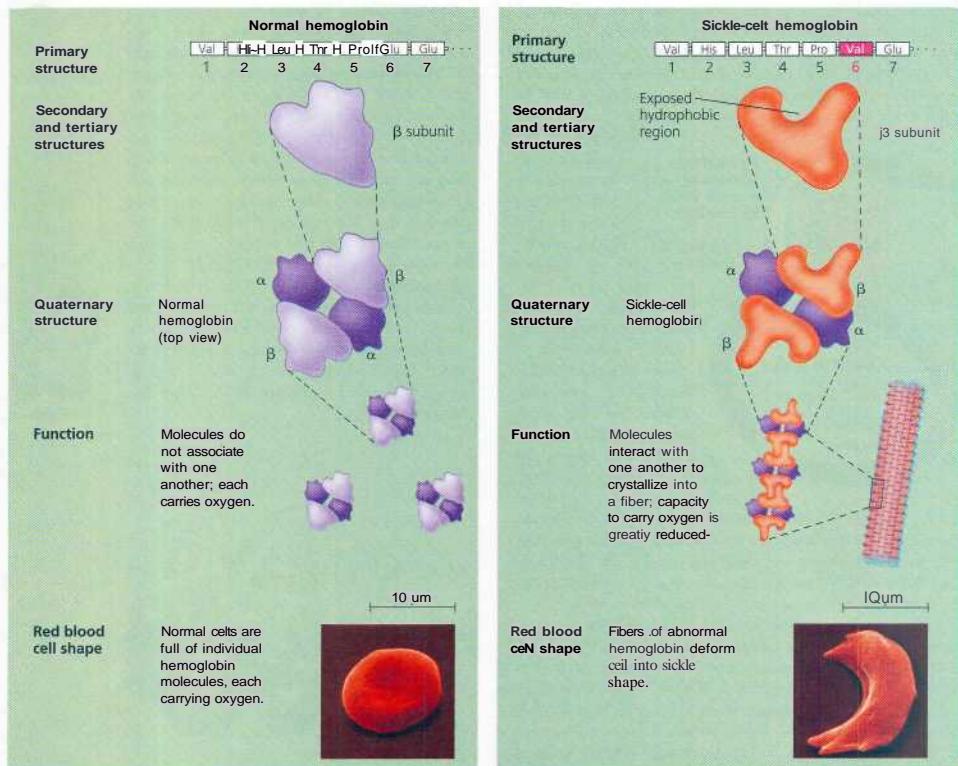

The conformation of a protein may be reinforced further by covalent bonds called disulfide bridges. Disulfide bridges form where two cysteine monomers, amino acids with sulphydryl groups ($-SH$) on their side chains, are brought close together by the folding of the protein. The sulfur of one cysteine bonds to the sulfur of the second, and the disulfide bridge (---S---S---) rivets parts of the protein together (see yellow lines in Figure 5.19a). All of these different kinds of bonds can occur in one protein, as shown above in a small part of a hypothetical protein.

Some proteins consist of two or more polypeptide chains aggregated into one functional macromolecule. Quaternary structure is the overall protein structure that results from the aggregation of these polypeptide subunits. For example, shown above is the complete, globular transthyretin protein, made up of its four polypeptides. Another example is collagen, shown on the right, which is a fibrous protein that has helical subunits intertwined into a larger triple helix, giving the long fibers great strength. This suits collagen fibers to their function as the girders of connective tissue in skin, bone, tendons, ligaments, and other body parts (collagen accounts for 40% of the protein in a human body). Hemoglobin, the oxygen-binding protein of red blood cells shown below, is another example of a globular protein with quaternary structure. It consists of four polypeptide subunits, two of one kind (α chains) and two of another kind (β chains). Both α and β subunits consist primarily of α -helical secondary structure. Each subunit has a nonpolypeptide component, called heme, with an iron atom that binds oxygen.

Sickle-Cell Disease: A Simple Change in Primary Structure

Even a slight change in primary structure can affect a protein's conformation and ability to function. For instance, the substitution of one amino acid (valine) for the normal one (glutamic acid) at a particular position in the primary structure of hemoglobin, the protein that carries oxygen in red blood cells, can cause *sickle-cell disease*, an inherited blood disorder. Normal red blood cells are disk-shaped, but in sickle-cell disease, the abnormal hemoglobin molecules tend to crystallize, deforming some of the cells into a sickle shape (Figure 5.21). The life of someone with the disease is punctuated by 'sickle-cell crises,' which occur when the angular cells clog tiny blood vessels, impeding blood flow. The toll taken on such patients is a dramatic example of how a simple change in protein structure can have devastating effects on protein function.

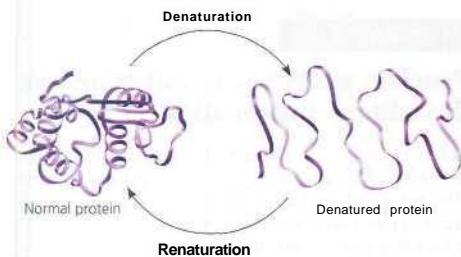

A Figure 5.21 A single amino acid substitution in a protein causes sickle-cell disease.

To show fiber formation clearly, the orientation of the hemoglobin molecule here is different from that in Figure 5.20.

What Determines Protein Conformation?

You've learned that a unique shape endows each protein with a specific function. But what are the key factors determining protein conformation? You already know most of the answer: A polypeptide chain of a given amino acid sequence can spontaneously arrange itself into a three-dimensional shape determined and maintained by the interactions responsible for secondary and tertiary structure. This folding normally occurs as the protein is being synthesized within the cell. However, protein conformation also depends on the physical and chemical conditions of the protein's environment. If the pH, salt concentration, temperature, or other aspects of its environment are altered, the protein may unravel and lose its native conformation, a change called denaturation (Figure S.22). Because it is misshapen, the denatured protein is biologically inactive.

A. Figure 5.22 Denaturation and renaturation of a protein.

High temperatures or various chemical treatments will denature a protein, causing it to lose its conformation and hence its ability to function. If the denatured protein remains dissolved, it can often renature when the chemical and physical aspects of its environment are restored to normal.

Most proteins become denatured if they are transferred from an aqueous environment to an organic solvent, such as ether or chloroform; the polypeptide chain refolds so that its hydrophobic regions face outward toward the solvent. Other denaturation agents include chemicals that disrupt the hydrogen bonds, ionic bonds, and disulfide bridges that maintain a protein's shape. Denaturation can also result from excessive heat, which agitates the polypeptide chain enough to overpower the weak interactions that stabilize conformation. The white of an egg becomes opaque during cooking because the denatured proteins are insoluble and solidify. This also explains why extremely high fevers can be fatal: Proteins in the blood become denatured by such high body temperatures.

When a protein in a test-tube solution has been denatured by heat or chemicals, it will often return to its functional shape when the denaturing agent is removed. We can conclude that the information for building specific shape is intrinsic to the protein's primary structure. The sequence of amino acids determines conformation—where an α helix can

form, where β pleated sheets can occur, where disulfide bridges are located, where ionic bonds can form, and so on. However, in the crowded environment inside a cell, correct folding may be more of a problem than it is in a test tube.

The Protein-Folding Problem

Biochemists now know the amino acid sequences of more than 875,000 proteins and the three-dimensional shapes of about 7,000. One would think that by correlating the primary structures of many proteins with their conformations, it would be relatively easy to discover the rules of protein folding. Unfortunately, the protein-folding problem is not that simple. Most proteins probably go through several intermediate states on their way to a stable conformation, and looking at the mature conformation does not reveal the stages of folding required to achieve that form. However, biochemists have developed methods for tracking a protein through its intermediate stages of folding. Researchers have also discovered chaperonins (also called chaperone proteins), protein molecules that assist the proper folding of other proteins (Figure 5.23). Chaperonins do not actually specify the correct final structure of a polypeptide. Instead, they work by keeping the new polypeptide segregated from "bad influences" in the cytoplasmic environment while it folds spontaneously. The well-studied chaperonin shown in Figure 5.23, from the bacterium *E. coli*, is a giant multiprotein complex shaped like a hollow cylinder. The cavity provides shelter for folding polypeptides of various types.

Even when scientists have an actual protein in hand, determining its exact three-dimensional structure is not simple, for a single protein molecule is built of thousands of atoms. X-ray crystallography is an important method used to determine a protein's three-dimensional structure (Figure 5.24). Another method that has recently been applied to this problem is nuclear magnetic resonance (NMR) spectroscopy, which does not require protein crystallization. These approaches have contributed greatly to our understanding of protein structure and have also given us valuable hints about protein function.

► Figure 5.23 A chaperonin in action. The computer graphic (left) shows a large chaperonin protein complex with an interior space that provides a shelter for the proper folding of newly made polypeptides. The complex consists of two proteins: One protein is a hollow cylinder; the other is a cap that can fit on either end.

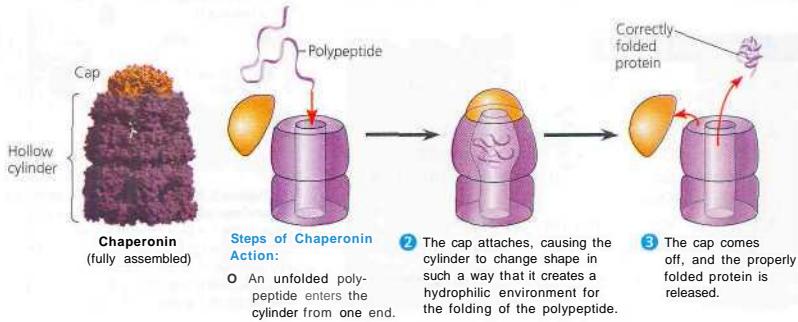

Figure 5.24

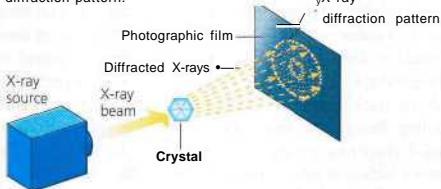

Research Method X-Ray Crystallography

APPLICATION

Scientists use X-ray crystallography to determine the three-dimensional structure of macromolecules such as nucleic acids and proteins. In this figure we will examine how researchers at the University of California, Riverside, determined the structure of the protein ribonuclease, an enzyme whose function involves binding to a nucleic acid molecule.

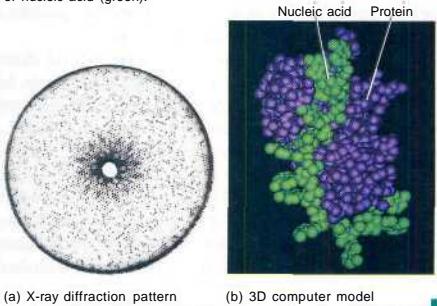

TECHNIQUE

Researchers aim an X-ray beam through the crystallized protein. The atoms of the crystal deflect (reflect) the X-rays into an orderly array. The diffracted X-rays expose photographic film, producing a pattern of spots known as an X-ray diffraction pattern.

RESULTS

Using data from X-ray diffraction patterns, as well as the amino acid sequence determined by chemical methods, scientists build a 3D computer model of the protein, such as this model of the protein ribonuclease (purple) bound to a short strand of nucleic acid (green).

Concept Check 5.4

- Why does a denatured protein no longer function normally?
- Differentiate between secondary and tertiary structure by describing the parts of the polypeptide chain that participate in the bonds that hold together each level of structure.
- A genetic mutation can change a protein's primary structure. How can this destroy the protein's function?

For suggested answers, see Appendix A.

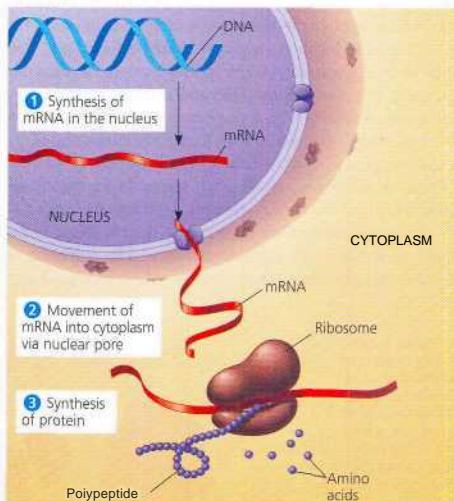

Concept 5.5

Nucleic acids store and transmit hereditary information

If the primary structure of polypeptides determines the conformation of a protein, what determines primary structure? The amino acid sequence of a polypeptide is programmed by a unit of inheritance known as a gene. Genes consist of DNA, which is a polymer belonging to the class of compounds known as nucleic acids.

The Roles of Nucleic Acids

There are two types of nucleic acids: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). These are the molecules that enable living organisms to reproduce their complex components from one generation to the next. Unique among molecules, DNA provides directions for its own replication. DNA also directs RNA synthesis and, through RNA, controls protein synthesis (Figure 5.25).

A Figure 5.25 DNA -> RNA -> protein: a diagrammatic overview of information flow in a cell. In a eukaryotic cell, DNA in the nucleus programs protein production in the cytoplasm by dictating the synthesis of messenger RNA (mRNA), which travels to the cytoplasm and binds to ribosomes. As a ribosome (greatly enlarged in this drawing) moves along the mRNA, the genetic message is translated into a polypeptide of specific amino acid sequence.

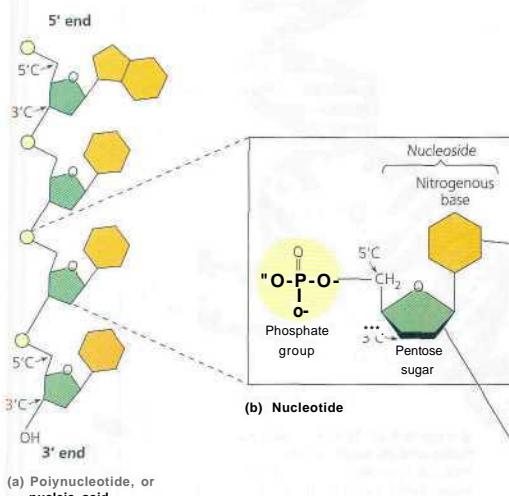

DNA is the genetic material that organisms inherit from their parents. Each chromosome contains one long DNA molecule, usually consisting of from several hundred to more than a thousand genes. When a cell reproduces itself by dividing, its DNA molecules are copied and passed along from one generation of cells to the next. Encoded in the structure of DNA is the information that programs all the cell's activities. The DNA, however, is not directly involved in running the operations of the cell, any more than computer software by itself can print a bank statement or read the bar code on a box of cereal. Just as a printer is needed to print out a statement and a scanner is needed to read a bar code, proteins are required to implement genetic programs. The molecular hardware of the cell—the tools for most biological functions—consists of proteins. For example, the oxygen carrier in the blood is the protein hemoglobin, not the DNA that specifies its structure.

How does RNA, the other type of nucleic acid, fit into the flow of genetic information from DNA to proteins? Each gene along the length of a DNA molecule directs the synthesis of a type of RNA called *messenger RNA* (mRNA). The mRNA molecule then interacts with the cell's protein-synthesizing

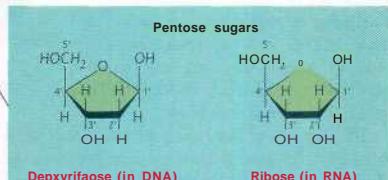

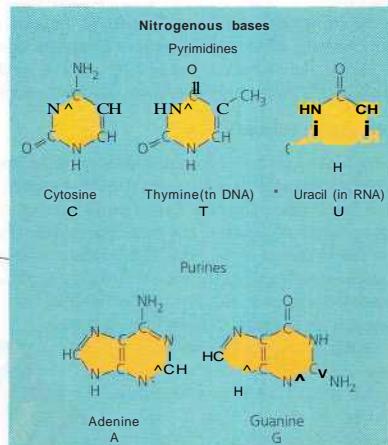

machinery to direct the production of a polypeptide. We can summarize the flow of genetic information as DNA \rightsquigarrow RNA \rightsquigarrow protein (see Figure 5.25). The actual sites of protein synthesis are cellular structures called ribosomes. In a eukaryotic cell, ribosomes are located in the cytoplasm, but DNA resides in the nucleus. Messenger RNA conveys the genetic instructions for building proteins from the nucleus to the cytoplasm. Prokaryotic cells lack nuclei, but they still use RNA to send a message from the DNA to the ribosomes and other equipment of the cell that translate the coded information into amino acid sequences.

The Structure of Nucleic Acids

Nucleic acids are macromolecules that exist as polymers called **polynucleotides** (Figure 5.26a). As indicated by the name, each polynucleotide consists of monomers called **nucleotides**. A nucleotide is itself composed of three parts: a nitrogenous base, a pentose (five-carbon sugar), and a phosphate group (Figure 5.26b). The portion of this unit without the phosphate group is called a **nucleoside**.

A Figure 5.26 The components of nucleic acids. (a) A polynucleotide has a regular sugar-phosphate backbone with variable appendages, the four kinds of nitrogenous bases. RNA usually exists in the form of a single polynucleotide, like the one shown here. (b) A nucleotide monomer is made up of three components: a nitrogenous base, a sugar, and a phosphate group, linked together as shown here. Without the phosphate group, the resulting structure is called a nucleoside. (c) The components of the nucleoside include a nitrogenous base (either a purine or a pyrimidine) and a pentose sugar (either deoxyribose or ribose).

(c) Nucleoside components

Nucleotide Monomers

To build a nucleotide, let's first consider the two components of the nucleoside: the nitrogenous base and the sugar (Figure 5.26c). There are two families of nitrogenous bases: pyrimidines and purines. A pyrimidine has a six-membered ring of carbon and nitrogen atoms. (The nitrogen atoms tend to take up H⁺ from solution, which explains the term *nitrogenous base*.) The members of the pyrimidine family are cytosine (C), thymine (T), and uracil (U). Purines are larger, with a six-membered ring fused to a five-membered ring. The purines are adenine (A) and guanine (G). The specific pyrimidines and purines differ in the functional groups attached to the rings. Adenine, guanine, and cytosine are found in both types of nucleic acid; thymine is found only in DNA and uracil only in RNA.

The pentose connected to the nitrogenous base is ribose in the nucleotides of RNA and deoxyribose in DNA (see Figure 5.26c). The only difference between these two sugars is that deoxyribose lacks an oxygen atom on the second carbon in the ring; hence its name. Because the atoms in both the nitrogenous base and the sugar are numbered, the sugar atoms have a prime (') after the number to distinguish them. Thus, the second carbon in the sugar ring is the 2' ("2 prime") carbon, and the carbon that sticks up from the ring is called the 5' carbon.

So far, we have built a nucleoside. To complete the construction of a nucleotide, we attach a phosphate group to the 5' carbon of the sugar (see Figure 5.26b). The molecule is now a nucleoside monophosphate, better known as a nucleotide.

Nucleotide Polymers

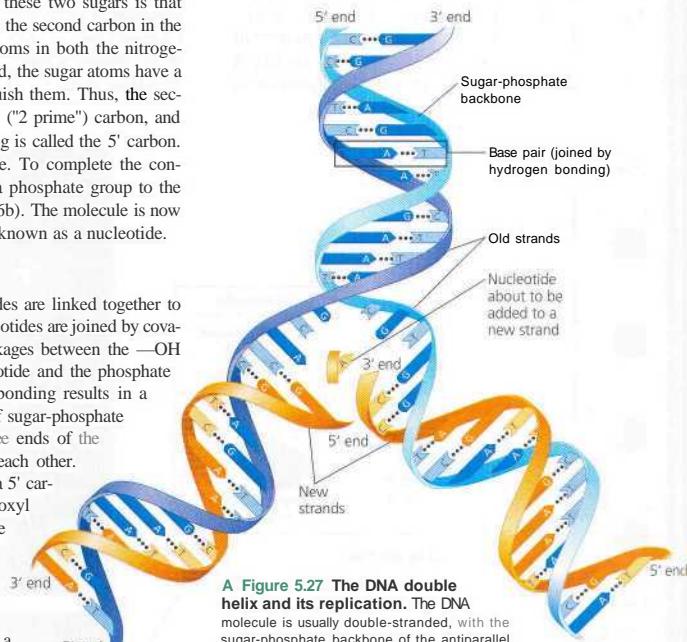

Now we can see how these nucleotides are linked together to build a polynucleotide. Adjacent nucleotides are joined by covalent bonds called phosphodiester linkages between the —OH group on the 3' carbon of one nucleotide and the phosphate on the 5' carbon of the next. This bonding results in a backbone with a repeating pattern of sugar-phosphate units (see Figure 5.26a). The two free ends of the polymer are distinctly different from each other. One end has a phosphate attached to a 5' carbon, and the other end has a hydroxyl group on a 3' carbon; we refer to these as the 5' end and the 3' end, respectively. So we can say that the DNA strand has a built-in directionality along its sugar-phosphate backbone, from 5' to 3', somewhat like a one-way street. All along this sugar-phosphate backbone are appendages consisting of the nitrogenous bases.

The sequence of bases along a DNA (or mRNA) polymer is unique for each gene. Because genes are hundreds to thousands of nucleotides long, the number of possible base sequences is effectively limitless. A gene's meaning to the cell is encoded in its specific sequence of the four DNA bases. For example, the

sequence AGGTAACTT means one thing, whereas the sequence CGCTTTAAC has a different meaning. (Real genes, of course, are much longer.) The linear order of bases in a gene specifies the amino acid sequence—the primary structure—of a protein, which in turn specifies that protein's three-dimensional conformation and function in the cell.

The DNA Double Helix

The RNA molecules of cells consist of a single polynucleotide chain like the one shown in Figure 5.26. In contrast, cellular DNA molecules have two polynucleotides that spiral around an imaginary axis, forming a double helix (Figure 5.27). James Watson and Francis Crick, working at Cambridge University,

A Figure 5.27 The DNA double helix and its replication. The DNA molecule is usually double-stranded, with the sugar-phosphate backbone of the antiparallel polynucleotide strands (symbolized here by blue ribbons) on the outside of the helix. Holding the two strands together are pairs of nitrogenous bases attached to each other by hydrogen bonds. As illustrated here with symbolic shapes for the bases, adenine (A) can pair only with thymine (T), and guanine (G) can pair only with cytosine (C). When a cell prepares to divide, the two strands of the double helix separate, and each serves as a template for the precise ordering of nucleotides into new complementary strands (orange). Each DNA strand in this figure is the structural equivalent of the polynucleotide diagrammed in Figure 5.26a.

first proposed the double helix as the three-dimensional structure of DNA in 1953. The two sugar-phosphate backbones run in opposite 5' → 3' directions from each other, an arrangement referred to as **antiparallel**, somewhat like a divided highway. The sugar-phosphate backbones are on the outside of the helix, and the nitrogenous bases are paired in the interior of the helix. The two polynucleotides, or strands, as they are called, are held together by hydrogen bonds between the paired bases and by van der Waals interactions between the stacked bases. Most DNA molecules are very long, with thousands or even millions of base pairs connecting the two chains. One long DNA double helix includes many genes, each one a particular segment of the molecule.

Only certain bases in the double helix are compatible with each other. Adenine (A) always pairs with thymine (T), and guanine (G) always pairs with cytosine (C). If we were to read the sequence of bases along one strand as we traveled the length of the double helix, we would know the sequence of bases along the other strand. If a stretch of one strand has the base sequence 5'-AGGTCCG-3', then the base-pairing rules tell us that the same stretch of the other strand must have the sequence 3'-TCCAGGC-5'. The two strands of the double helix are *complementary*, each the predictable counterpart of the other. It is this feature of DNA that makes possible the precise copying of genes that is responsible for inheritance (see Figure 5.27). In preparation for cell division, each of the two strands of a DNA molecule serves as a template to order nucleotides into a new complementary strand. The result is two identical copies of the original double-stranded DNA molecule, which are then distributed to the two daughter cells. Thus, the structure of DNA accounts for its function in transmitting genetic information whenever a cell reproduces.

DNA and Proteins as Tape Measures of Evolution

We are accustomed to thinking of shared traits, such as hair and milk production in mammals, as evidence of shared ancestors. Because we now understand that DNA carries heritable information in the form of genes, we can see that genes and their products (proteins) document the hereditary background of an organism. The linear sequences of nucleotides in DNA molecules are passed from parents to offspring; these sequences determine the amino acid sequences of proteins. Siblings have greater similarity in their DNA and proteins than do unrelated individuals of the same species. If the evolutionary view of life is valid, we should be able to extend this concept of "molecular genealogy" to relationships *between* species: We should expect two species that appear to be closely related based on fossil and anatomical evidence to also share a greater proportion of their DNA and protein sequences than do more distantly related species. In fact, that is the case. For example, if we compare a polypeptide chain of human hemoglobin with the corresponding hemoglobin polypeptide in five other vertebrates, we find

the following. In this chain of 146 amino acids, humans and gorillas differ in just 1 amino acid, humans and gibbons differ in 2 amino acids, and humans and rhesus monkeys differ in 8 amino acids. More distantly related species have chains that are less similar. Humans and mice differ in 27 amino acids, and humans and frogs differ in 67 amino acids. Molecular biology has added a new tape measure to the toolkit biologists use to assess evolutionary kinship.

Concept Check 5.5

1. Go to Figure 5.26a and number all the carbons in the sugars for the top three nucleotides; circle the nitrogenous bases and star the phosphates.
2. In a DNA double helix, a region along one DNA strand has this sequence of nitrogenous bases: 5'-TAGGCCT-3'. List the base sequence along the other strand of the molecule, clearly indicating the 5' and 3' ends of this strand.

For suggested answers, see Appendix A.

The Theme of Emergent Properties in the Chemistry of Life: A Review

Recall that life is organized along a hierarchy of structural levels (see Figure 1.3). With each increasing level of order, new properties emerge in addition to those of the component parts. In Chapters 2–5, we have dissected the chemistry of life using the strategy of the reductionist. But we have also begun to develop a more integrated view of life as we have seen how properties emerge with increasing order.

We have seen that the unusual behavior of water, so essential to life on Earth, results from interactions of the water molecules, themselves an ordered arrangement of hydrogen and oxygen atoms. We reduced the great complexity and diversity of organic compounds to the chemical characteristics of carbon, but we also saw that the unique properties of organic compounds are related to the specific structural arrangements of carbon skeletons and their appended functional groups. We learned that small organic molecules are often assembled into giant molecules, but we also discovered that a macromolecule does not behave like a composite of its monomers but rather takes on additional properties owing to the interactions between those monomers.

By completing our overview of the molecular basis of life with an introduction to the important classes of macromolecules that build living cells, we have built a bridge to Unit Two, where we will study the cells structure and function. We will maintain our balance between the need to reduce life to a conglomerate of simpler processes and the ultimate satisfaction of viewing those processes in their integrated context.

Chapter 5 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 5.1

Most macromolecules are polymers, built from monomers

- **The Synthesis and Breakdown of Polymers** (pp. 68–69)

Carbohydrates, lipids, proteins, and nucleic acids are the four major classes of organic compounds in cells. Many of these compounds are very large molecules. Most macromolecules are polymers, chains of identical or similar monomers. Monomers form larger molecules by condensation reactions, in which water molecules are released (dehydration). Polymers can disassemble by the reverse process, hydrolysis.

Activity Making and Breaking Polymers

- **The Diversity of Polymers** (p. 69) Each class of polymer is formed from a specific set of monomers. Although organisms share the same limited number of monomer types, each organism is unique because of the specific arrangement of monomers into polymers. An immense variety of polymers can be built from a small set of monomers.

Concept 5.2

Carbohydrates serve as fuel and building material

- **Sugars** (pp. 70–71) Sugars, the smallest carbohydrates, serve as fuel and carbon sources. Monosaccharides are the simplest sugars. They are used for fuel, converted to other organic molecules, or combined into polymers. Disaccharides consist of two monosaccharides connected by a glycosidic linkage.

Activity Models of Glucose

- **Polysaccharides** (pp. 71–74) Polysaccharides, polymers of sugars, have storage and structural roles. The monomers of polysaccharides are connected by glycosidic linkages. Starch in plants and glycogen in animals are both storage polymers of glucose. Cellulose is an important structural polymer of glucose in plant cell walls. Starch, glycogen, and cellulose differ in the positions and orientations of their glycosidic linkages.

Activity Carbohydrates

Concept 5.3

Lipids are a diverse group of hydrophobic molecules

- **Fats** (pp. 75–76) FAs store large amounts of energy. Also known as triacylglycerols, fats are constructed by the joining of a glycerol molecule to three fatty acids by dehydration reactions. Saturated fatty acids have the maximum number of hydrogen atoms. Unsaturated fatty acids (present in oils) have one or more double bonds in their hydrocarbon chains.

- **Phospholipids** (pp. 76–77) Phospholipids, which are major components of cell membranes, consist of two fatty acids and a phosphate group linked to glycerol. Thus, the "head" of a phospholipid is hydrophilic and the "tail" hydrophobic.

- **Steroids** (p. 77) Steroids include cholesterol and certain hormones. Steroids have a basic structure of four fused rings of carbon atoms.

Activity Lipids

Concept 5.4

Proteins have many structures, resulting in a wide range of functions

- **Polypeptides** (pp. 78–81) A polypeptide is a polymer of amino acids connected in a specific sequence. A protein consists of one or more polypeptide chains folded into a specific three-dimensional conformation. Polypeptides are constructed from 20 different amino acids, each with a characteristic side chain (R group). The carboxyl and amino groups of adjacent amino acids link together in peptide bonds.

- **Protein Conformation and Function** (pp. 81–86) The primary structure of a protein is its unique sequence of amino acids. Secondary structure is the folding or coiling of the polypeptide into repeating configurations, mainly the *α* helix and the *β* pleated sheet, which result from hydrogen bonding between parts of the polypeptide backbone. Tertiary structure is the overall three-dimensional shape of a polypeptide and results from interactions between amino acid R groups. Proteins made of more than one polypeptide chain have a quaternary level of structure. Protein shape is ultimately determined by its primary structure, but the structure and function of a protein are sensitive to physical and chemical conditions.

Activity Protein Functions

Activity Protein Structure

Biology Labs On-Line [Hemoglobin Lab](#)

Concept 5.5

Nucleic acids store and transmit hereditary information

- **The Roles of Nucleic Acids** (pp. 86–87) DNA stores information for the synthesis of specific proteins. RNA (specifically, mRNA) carries this genetic information to the protein-synthesizing machinery.

- **The Structure of Nucleic Acids** (pp. 87–88) Each nucleotide monomer consists of a pentose covalently bonded to a phosphate group and to one of four different nitrogenous bases (A, G, C, and T or U). RNA has ribose as its pentose; DNA has deoxyribose. RNA has U; DNA, T. In a polynucleotide, nucleotides are joined to form a sugar-phosphate backbone from which the nitrogenous bases project. Each polynucleotide strand has polarity, with a 5' end and a 3' end. The sequence of bases along a gene specifies the amino acid sequence of a particular protein.

- **The DNA Double Helix** (pp. 88–89) DNA is a helical, double-stranded macromolecule with bases projecting into the interior of the molecule from the two antiparallel polynucleotide strands. Because A always hydrogen-bonds to T, and C to G, the nucleotide sequences of the two strands are complementary. One strand can serve as a template for the formation of the other. This unique feature of DNA provides a mechanism for the continuity of life.

- **DNA and Proteins as Tape Measures of Evolution** (p. 89) Molecular comparisons help biologists sort out the evolutionary connections among species.

Activity Nucleic Acid Functions

Activity Nucleic Acid Structure

- **The Theme of Emergent Properties in the Chemistry of Life: A Review** (p. 89) Higher levels of organization result in the emergence of new properties. Organization is the key to the chemistry of life.

TESTING YOUR KNOWLEDGE

Evolution Connection

Comparisons of the amino acid sequences of proteins or the nucleotide sequences of genes can shed light on the evolutionary divergence of related organisms. Would you expect all the proteins *or* genes of a given set of organisms living on Earth today to show the same degree of divergence? Why or why not?

Scientific Inquiry

During the Napoleonic Wars in the early 1800s, there was a sugar shortage in Europe because supply ships were blockaded from harbors. To create artificial sweeteners, German scientists hydrolyzed wheat starch. They did this by adding hydrochloric acid to heated starch solutions, which caused some of the glycosidic linkages between the glucose monomers to break. The process broke only about 50% of the glycosidic linkages, however, so the sweetener

was less sweet than sugar. In addition, consumers complained of a slight bitterness resulting from by-products of the reaction. Sketch a glycosidic linkage in starch using Figures 5.5a and 5.7b for reference. Show how the acid was able to break this bond. Why do you think the acid broke only 50% of the linkages in the wheat starch?

Biological inquiry: A Workbook of investigative Cases *Explore macromolecules further with the case "Picture Perfect."* BioSogy labs On-Line *HemoglobinLab*

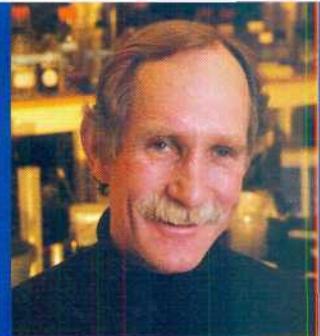

Science, Technology, and Society

Some amateur and professional athletes take anabolic steroids to help them "bulk up" or build strength. The health risks of this practice are extensively documented. Apart from health considerations, how do you feel about the use of chemicals to enhance athletic performance? Do you think an athlete who takes anabolic steroids is cheating, or is the use of such chemicals just part of the preparation required to succeed in a competitive sport? Defend your answer.

UNIT

2

The Cell

AN INTERVIEW WITH **Peter Agre**

In 2003 Peter Agre received the Nobel Prize in Chemistry for the discovery of aquaporins, "water pore" proteins that allow water molecules to rapidly cross the cell membrane. (He shared the prize with Roderick MacKinnon of Rockefeller University, who works on the other main aspect of cellular "plumbing"—the transport of ions.) A medical doctor as well as a researcher in basic science, Dr. Agre is a professor in the Departments of Biological Chemistry and Medicine at the Johns Hopkins University School of Medicine.

How did you start in science?

As a little kid, really. I grew up in Northfield, Minnesota, where my dad was teaching chemistry at St. Olaf College. The kids in our family had an idyllic life, playing in apple orchards and roaming the campus. We lived right across the street from my dad's laboratory, a really nice lab with cheerful students who did summer research. I'd do little experiments with my father's help. We'd change the pH of some solution, and the indicator dye would turn pink or blue—it was amazing! As an adolescent I didn't want anything to do with any of that. But the first merit badge I ever earned as a Boy Scout was in chemistry. Then I became more interested in medicine.

What was the appeal of medicine?

In part, the people. The local doctors were really interesting and nice people, and it seemed like they did a lot of good things.

High school was a bit of a detour—I was kind of a hell raiser then. My friends and I started an underground newspaper (this was 1967, and I thought a revolution was about to occur). I didn't do a lot of school work. So I was invited to leave high school. I went to night school and then got into Augsburg College.

What turned you on to research?

At medical school, I spent time in a research lab, and that really fired me up. I got to work with a group of vibrant scientists from all over the world. I learned you could approach complex problems at a molecular level—reductionist biology. We purified a variant of cholera toxin produced by certain strains of the bacterium *E. coli*. Like the toxin of the true cholera bacterium *Vibrio cholerae*, this can cause a terrible and sometimes fatal diarrhea.

If young people saw scientists the way I did in that lab, they would all want to be scientists. Too many people still stereotype scientists in a negative way—something like Doc from *Bach to the Future*. I'm afraid we've lost good role models in science. And too often we scientists are so stressed out trying to get grants funded that our work doesn't look appealing to students.

People need to realize how much science is a social endeavor. Scientists have personalities and interests and fears and limitations. We're not cyberironic machines. And we collaborate. Unless you're at the level of Leonardo da Vinci, you get a lot of ideas from other people.

Tell us about combining medical practice with basic research.

Until 1993, I was an attending physician in Hematology here. I stopped in part because I was busy with starting a new graduate program in cellular and molecular medicine. (It provides Ph.D. training in basic science but with direct medical relevance.) Combining medical practice with basic research is a challenge because there are only so many hours in the day. I'm married with four children, and, as much as I liked my patients, my heart was more in the research. In practicing medicine, you can help individual patients, but with research, you might make a discovery that would help thousands of patients. As a student, I doubted I had what it took to succeed in basic science, but I wanted to try it.

I still have my medical license, which I use for Boy Scout camp physicals, ringside positions as medical doctor to amateur wrestlers, and inner city kids—I'm their doc. Anyway, my wife's not convinced that research is going to carry me to retirement. She may be right. I think it's better in life not to be overconfident.

Let's talk about the research that led to the discovery of aquaporins. I'm a blood specialist (hematologist), and my particular interest has been proteins found in the plasma membrane of red blood cells. The plasma membrane is a phospholipid bilayer with inserted cholesterol molecules, "integral" proteins that span the bilayer, and membrane-associated proteins that bind to the membrane's inner surface. With red cells, it's easy to study plasma membrane in pure form, and there are interesting disorders associated with defects in the proteins.

When I joined the faculty at Hopkins, I began to study the Rh blood antigens. Blood group antigens are membrane glycoproteins of red cells that exist in the population in two or more forms. The differences can be in the attached carbohydrate, as with the antigens of the ABO blood groups (see Chapter 43), or they can be within the core protein. Rh is of medical importance because of Rh incompatibility, which occurs when Rh negative mothers have Rh positive babies and become sensitized to the Rh antigen. Unless the mother is treated, there's a significant risk that in subsequent pregnancies, her immune system will attack the baby's red blood cells. Surprisingly as of the late 1980s, no one had yet been able to isolate the Rh antigen.

Membrane-spanning proteins like the Rh protein are really messy to work with. But we worked out a method to isolate and partially purify the Rh protein. Our sample seemed to consist of two proteins, but we were sure that

the smaller one was just a breakdown product of the larger one. We were completely wrong, though: U was a water channel protein, which we later named aquaporin-1.

How did you figure that out?

It took a lot of convincing to make myself believe that this protein was even a new discovery. Using antibodies we made to the protein, we showed it to be one of the most abundant proteins in red cell membranes (200,000 copies per cell!) and even more abundant in certain renal (kidney) cells, talked to 15 or so membrane biochemists. What could it be? Although many people study red cells, no one had ever seen this protein before because it doesn't stain with the usual protein stains. It was John Parker, a hematologist and superb red-cell physiologist, who finally said, "Maybe this protein is involved in water transport."

To test this hypothesis, we performed a simple experiment using frog egg cells: We injected the cells with mRNA that the cells translated into aquaporin and found that we could turn the cells from being almost watertight (without aquaporin) into highly water-permeable (with aquaporin). The cells with aquaporin would swell and explode in distilled water as a result of osmosis. With aquaporins, the cell membrane became permeable to water but not to things dissolved in it (solutes), so water molecules crossed the membrane from the side with less solute (distilled water) to the side with more (the cell interior).

You know, as a scientist, you can benefit from being a bit like Huckleberry Finn. You should explore your fancy to some degree. If something interesting shows up, it's good to go for it.

Why do cells have water channel proteins?

Not all cells do. Before our discovery, however, many physiologists thought that diffusion through the phospholipid bilayer was enough for getting water into and out of all cells. Others said this couldn't be enough, especially for cells whose water permeability needs to be very high or regulated—for example, cells forming the tubules of the kidneys, which control the concentration of the urine. A number of researchers had made observations indicating that diffusion through the phospholipid bilayer wasn't everything. But there was a lot of skepticism until our experiment with frog eggs ended the controversy.

Water transport is very important in our bodies. For example, our kidneys must filter and reabsorb many liters of water every day. If we don't reabsorb that water, we die of dehydration. Aquaporins allow us to reabsorb enough water without reabsorbing ions.

How do aquaporins work?

The structure of an aquaporin molecule helps explain how it functions. The protein looks like an hourglass spanning the membrane. The two halves are symmetrical with opposite orientations. An hourglass works equally well if its

right side up or upside down, and aquaporins work equally well for the uptake or release of water. The driving force is not some kind of a pump action, but simply osmosis. An aquaporin allows osmosis to occur extremely rapidly. Nothing larger than water molecules can fit through the channel. In addition, the passage of ions is prevented—even small ones like the hydronium ions (H_3O^{+}) formed by the combining of H^+ with H_2O (see p. 51). They are repelled by positively charged amino acids at the narrowest part of the channel.

What happens when mutations disrupt aquaporin function?

Mutations in aquaporin genes can cause health problems. People whose kidney cells have defective aquaporin-2 molecules need to drink 20 liters of water a day to prevent dehydration. They can't concentrate their urine enough. Individuals who can't make aquaporin-1 generally do OK in modern life, but they get dehydrated much more easily than other people. In addition, some patients make too much aquaporin, causing them to retain too much fluid. Fluid retention in pregnant women is caused by the synthesis of too much aquaporin-2.

Knowledge of aquaporins may in the future contribute to the solution of medical problems. Specific aquaporins, such as those of the malaria parasite, might be useful targets for new drugs.

What has the study of aquaporins revealed about evolution?

Several hundred aquaporins are known so far. Plants have the most; rice has around 50, whereas mammals have only about 10. Apparently, aquaporins are even more important for plants than animals. The presence of aquaporins in almost all organisms and similarities among the molecules suggest that aquaporin arose very early in evolution.

"Science is a social endeavor. Scientists have personalities and interests and fears and limitations. We're not cybertronic machines. And we collaborate. Unless you're at the level of Leonardo da Vinci, you get a lot of ideas from other people."

What are your major goals now?

Of great importance to me right now is the success of the next generation of scientists. As a scientist, there are three things that count: original discoveries, the respect of your peers, and training future scientists—and the third is perhaps the most important in the long run. Almost everything we scientists do eventually gets revised. We usually pick up a story and carry it for a while until someone else takes it over. So the educating of young scientists is a big issue, as is scientific literacy for everyone.

Key Concepts

- 8.1 To study cells, biologists use microscopes and the tools of biochemistry
- 6.2 Eukaryotic cells have internal membranes that compartmentalize their functions
- 6.3 The eukaryotic cell's genetic instructions are housed in the nucleus and carried out by the ribosomes
- 6.4 The endomembrane system regulates protein traffic and performs metabolic functions in the cell
- 6.5 Mitochondria and chloroplasts change energy from one form to another
- 6.6 The cytoskeleton is a network of fibers that organizes structures and activities in the cell
- 6.7 Extracellular components and connections between cells help coordinate cellular activities

Overview

The Importance of Cells

The cell is as fundamental to biology as the atom is to chemistry: All organisms are made of cells. In the hierarchy of biological organization, the cell is the simplest collection of matter that can live. Indeed, there are diverse forms of life existing as single-celled organisms. More complex organisms, including plants and animals, are multicellular; their bodies are cooperatives of many kinds of specialized cells that could not survive for long on their own. However, even when they are arranged into higher levels of organization, such as tissues and organs, cells can be singled out as the organisms basic units of structure and function. The contraction of muscle cells moves your eyes as you read this sentence; when you decide to turn the

next page, nerve cells will transmit that decision from your brain to the muscle cells of your hand. Everything an organism does occurs fundamentally at the cellular level.

The cell is a microcosm that demonstrates most of the themes introduced in Chapter 1. Life at the cellular level arises from structural order, reinforcing the themes of emergent properties and the correlation between structure and function. For example, the movement of an animal cell depends on an intricate interplay of the structures that make up a cellular skeleton (green and red in the micrograph in **Figure 6.1**). Another recurring theme in biology is the interaction of organisms with their environment. Cells sense and respond to environmental fluctuations. And keep in mind the one biological theme that unifies all others: evolution. All cells are related by their descent from earlier cells. However, they have been modified in many different ways during the long evolutionary history of life on Earth.

Although cells can differ substantially from each other, they share certain common characteristics. In this chapter, we'll first learn about the tools and experimental approaches that have allowed us to understand subcellular details; then we'll tour the cell and become acquainted with its components.

Concept 6.1

To study cells, biologists use microscopes and the tools of biochemistry

It can be difficult to understand how a cell, usually too small to be seen by the unaided eye, can be so complex. How can cell biologists possibly investigate the inner workings of such tiny entities? Before we actually tour the cell, it will be helpful to learn how cells are studied.

Bilcrosopy

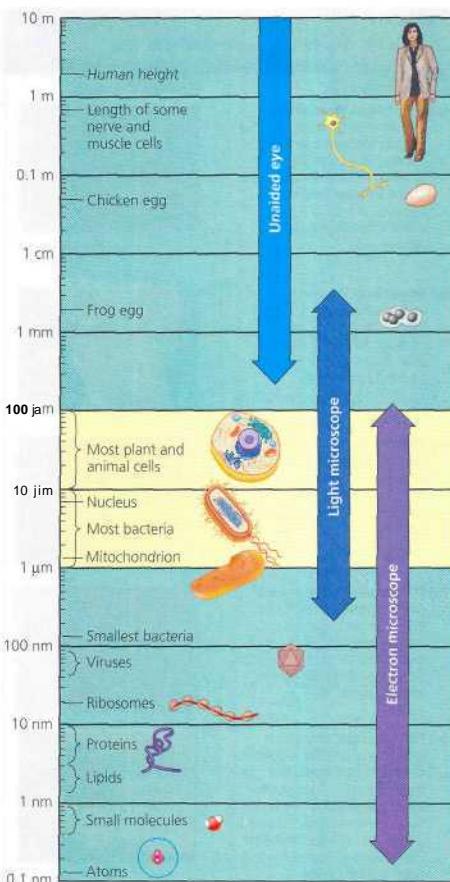

The advance of a scientific field often parallels the invention of instruments that extend human senses to new limits. The discovery and early study of cells progressed with the invention of microscopes in 1590 and their improvement in the 17th century. Microscopes of various types are still indispensable tools for the study of cells.

The microscopes first used by Renaissance scientists, as well as the microscopes you are likely to use in the laboratory, are all **light microscopes (LMs)**. Visible light is passed through the specimen and then through glass lenses. The lenses refract (bend) the light in such a way that the image of the specimen is magnified as it is projected into the eye, onto photograph film, or onto a video screen. (See the diagram of microscope structure in Appendix C.)

Two important parameters in microscopy are magnification and resolving power, or resolution. *Magnification* in microscopy is the ratio of an object's image to its real size. *Resolution* is a measure of the clarity of the image; it is the minimum distance two points can be separated and still be distinguished as two separate points. For example, what appears to the unaided eye as one star in the sky may be resolved as twin stars with a telescope.

Just as the resolving power of the human eye is limited, the resolution of telescopes and microscopes is limited. Microscopes can be designed to magnify objects as much as desired, but the light microscope cannot resolve detail finer than about 0.2 micrometer (μm), or 200 nanometers (nm), the size of a small bacterium (Figure 6.2). This resolution is limited by the shortest wavelength of light used to illuminate the specimen. Light microscopes can magnify effectively to about 1,000 times the size of the actual specimen; at greater magnifications, the image becomes increasingly blurry. Most of the improvements in light microscopy since the beginning of the 20th century have involved new methods for enhancing contrast, which clarifies the details that can be resolved (Figure 6.3, next page). In addition, scientists have developed methods for staining or labeling particular cell components so that they stand out visually.

Although cells were discovered by Robert Hooke in 1665, the geography of the cell was largely uncharted until the 1950s. Most subcellular structures, or **organelles**, are too small to be resolved by the light microscope. Cell biology advanced rapidly in the 1950s with the **introduction** of the electron microscope. Instead of using light, the electron microscope (EM) focuses a beam of electrons through the specimen or onto its surface (see Appendix C). Resolution is inversely related to the wavelength of the radiation a microscope uses for imaging, and electron beams have wavelengths much shorter than the wavelengths of visible light. Modern electron microscopes can theoretically achieve a resolution of about 0.002 nm, but the practical limit for biological structures is generally only about 2 nm—still a hundredfold improvement over the light microscope. Biologists use the term *cell ultrastructure* to refer to a cell's anatomy as revealed by an electron microscope.

Measurements

- 1 centimeter (cm) = 10^{-2} meter (m) = 0.4 inch
- 1 millimeter (mm) = 10^{-3} m
- 1 micrometer (μm) = 10^{-6} mm = 10^{-9} m
- 1 nanometer (nm) = 10^{-9} μm = 10^{-10} m

- **Figure 6.2 The size range of cells.** Most cells are between 1 and 100 μm in diameter (yellow region of chart) and are therefore visible only under a microscope. Notice that the scale along the left side is logarithmic to accommodate the range of sizes shown. Starting at the top of the scale with 10 m and going down, each reference measurement marks a tenfold decrease in diameter or length. For a complete table of the metric system, see Appendix B.

Figure 6.3
Research Method Light Microscopy

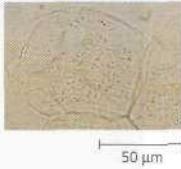

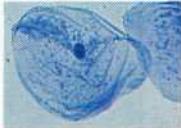

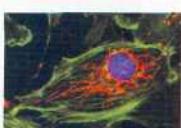

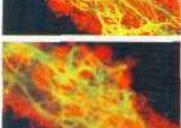

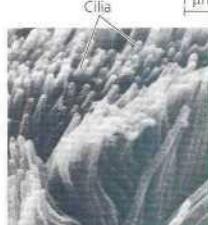

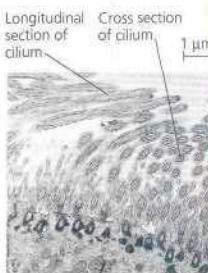

| TECHNIQUE | RESULTS |
|---|---|
| (a) Brightfield (unstained specimen). Passes light directly through specimen. Unless cell is naturally pigmented or artificially stained, image has little contrast. [Parts (a)-(d) show a human cheek epithelial cell.] |  50 µm |
| (b) Brightfield (stained specimen). Staining with various dyes enhances contrast, but most staining procedures require that cells be fixed (preserved). |  |
| (c) Phase-contrast. Enhances contrast in unstained cells by amplifying variations in density within specimen; especially useful for examining living, unpigmented cells. |  |
| (d) Differential-i-interference-contrast (Nomarski). Like phase-contrast microscopy, it uses optical modifications to exaggerate differences in density, making the image appear almost 3D. |  |
| (e) Fluorescence. Shows the locations of specific molecules in the cell by tagging the molecules with fluorescent dyes or antibodies. These fluorescent substances absorb ultraviolet radiation and emit visible light, as shown here in a cell from an artery. |  50 µm |
| (f) Confocal. Uses lasers and special optics for "optical sectioning" of fluorescently-stained specimens. Only a single plane of focus is illuminated; out-of-focus fluorescence above and below the plane is subtracted by a computer. A sharp image results, as seen in stained nervous tissue (top), where nerve cells are green, support cells are red, and regions of overlap are yellow. A standard fluorescence micrograph (bottom) of this relatively thick tissue is blurry. |  50 µm  50 µm |

Figure 6.4
Research Method Electron Microscopy

| TECHNIQUE | RESULTS |
|--|---|
| (a) Scanning electron microscopy (SEM). Micrographs taken with a scanning electron microscope show a 3D image of the surface of a specimen. This SEM shows the surface of a cell from a rabbit trachea (windpipe) covered with motile organelles called cilia. Beating of the cilia helps move inhaled debris upward toward the throat. |  1 µm |
| (b) Transmission electron microscope (TEM). A transmission electron microscope profiles a thin section of a specimen. Here we see a section through a tracheal cell, revealing its ultrastructure. In preparing the TEM, some cilia were cut along their lengths, creating longitudinal sections, while other cilia were cut straight across, creating cross sections. |  Longitudinal section of cilium Cross section of cilium 1 µm |

There are two basic types of electron microscopes: the scanning electron microscope (SEM) and the transmission electron microscope (TEM). The SEM is especially useful for detailed study of the surface of a specimen (**Figure 6.4a**). The electron beam scans the surface of the sample, which is usually coated with a thin film of gold. The beam excites electrons on the sample's surface, and these secondary electrons are detected by a device that translates the pattern of electrons into an electronic signal to a video screen. The result is an image of the topography of the specimen. The SEM has great depth of field, which results in an image that appears three-dimensional.

Cell biologists use the TEM mainly to study the internal ultrastructure of cells (**Figure 6.4b**). The TEM aims an electron beam through a very thin section of the specimen, similar to the way a light microscope transmits light through a slide. The specimen has been stained with atoms of heavy metals, which attach to certain cellular structures, thus enhancing the electron density of some parts of the cell more than others. The electrons passing through the specimen are scattered more in the denser regions, so fewer electrons are transmitted. The image is created by the pattern of transmitted electrons. Instead of using glass lenses, the TEM uses electromagnets as lenses to bend the paths of the electrons, ultimately focusing the image onto a screen for viewing or onto photographic film. Some microscopes are

equipped with a digital camera to photograph the image on the screen; others are equipped with a digital detector in place of both screen and camera.

Electron microscopes reveal many organelles that are impossible to resolve with the light microscope. But the light microscope offers advantages, especially for the study of living cells. A disadvantage of electron microscopy is that the methods used to prepare the specimen kill the cells. Also, specimen preparation can introduce artifacts, structural features seen in micrographs that do not exist in the living cell (as is true for all microscopy techniques). From this point on in the book, micrographs are identified by the type of microscopy: LM for s. light micrograph, SEM for a scanning electron micrograph, and TEM for a transmission electron micrograph.

Microscopes are the most important tools of cytology, the study of cell structure. But simply describing the diverse organelles within the cell reveals little about their function. Modern cell biology developed from an integration of cytology with biochemistry, the study of the molecules and chemical processes (metabolism) of cells. A biochemical approach called cell fractionation has been particularly important in cell biology.

isolating Organelles by Cell Fractionation

The goal of cell fractionation is to take cells apart and separate the major organelles from one another (**Figure 6.5**). The instrument used to fractionate cells is the centrifuge, which can spin test tubes holding mixtures of disrupted cells at various speeds. The centrifugal force separates the cell components by size and density. The most powerful machines, called **ultracentrifuges**, can spin as fast as 130,000 revolutions per minute (rpm) and apply forces on particles of more than 1 million times the force of gravity (1,000,000 g).

Cell fractionation enables the researcher to prepare specific components of cells in bulk quantity to study their composition and functions. By following this approach, biologists have been able to assign various functions of the cell to the different organelles, a task that would be far more difficult with intact cells. For example, one cellular fraction collected by centrifugation has enzymes that function in the metabolic process known as cellular respiration. The electron microscope reveals this fraction to be very rich in the organelles called mitochondria. This evidence helped cell biologists determine that mitochondria are the sites of cellular respiration. Cytology and biochemistry complement each other in correlating cellular structure and function.

Concept Check 6.1

- Which type of microscope would you use to study
 - the changes in shape of a living white blood cell,
 - the details of surface texture of a hair, and
 - the detailed structure of an organelle?

For suggested answers, see Appendix A.

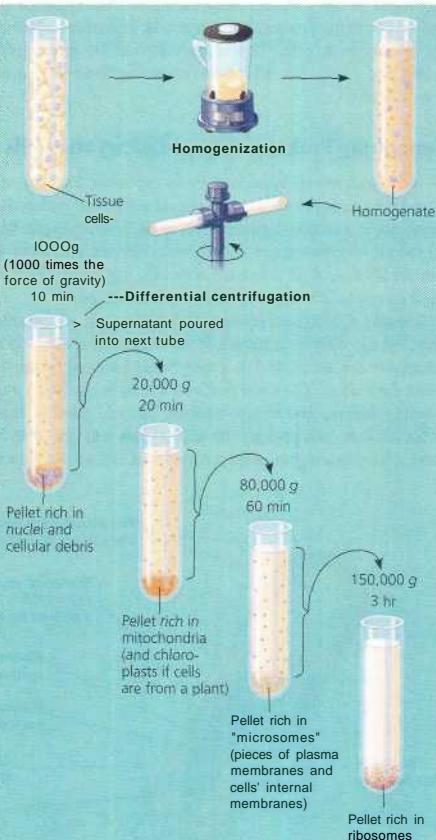

Figure 6.5
Research Method Cell Fractionation

APPLICATION

Cell fractionation is used to isolate (fractionate) cell components, based on size and density.

TECHNIQUE

First, cells are homogenized in a blender to break them up. The resulting mixture (cell homogenate) is then centrifuged at various speeds and durations to fractionate the cell components, forming a series of pellets.

RESULTS

In the original experiments, the researchers used microscopy to identify the organelles in each pellet, establishing a baseline for further experiments. In the next series of experiments, researchers used biochemical methods to determine the metabolic functions associated with each type of organelle. Researchers currently use cell fractionation to isolate particular organelles in order to study further details of their function.

Concept 6.2

Eukaryotic cells have internal membranes that compartmentalize their functions

The basic structural and functional unit of every organism is one of two types of cells—prokaryotic or eukaryotic. Only organisms of the domains Bacteria and Archaea consist of prokaryotic cells. Protists, fungi, animals, and plants all consist of eukaryotic cells. This chapter focuses on generalized animal and plant cells, after first comparing them with prokaryotic cells.

Comparing Prokaryotic and Eukaryotic Cells

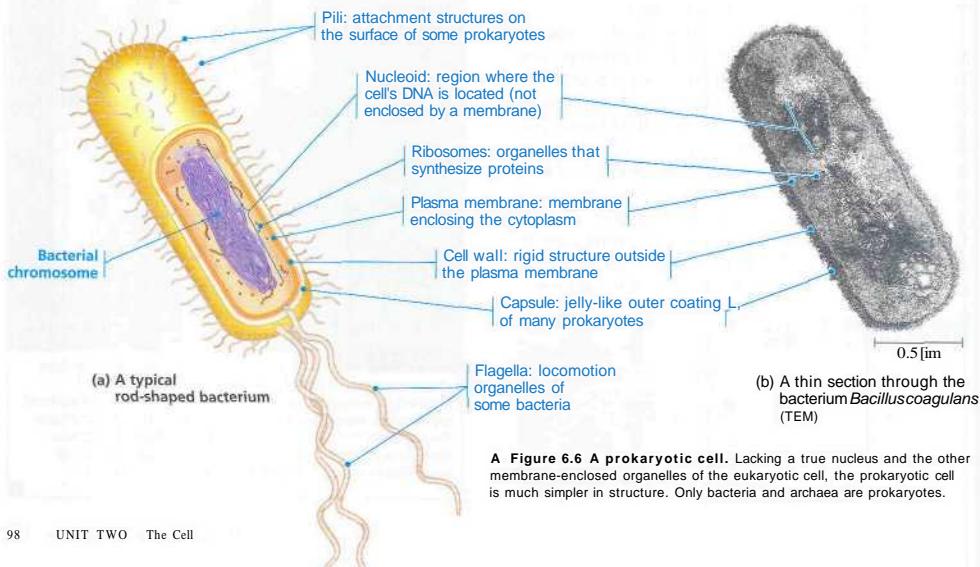

All cells have several basic features in common: They are all bounded by a membrane, called a *plasma membrane*. Within the membrane is a semifluid substance, *cytosol*, in which organelles are found. All cells contain *chromosomes*, carrying genes in the form of DNA. And all cells have *ribosomes*, tiny organelles that make proteins according to instructions from the genes.

A major difference between prokaryotic and eukaryotic cells, indicated by their names, is that the chromosomes of a eukaryotic cell are located in a membrane-enclosed organelle called the *nucleus*. The word *prokaryotic* is from the Greek *pro*, meaning "before," and *karyon*, meaning "kernel," referring here to the nucleus. In a prokaryotic cell (Figure 6.6), the DNA is concentrated in a region called the *nucleoid*, but no membrane

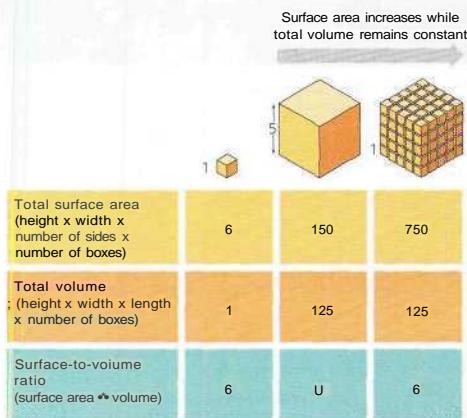

separates this region from the rest of the cell. In contrast, the **eukaryotic cell** (Greek *eu*, true, and *karyon*) has a **true nucleus**, bounded by a membranous nuclear envelope (see Figure 6.Q, pp. 100–101). The entire region between the nucleus and the plasma membrane is called the **cytoplasm**, a term also used for the interior of a prokaryotic cell. Within the cytoplasm of a eukaryotic cell, suspended in cytosol, are a variety of membrane-bounded organelles of specialized form and function. These are absent in prokaryotic cells. Thus, the presence or absence of a true nucleus is just one example of the disparity in structural complexity between the two types of cells.

Eukaryotic cells are generally quite a bit bigger than prokaryotic cells (see Figure 6.2). Size is a general aspect of cell structure that relates to function. The logistics of carrying out cellular metabolism sets limits on cell size. At the lower limit, the smallest cells known are bacteria called mycoplasmas, which have diameters between 0.1 and 1.0 μm . These are perhaps the smallest packages with enough DNA to program metabolism and enough enzymes and other cellular equipment to carry out the activities necessary for a cell to sustain itself and reproduce. Most bacteria are 1–10 μm in diameter, a dimension about ten times greater than that of mycoplasmas. Eukaryotic cells are typically 10–100 μm in diameter.

Metabolic requirements also impose theoretical upper limits on the size that is practical for a single cell. As an object of a particular shape increases in size, its volume grows proportionately more than its surface area. (Area is proportional to a linear dimension squared, whereas volume is proportional to the linear dimension cubed.) Thus, the smaller the object, the greater its ratio of surface area to volume (Figure 6.7).

A Figure 6.6 A prokaryotic cell. Lacking a true nucleus and the other membrane-enclosed organelles of the eukaryotic cell, the prokaryotic cell is much simpler in structure. Only bacteria and archaea are prokaryotes.

A Figure 6.7 Geometric relationships between surface area and volume. In this diagram, cells are represented as boxes. Using arbitrary units of length, we can calculate the cell's surface area (in square units), volume (in cubic units), and ratio of surface area to volume. The smaller the cell, the higher the surface-to-volume ratio. A high surface-to-volume ratio facilitates the exchange of materials between a cell and its environment.

At the boundary of every cell, the **plasma membrane** functions as a selective barrier that allows sufficient passage of oxygen, nutrients, and wastes to service the entire volume of the cell (**Figure 6.8**). For each square micrometer of membrane, only so much of a particular substance can cross per second. Rates of chemical exchange with the extracellular environment might be inadequate to maintain a cell with a very large cytoplasm. The need for a surface area sufficiently large to accommodate the volume helps explain the microscopic size of most cells. Larger organisms do not generally have *larger* cells than smaller organisms—simply *more* cells. A sufficiently high ratio of surface area to volume is especially important in cells that exchange a lot of material with their surroundings, such as

intestinal cells. Such cells may have many long, thin projections from their surface called microvilli, which increase surface area without an appreciable increase in volume.

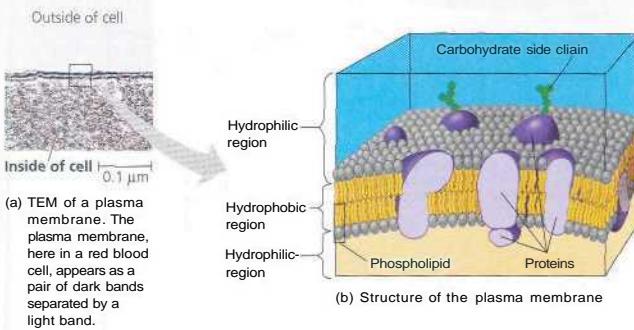

Prokaryotic cells will be described in detail in Chapters 18 and 27 (see Table 27.2 for a comparison of prokaryotes and eukaryotes), and the possible evolutionary relationships between prokaryotic and eukaryotic cells will be discussed in Chapter 28. Most of the discussion of cell structure that follows in this chapter applies to eukaryotic cells.

A Panoramic View of the Eukaryotic Cell

In addition to the plasma membrane at its outer surface, a eukaryotic cell has extensive and elaborately arranged internal membranes, which partition the cell into compartments—the membranous organelles mentioned earlier. These membranes also participate directly in the cell's metabolism, because many enzymes are built right into the membranes. Furthermore, the cell's compartments provide different local environments that facilitate specific metabolic functions, so incompatible processes can go on simultaneously inside the same cell.

Membranes of various kinds are fundamental to the organization of the cell. In general, biological membranes consist of a double layer of phospholipids and other lipids. Embedded in this lipid bilayer or attached to its surfaces are diverse proteins (see Figure 6.8). However, each type of membrane has a unique composition of lipids and proteins suited to that membrane's specific functions. For example, enzymes embedded in the membranes of the organelles called mitochondria function in cellular respiration,

Before continuing with this chapter, examine the overviews of eukaryotic cells in **Figure 6.9** on the next two pages. These generalized cell diagrams introduce the various organelles and provide a map of the cell for the detailed tour upon which we will now embark. Figure 6.9 also contrasts animal and plant cells. As eukaryotic cells, they have much more in common than either has with any prokaryotic cell. As you will see, however, there are important differences between animal and plant cells.

•4 Figure 6.8 The plasma membrane.

The plasma membrane and the membranes of organelles consist of a double layer (bilayer) of phospholipids with various proteins attached to or embedded in it. The phospholipid tails in the interior of a membrane are hydrophobic; the interior portions of membrane proteins are also hydrophobic. The phospholipid heads, exterior proteins, exterior parts of proteins, and carbohydrate side chains are hydrophilic and in contact with the aqueous solution on either side of the membrane. Carbohydrate side chains are found only on the outer surface of the plasma membrane. The specific functions of a membrane depend on the kinds of phospholipids and proteins present.

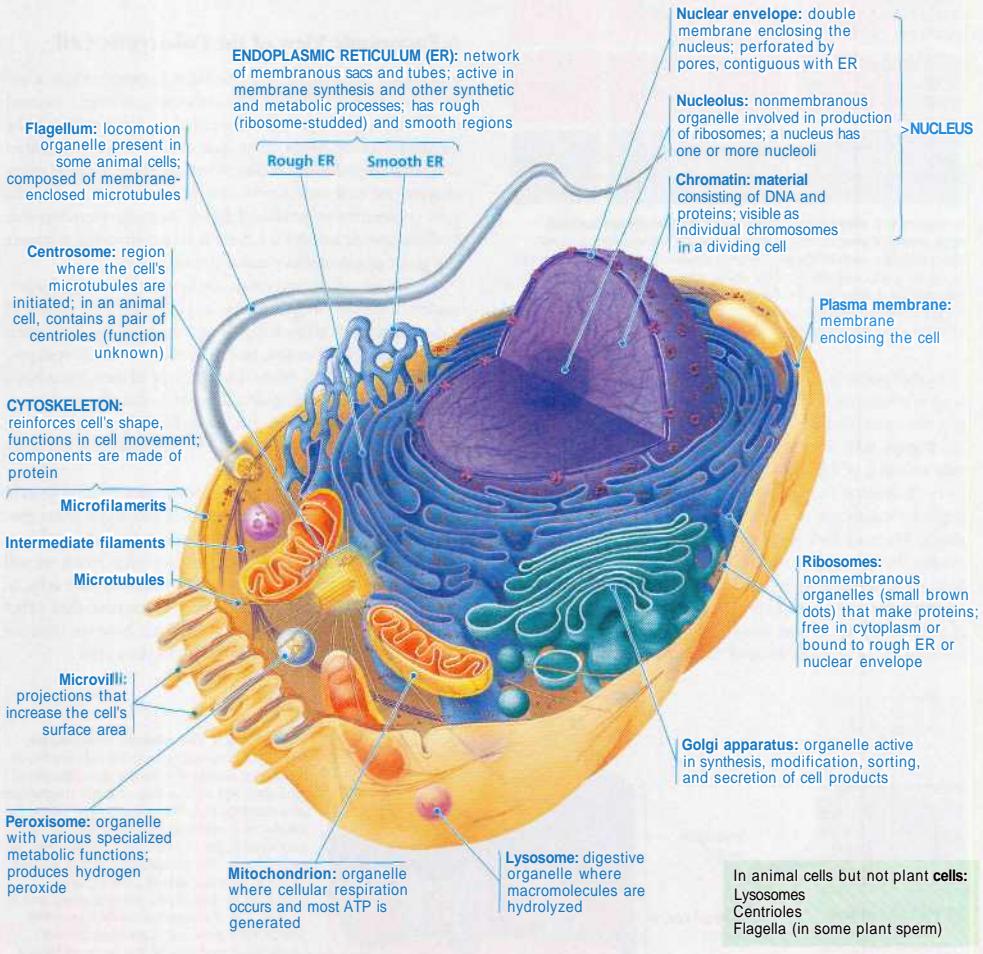

Figure 6.9

Exploring Animal and Plant Cells

ANIMAL CELL

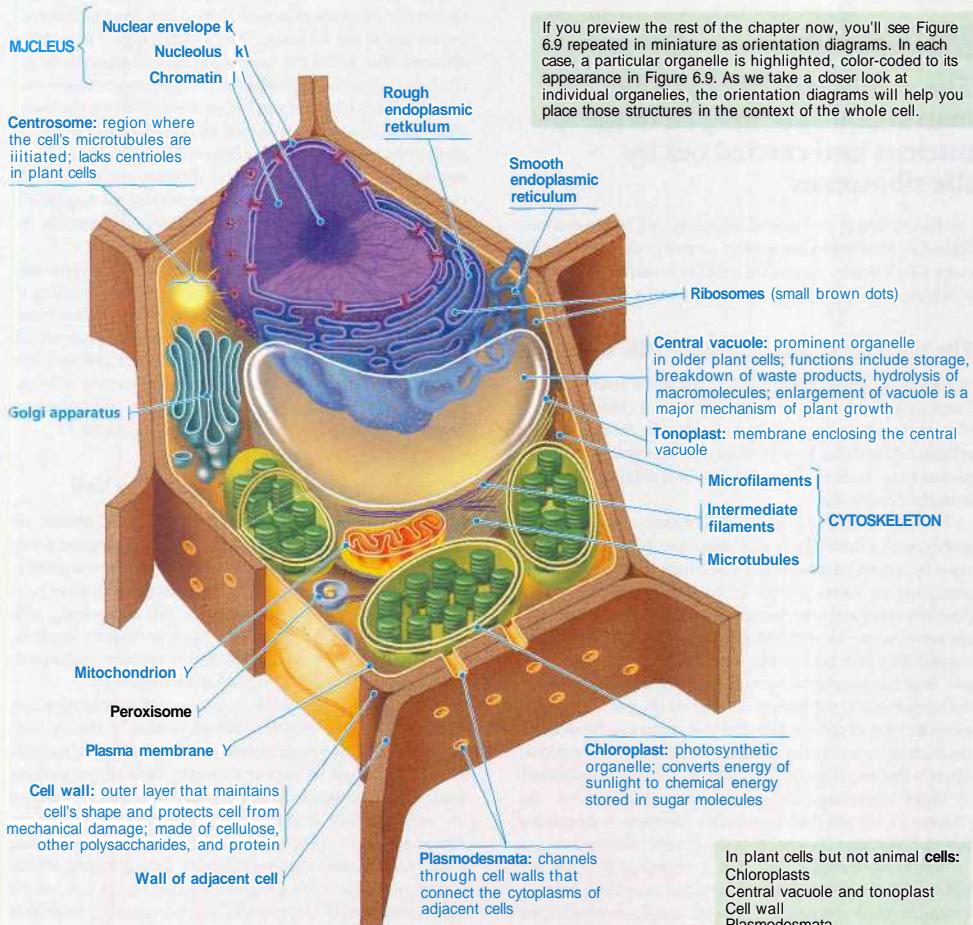

This drawing of a generalized animal cell incorporates the most common structures of animal cells (no cell actually looks just like this). As shown by this cutaway view, the cell has a variety of organelles ("little organs"), many of which are bounded by membranes. The most prominent organelle in an animal cell is usually the nucleus.

Most of the cell's metabolic activities occur in the cytoplasm, the entire region between the nucleus and the plasma membrane. The cytoplasm contains many organelles suspended in a semifluid medium, the cytosol. Pervading much of the cytoplasm is a labyrinth of membranes called the endoplasmic reticulum (ER).

This drawing of a generalized plant cell reveals the similarities and differences between an animal cell and a plant cell. In addition to most of the features seen in an animal cell, a plant cell has membrane-enclosed organelles called plastids. The most important

type of plastid is the chloroplast, which carries out photosynthesis. Many plant cells have a large central vacuole; some may have one or more smaller vacuoles. Outside a plant cell's plasma membrane is a thick cell wall, perforated by channels called plasmodesmata.

Concept Check 6.2

- After carefully reviewing Figure 6.9, briefly describe the structure and function of each of the following organelles: nucleus, mitochondrion, chloroplast, central vacuole, endoplasmic reticulum, and Golgi apparatus.

For suggested answers, see Appendix A.

Concept 6.3

The eukaryotic cell's genetic instructions are housed in the nucleus and carried out by the ribosomes

On the first stop of our detailed tour of the cell, let's look at two organelles involved in the genetic control of the cell: the nucleus, which houses most of the cell's DNA, and the ribosomes, which use information from the DNA to make proteins.

The Nucleus: Genetic Library of the Cell

The nucleus contains most of the genes in the eukaryotic cell (some genes are located in mitochondria and chloroplasts). It is generally the most conspicuous organelle in a eukaryotic cell, averaging about 5 μm in diameter. The nuclear envelope encloses the nucleus (Figure 6.10), separating its contents from the cytoplasm.

The nuclear envelope is a *double* membrane. The two membranes, each a lipid bilayer with associated proteins, are separated by a space of 20–40 nm. The envelope is perforated by pores that are about 100 nm in diameter. At the lip of each pore, the inner and outer membranes of the nuclear envelope are continuous. An intricate protein structure called a *pore complex* lines each pore and regulates the entry and exit of certain large macromolecules and particles. Except at the pores, the nuclear side of the envelope is lined by the nuclear lamina, a netlike array of protein filaments that maintains the shape of the nucleus by mechanically supporting the nuclear envelope. There is also much evidence for a *nuclear matrix*, a framework of fibers extending throughout the nuclear interior. (In Chapter 19, we will examine possible functions of the nuclear lamina and matrix in organizing the genetic material)

Within the nucleus, the DNA is organized into discrete units called chromosomes, structures that carry the genetic information. Each chromosome is made up of a material called chromatin, a complex of proteins and DNA. Stained chromatin usually appears through both light microscopes and electron microscopes as a diffuse mass. As a cell prepares to

divide, however, the thin chromatin fibers coil up (condense), becoming thick enough to be distinguished as the familiar separate structures we know as chromosomes. Each eukaryotic species has a characteristic number of chromosomes. A typical human cell, for example, has 46 chromosomes in its nucleus; the exceptions are the sex cells (eggs and sperm), which have only 23 chromosomes in humans. A fruit fly cell has 8 chromosomes in most cells, with 4 in the sex cells.

A prominent structure within the nondividing nucleus is the nucleolus (plural, *nucleoli*), which appears through the electron microscope as a mass of densely stained granules and fibers adjoining part of the chromatin. Here a special type of RNA called *ribosomal RNA* (rRNA) is synthesized from instructions in the DNA. Also, proteins imported from the cytoplasm are assembled with rRNA into large and small ribosomal subunits in the nucleolus. These subunits then exit the nucleus through the nuclear pores to the cytoplasm, where a large and a small subunit can assemble into a ribosome. Sometimes there are two or more nucleoli; the number depends on the species and the stage in the cell's reproductive cycle. Recent studies have suggested that the nucleolus may perform additional functions as well.

As we saw in Figure 5.25, the nucleus directs protein synthesis by synthesizing messenger RNA (mRNA) according to instructions provided by the DNA. The mRNA is then transported to the cytoplasm via the nuclear pores. Once an mRNA molecule reaches the cytoplasm, ribosomes translate the mRNA's genetic message into the primary structure of a specific polypeptide. This process of transcribing and translating genetic information is described in detail in Chapter 17.

Ribosomes: Protein Factories in the Cell

Ribosomes, particles made of ribosomal RNA and protein, are the organelles that carry out protein synthesis (Figure 6.11). Cells that have high rates of protein synthesis have a particularly large number of ribosomes. For example, a human pancreas cell has a few million ribosomes. Not surprisingly, cells active in protein synthesis also have prominent nucleoli. (Keep in mind that both nucleoli and ribosomes, unlike most other organelles, are not enclosed in membrane.)

Ribosomes build proteins in two cytoplasmic locales (see Figure 6.11). *Free ribosomes* are suspended in the cytosol, while *bound ribosomes* are attached to the outside of the endoplasmic reticulum or nuclear envelope. Most of the proteins made on free ribosomes function within the cytosol; examples are enzymes that catalyze the first steps of sugar breakdown. Bound ribosomes generally make proteins that are destined either for insertion into membranes, for packaging within certain organelles such as lysosomes (see Figure 6.9), or for export from the cell (secretion). Cells that specialize in protein secretion—for instance, the cells of the pancreas that secrete digestive enzymes—frequently have a high proportion of bound ribosomes. Bound and free ribosomes are structurally "

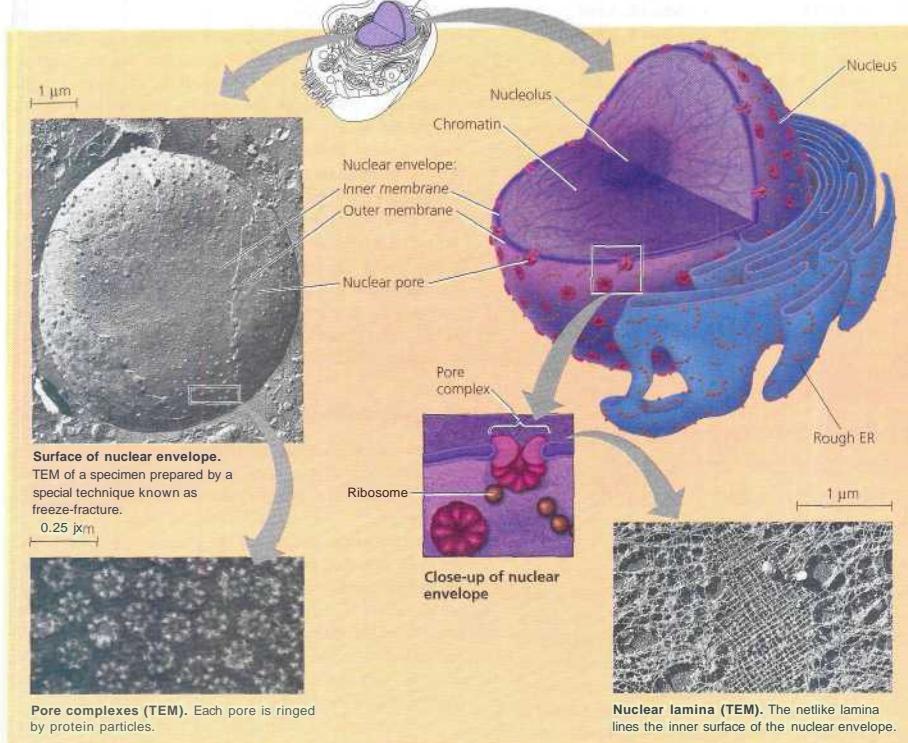

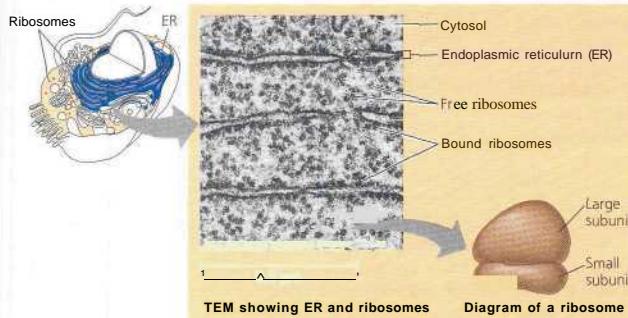

Figure 6.10 The nucleus and its envelope. Within the nucleus are the chromosomes, which appear as a mass of chromatin (DNA and associated proteins), and one or more nucleoli (singular, nucleolus), which function in ribosome synthesis. The nuclear envelope, which consists of two membranes separated by a narrow space, is perforated with pores and lined by the nuclear lamina.

< Figure 6.11 Ribosomes. This electron micrograph of part of a pancreas cell shows many ribosomes, both free (in the cytosol) and bound (to the endoplasmic reticulum). The simplified diagram of a ribosome shows its two subunits.

identical and can alternate between the two roles; the cell adjusts the relative numbers of each as metabolic changes alter the types of proteins that must be synthesized. You will learn more about ribosome structure and function in Chapter 17.

Concept Check 6.3

- What role do the ribosomes play in carrying out the genetic instructions?
- Describe the composition of chromatin and of nucleoli and the function(s) of each.

For suggested answers, see Appendix A.

Concept 6.4

The endomembrane system regulates protein traffic and performs metabolic functions in the cell

Many of the different membranes of the eukaryotic cell are part of an **endomembrane system**, which carries out a variety of tasks in the cell. These tasks include synthesis of proteins and their transport into membranes and organelles or out of the cell, metabolism and movement of lipids, and detoxification of poisons. The membranes of this system are related either through direct physical continuity or by the transfer of membrane segments as tiny **vesicles** (sacs made of membrane). Despite these relationships, the various membranes are not identical in structure and function. Moreover, the thickness, molecular composition, and types of chemical reactions carried out by proteins in a given membrane are not fixed, but may be modified several times during the membrane's life. The endomembrane system includes the nuclear envelope, endoplasmic reticulum, Golgi apparatus, lysosomes, various kinds of vacuoles, and the plasma membrane (not actually an endomembrane in physical location, but nevertheless related to the endoplasmic reticulum and other internal membranes). We have already discussed the nuclear envelope and will now focus on the endoplasmic reticulum and the other endomembranes to which the endoplasmic reticulum gives rise.

The Endoplasmic Reticulum: Biosynthetic Factory

The **endoplasmic reticulum (ER)** is such an extensive network of membranes that it accounts for more than half the total membrane in many eukaryotic cells. (The word *endo-*

plasmk means "within the cytoplasm," and *reticulum* is Latin for 'little net.') The ER consists of a network of membranous tubules and sacs called cisternae (from the Latin *cisterna*, a reservoir for a liquid). The ER membrane separates the internal compartment of the ER, called the ER lumen (cavity) or cisternal space, from the cytosol. And because the ER membrane is continuous with the nuclear envelope, the space between the two membranes *Qf* the envelope is continuous with the lumen of the ER (**Figure 6.12**).

There are two distinct, though connected, regions of ER that differ in **structure** and function: smooth ER and rough ER. **Smooth ER** is so named because its outer surface lacks ribosomes. **Rough ER** has ribosomes that stud the outer surface of the membrane and thus appears rough through the electron microscope. As already mentioned, ribosomes are also attached to the cytoplasmic side of the nuclear envelope's outer membrane, which is continuous with rough ER.

Functions of Smooth ER

The smooth ER of various cell types functions in diverse metabolic processes. These processes include synthesis of lipids, metabolism of carbohydrates, and detoxification of drugs and poisons.

Enzymes of the smooth ER are important to the synthesis of lipids, including oils, phospholipids, and steroids. Among the steroids produced by the smooth ER in animal cells are the sex hormones of vertebrates and the various steroid hormones secreted by the adrenal glands. The cells that actually synthesize and secrete these hormones—in the testes and ovaries, for example—are rich in smooth ER, a structural feature that fits the function of these cells.

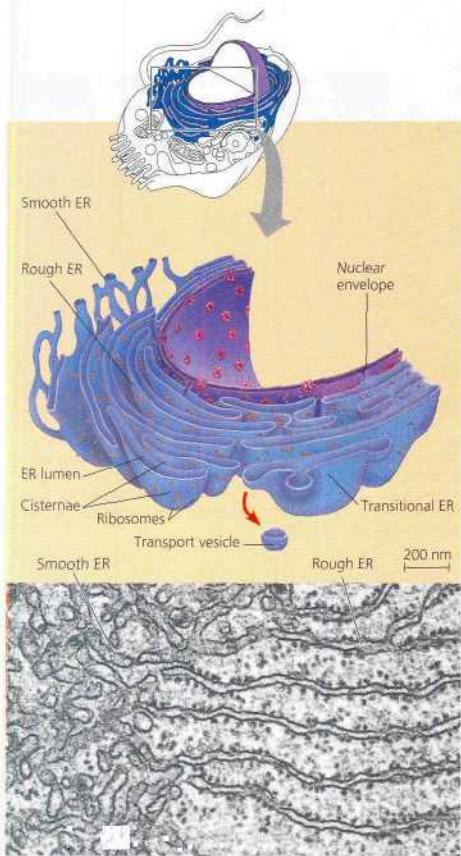

In the smooth ER, other enzymes help detoxify drugs and poisons, especially in liver cells. Detoxification usually involves adding hydroxyl groups to drugs, making them more soluble and easier to flush from the body. The sedative phenobarbital and other barbiturates are examples of drugs metabolized in this manner by smooth ER in liver cells. In fact, barbiturates, alcohol, and many other drugs induce the proliferation of smooth ER and its associated detoxification enzymes, thus increasing the rate of detoxification. This, in turn, increases tolerance to the drugs, meaning that higher doses are required to achieve a particular effect, such as sedation. Also, because some of the detoxification enzymes have relatively broad action, the proliferation of smooth ER in response to one drug can increase tolerance to other drugs as well. Barbiturate abuse, for example, may decrease the effectiveness of certain antibiotics and other useful drugs.

The smooth ER also stores calcium ions. In muscle cells, for example, a specialized smooth ER membrane pumps calcium ions from the cytosol into the ER lumen. When a muscle cell is stimulated by a nerve impulse, calcium ions rush back across the ER membrane into the cytosol and trigger

contraction of the muscle cell. In other cell types, calcium ion release from the smooth ER can trigger different responses.

Functions of Rough ER

Many types of specialized cells secrete proteins produced by ribosomes attached to rough ER. For example, certain cells in the pancreas secrete the protein insulin, a hormone, into the

A Figure 6.12 Endoplasmic reticulum (ER). A membranous system of interconnected tubules and flattened sacs called cisternae, the ER is also continuous with the nuclear envelope. (The drawing is a cutaway view.) The membrane of the ER encloses a continuous compartment called the ER lumen (or asternal space). Rough ER, which is studded on its outer surface with ribosomes, can be distinguished from smooth ER in the electron micrograph (TEM). Transport vesicles bud off from a region of the rough ER called transitional ER and travel to the Golgi apparatus and other destinations.

bloodstream (see Figure 6.11). As a polypeptide chain grows from a bound ribosome, it is threaded into the ER lumen through a pore formed by a protein complex in the ER membrane. As the new protein enters the ER lumen, it folds into its native conformation. Most secretory proteins are glycoproteins, proteins that have carbohydrates covalently bonded to them. The carbohydrate is attached to the protein in the ER by specialized molecules built into the ER membrane.

Once secretory proteins are formed, the ER membrane keeps them separate from the proteins, produced by free ribosomes, that will remain in the cytosol. Secretory proteins depart from the ER wrapped in the membranes of vesicles that bud like bubbles from a specialized region called transitional ER (see Figure 6.12). Vesicles in transit from one part of the cell to another are called transport vesicles; we will learn their fate in the next section.

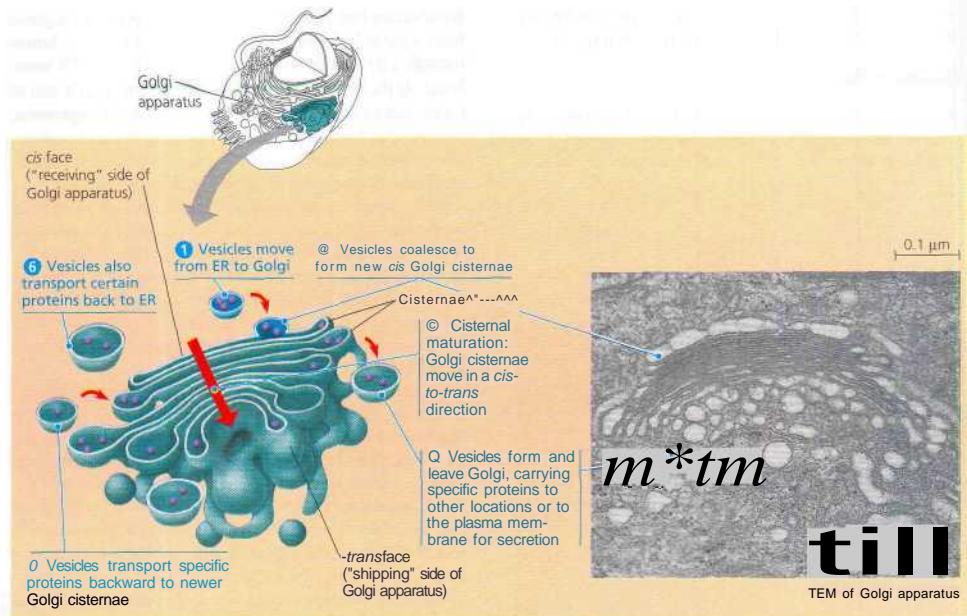

In addition to making secretory proteins, rough ER is a membrane factory for the cell; it grows in place by adding membrane proteins and phospholipids to its own membrane. As polypeptides destined to be membrane proteins grow from the ribosomes, they are inserted into the ER membrane itself and are anchored there by their hydrophobic portions. The rough ER also makes its own membrane phospholipids; enzymes built into the ER membrane assemble phospholipids from precursors in the cytosol. The ER membrane expands and is transferred in the form of transport vesicles to other components of the endomembrane system.

The Golgi Apparatus: Shipping and Receiving Center

After leaving the ER, many transport vesicles travel to the Golgi apparatus. We can think of the Golgi as a center of manufacturing, warehousing, sorting, and shipping. Here, products of the ER are modified and stored and then sent to other destinations. Not surprisingly, the Golgi apparatus is especially extensive in cells specialized for secretion.

The Golgi apparatus consists of flattened membranous sacs—cisternae—looking like a stack of pita bread (Figure 6.13, on the next page). A cell may have many or even hundreds of these stacks. The membrane of each cisterna in a stack separates its internal space from the cytosol. Vesicles concentrated in the vicinity of the Golgi apparatus are engaged in the transfer of material between the parts of the Golgi and other structures.

A Golgi stack has a distinct polarity, with the membranes of cisternae on opposite sides of the stack differing in thickness and molecular composition. The two poles of a Golgi stack are referred to as the *cis* face and the *trans* face; these act, respectively, as the receiving and shipping departments of the Golgi apparatus. The *cis* face is usually located near the ER. Transport vesicles move material from the ER to the Golgi apparatus. A vesicle that buds from the ER can add its membrane and the contents of its lumen to the *cis* face by fusing with a

A Figure 6.13 The Golgi apparatus. The Golgi apparatus consists of stacks of flattened sacs, or cisternae, which, unlike ER cisternae, are not physically connected. (The drawing is a cutaway view.) A Golgi stack receives and dispatches transport vesicles and the products

they contain. A Golgi stack has a structural and functional polarity, with a *cis* face that receives vesicles containing ER products and a *trans* face that dispatches vesicles. The cisternal maturation model suggests that the Golgi cisternae themselves appear to "mature,"

moving from the *cis* to the *trans* face while carrying some proteins along. In addition, some vesicles recycle enzymes that had been carried forward, in moving cisternae, "backward" to a newer region where their functions are needed (TEM).

Golgi membrane. The *trans* face gives rise to vesicles, which pinch off and travel to other sites.

Products of the ER are usually modified during their transit from the *cis* region to the *trans* region of the Golgi. Proteins and phospholipids of membranes may be altered. For example, various Golgi enzymes modify the carbohydrate portions of glycoproteins. Carbohydrates are first added to proteins in the rough ER, often during the process of polypeptide synthesis. The carbohydrate on the resulting glycoprotein is then modified as it passes through the rest of the ER and the Golgi. The Golgi removes some sugar monomers and substitutes others, producing a large variety of carbohydrates.

In addition to its finishing work, the Golgi apparatus manufactures certain macromolecules by itself. Many polysaccharides secreted by cells are Golgi products, including pectins and certain other non-cellulose polysaccharides made by plant cells and incorporated along with cellulose into their cell walls. (Cellulose is made by enzymes located within the plasma membrane, which directly deposit this polysaccharide

on the outside surface.) Golgi products that will be secreted depart from the *trans* face of the Golgi inside transport vesicles that eventually fuse with the plasma membrane.

The Golgi manufactures and refines its products in stages, with different cisternae between the *cis* and *trans* regions containing unique teams of enzymes. Until recently, we viewed the Golgi as a static structure, with products in various stages of processing transferred from one cisterna to the next by vesicles. While this may occur, recent research has given rise to a new model of the Golgi as a more dynamic structure. According to the model called the *cisternal maturation model*, the cisternae of the Golgi actually progress forward from the *cis* to the *trans* face of the Golgi, carrying and modifying their protein cargo as they move. Figure 6.13 shows the details of this model.

Before a Golgi stack dispatches its products by budding vesicles from the *trans* face, it sorts these products and targets them for various parts of the cell. Molecular identification tags, such as phosphate groups that have been added to the Golgi

products, aid in sorting by acting like ZIP codes on mailing labels. Finally transport vesicles budded from the Golgi may have external molecules on their membranes that recognize "docking sites" on the surface of specific organelles or on the plasma membrane, thus targeting them appropriately.

Lysosomes: Digestive Compartments

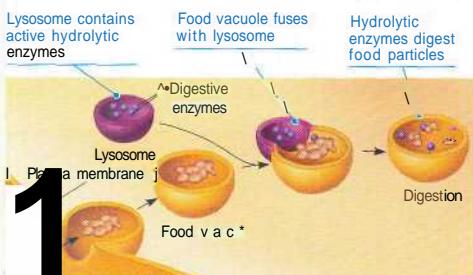

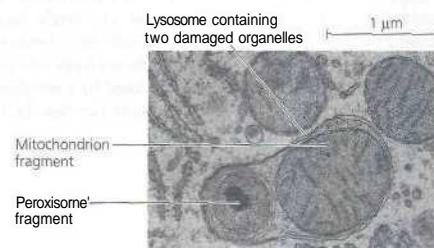

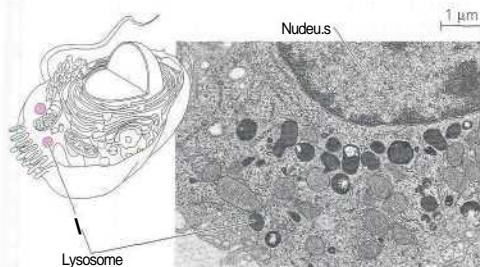

A **lysosome** is a membranous sac of hydrolytic enzymes that an animal cell uses to digest all kinds of macromolecules. Lysosomal enzymes work best in the acidic environment found in lysosomes. If a lysosome breaks open or leaks its contents, the released enzymes are not very active, because the cytosol has a neutral pH. However, excessive leakage from a large number of lysosomes can destroy a cell by autodigestion.

Hydrolytic enzymes and lysosomal membrane are made by rough ER and then transferred to the Golgi apparatus for further processing. At least some lysosomes probably arise by budding from the *trans* face of the Golgi apparatus (see Figure 6.13).

Proteins of the inner surface of the lysosomal membrane and the digestive enzymes themselves are thought to be spared from destruction by having three-dimensional conformations that protect vulnerable bonds from enzymatic attack.

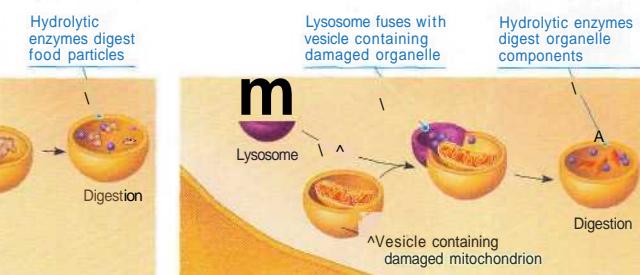

Lysosomes carry out intracellular digestion in a variety of circumstances. Amoebas and many other protists eat by engulfing smaller organisms or other food particles, a process called phagocytosis (from the Greek *phagdn*, to eat, and *kyios*, vessel, referring here to the cell). The *food vacuole* formed in this way then fuses with a lysosome, whose enzymes digest the food (Figure 6.14a). Digestion products, including simple sugars, amino acids, and other monomers, pass into the cytosol and become nutrients for the cell. Some human cells also carry out phagocytosis. Among them are macrophages, a type of white blood cell that helps defend the body by engulfing and destroying bacteria and other invaders (see Figure 6.32).

Lysosomes also use their hydrolytic enzymes to recycle the cell's own organic material, a process called *autophagy*. During autophagy, a damaged organelle or small amount of cytosol

(a) Phagocytosis: lysosome digesting food

A Figure 6.14 Lysosomes, Lysosomes digest (hydrolyze) materials taken into the cell and recycle intracellular materials. (a) Top In this macrophage (a type of white blood cell) from a rat, the lysosomes are very dark because of a specific stain that reacts with one of the

products of digestion within the lysosome (TEM). Macrophages ingest bacteria and viruses and destroy them using lysosomes. Bottom This diagram shows one lysosome fusing with a food vacuole during the process of phagocytosis. (b) Top In the cytoplasm of this rat liver cell, a

lysosome has engulfed two disabled organelles, a mitochondrion and a peroxisome, in the process of autophagy (TEM). Bottom This diagram shows a lysosome fusing with a vesicle containing a damaged mitochondrion.

becomes surrounded by a membrane, and a lysosome fuses with this vesicle (**Figure 6.14b**). The lysosomal enzymes dismantle the enclosed material, and the organic monomers are returned to the cytosol for reuse. With the help of lysosomes, the cell continually renews itself. A human liver cell, for example, recycles half of its macromolecules each week.

The cells of people with inherited lysosomal storage diseases lack a functioning hydrolytic enzyme normally present in lysosomes. The lysosomes become engorged with indigestible substrates, which begin to interfere with other cellular activities. In Tay-Sachs disease, for example, a lipid-digesting enzyme is missing or inactive, and the brain becomes impaired by an accumulation of lipids in the cells. Fortunately lysosomal storage diseases are rare in the general population.

Vacuoles: Diverse Maintenance Compartments

A plant or fungal cell may have one or several vacuoles. While vacuoles carry out hydrolysis and are thus similar to lysosomes, they carry out other functions as well. Food vacuoles, formed by phagocytosis, have already been mentioned (see Figure 6.14a). Many freshwater protists have contractile vacuoles that pump excess water out of the cell, thereby maintaining the appropriate concentration of salts and other molecules (see Figure 7.14). Mature plant cells generally contain a large central vacuole (**Figure 6.15**) enclosed by a membrane called the tonoplast. The central vacuole develops by the

coalescence of smaller vacuoles, themselves derived from the endoplasmic reticulum and Golgi apparatus. The vacuole is in this way an integral part of a plant cells endomembrane system. Like all cellular membranes, the tonoplast is selective in transporting solutes; as a result, the solution inside the vacuole, called cell sap, differs in composition from the cytosol.

The plant cell's central vacuole is a versatile compartment. It can hold reserves of important organic compounds, such as the proteins stockpiled in the vacuoles of storage cells in seeds. It is also the plant cells main repository of inorganic ions, such as potassium and chloride. Many plant cells use their vacuoles as disposal sites for metabolic by-products that would endanger the cell if they accumulated in the cytosol. Some vacuoles contain pigments that color the cells, such as the red and blue pigments of petals that help attract pollinating insects to flowers. Vacuoles may also help protect the plant against predators by containing compounds that are poisonous or unpalatable to animals. The vacuole has a major role in the growth of plant cells, which enlarge as their vacuoles absorb water, enabling the cell to become larger with a minimal investment in new cytoplasm. And because of the large vacuole, the cytosol often occupies only a thin layer between the plasma membrane and the tonoplast, so the ratio of membrane surface to cytosolic volume is great, even for a large plant cell.

The Endomembrane System: A Review

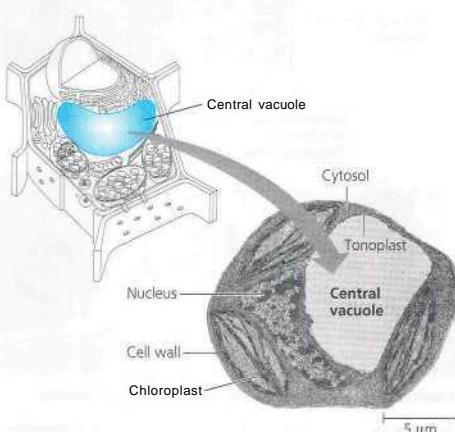

Figure 6.16 reviews the endomembrane system, showing the flow of membrane lipids and proteins through the various organelles. As the membrane moves from the ER to the Golgi and then elsewhere, its molecular composition and metabolic functions are modified, along with those of its contents. The endomembrane system is a complex and dynamic player in the cells compartmental organization.

We'll continue our tour of the cell with some membranous organelles that are *not* closely related to the endomembrane system, but play crucial roles in the energy transformations carried out by cells.

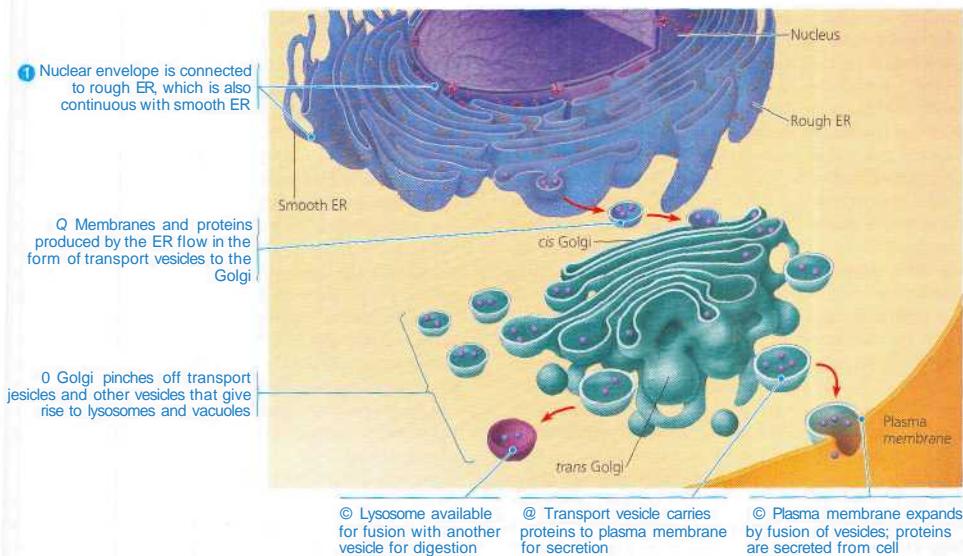

Concept Check 6.4

1. Describe the structural and functional distinctions between rough and smooth ER.
2. Imagine a protein that functions in the ER, but requires modification in the Golgi apparatus before it can achieve that function. Describe the protein's path through the cell, starting with the mRNA molecule that specifies the protein.
3. How do transport vesicles serve to integrate the endomembrane system?

For suggested answers, see Appendix A.

A Figure 6.15 The plant cell vacuole. The central vacuole is usually the largest compartment in a plant cell; the rest of the cytoplasm is generally confined to a narrow zone between the vacuolar membrane (tonoplast) and the plasma membrane (TEM).

A Figure 6.16 Review: relationships among organelles of the endomembrane system. The red arrows show some of the migration pathways for membranes and the materials they enclose.

Concept 6.5

Mitochondria and chloroplasts change energy from one form to another

Organisms transform energy they acquire from their surroundings. In eukaryotic cells, mitochondria and chloroplasts are the organelles that convert energy to forms that cells can use for work. Mitochondria (singular, *mitochondrion*) are the sites of cellular respiration, the metabolic process that generates ATP by extracting energy from sugars, fats, and other fuels with the help of oxygen. Chloroplasts, found only in plants and algae, are the sites of photosynthesis. They convert solar energy to chemical energy by absorbing sunlight and using it to drive the synthesis of organic compounds such as sugars from carbon dioxide and water.

Although mitochondria and chloroplasts are enclosed by membranes, they are not part of the endomembrane system. In contrast to organelles of the endomembrane system, each of these organelles has at least two membranes separating the innermost space from the cytosol. Their membrane proteins

are made not by the ER, but by free ribosomes in the cytosol and by **ribosomes** contained within these organelles themselves. Not only do these organelles have ribosomes, but they also contain a small amount of DNA. It is this DNA that programs the synthesis of the proteins made on the organelles own ribosomes. (Proteins imported from the cytosol—constituting most of the organelles proteins—are programmed by nuclear DNA.) Mitochondria and chloroplasts are semi-autonomous organelles that grow and reproduce within the cell. In Chapters 9 and 10, we will focus on how mitochondria and chloroplasts function. We will consider the evolution of these organelles in Chapter 28. Here we are concerned mainly with the structure of these energy transformers.

In this section, we will also consider the **peroxisome**, an oxidative organelle that is not part of the endomembrane system. Like mitochondria and chloroplasts, the peroxisome imports its proteins primarily from the cytosol.

Mitochondria: Chemical Energy Conversion

Mitochondria are found in nearly all eukaryotic cells, including those of plants, animals, fungi, and protists. Some cells have a single large mitochondrion, but more often a cell has

hundreds or even thousands of mitochondria; the number is correlated with the cell's level of metabolic activity. For example, motile or contractile cells have proportionally more mitochondria per volume than less active cells. Mitochondria are about 1–10 μm long. Time-lapse films of living cells reveal mitochondria moving around, changing their shapes, and dividing in two, unlike the static cylinders seen in electron micrographs of dead cells.

The mitochondrion is enclosed by two membranes, each a phospholipid bilayer with a unique collection of embedded proteins (Figure 6.17). The outer membrane is smooth, but the inner membrane is convoluted, with infoldings called cristae. The inner membrane divides the mitochondrion into two internal compartments. The first is the intermembrane space, the narrow region between the inner and outer membranes. The second compartment, the mitochondrial matrix, is enclosed by the inner membrane. The matrix contains many different enzymes as well as the mitochondrial DNA and ribosomes. Some of the metabolic steps of cellular respiration are catalyzed by enzymes in the matrix. Other proteins that function in respiration, including the enzyme that makes ATP⁺ are built into the inner membrane. As highly folded surfaces, the cristae give the inner mitochondrial membrane a large surface area for these proteins, thus enhancing the productivity of cellular respiration. This is another example of structure fitting function.

Chloroplasts: Capture of Light Energy

The chloroplast is a specialized member of a family of closely related plant organelles called plastids. *Amyloplasts* are colorless plastids that store starch (amylose), particularly in roots and tubers. *Oriomoplasts* have pigments that give fruits and

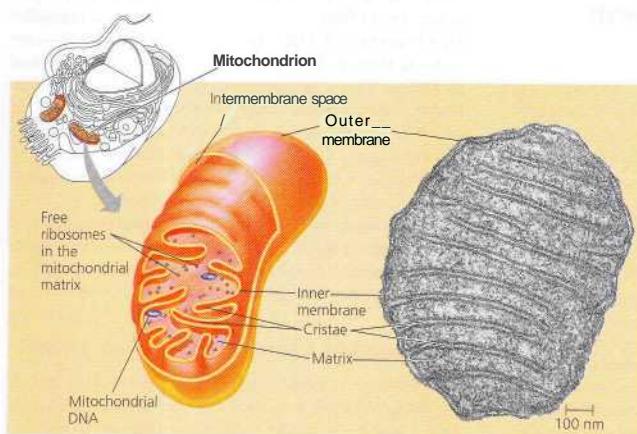

flowers their orange and yellow hues. *Chloroplasts* contain the green pigment chlorophyll, along with enzymes and other molecules that function in the photosynthetic production of sugar. These lens-shaped organelles, measuring about 2 μm by 5 μm , are found in leaves and other green organs of plants and in algae (Figure 6.18).

The contents of a chloroplast are partitioned from the cytosol by an envelope consisting of two membranes separated by a very narrow intermembrane space. Inside the chloroplast is another membranous system in the form of flattened, interconnected sacs called thylakoids. In some regions, thylakoids are stacked like poker chips; each stack is called a granum (plural, *grand*). The fluid outside the thylakoids is the stroma, which contains the chloroplast DNA and ribosomes as well as many enzymes. The membranes of the chloroplast divide the chloroplast space into three compartments: the intermembrane space, the stroma, and the thylakoid space. In Chapter 10, you will learn how this compartmental organization enables the chloroplast to convert light energy to chemical energy during photosynthesis.

As with mitochondria, the static and rigid appearance of chloroplasts in micrographs or schematic diagrams is not true to their dynamic behavior in the living cell. Their shapes are changeable, and they grow and occasionally pinch in two, reproducing themselves. They are mobile and move around the cell with mitochondria and other organelles along tracks of the cytoskeleton, a structural network we will consider later in this chapter.

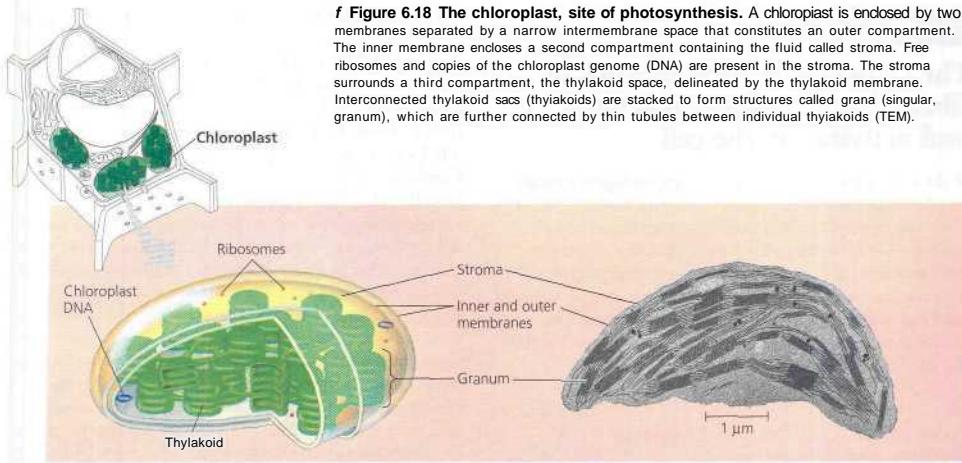

Peroxisomes: Oxidation

The peroxisome is a specialized metabolic compartment bounded by a single membrane (Figure 6.19). Peroxisomes

▲ Figure 6.17 The mitochondrion, site of cellular respiration. The inner and outer membranes of the mitochondrion are evident in the drawing and micrograph (TEM). The cristae are infoldings of the inner membrane. The cutaway drawing shows the two compartments bounded by the membranes: the intermembrane space and the mitochondrial matrix. Free ribosomes are seen in the matrix, along with one to several copies of the mitochondrial genome (DNA). The DNA molecules are usually circular and are attached to the inner mitochondrial membrane.

f Figure 6.18 The chloroplast, site of photosynthesis. A chloroplast is enclosed by two membranes separated by a narrow intermembrane space that constitutes an outer compartment. The inner membrane encloses a second compartment containing the fluid called stroma. Free ribosomes and copies of the chloroplast genome (DNA) are present in the stroma. The stroma surrounds a third compartment, the thylakoid space, delineated by the thylakoid membrane. Interconnected thylakoid sacs (thylakoids) are stacked to form structures called grana (singular, granum), which are further connected by thin tubules between individual thylakoids (TEM).

contain enzymes that transfer hydrogen from various substrates to oxygen, producing hydrogen peroxide (H_2O_2) as a by-product, from which the organelle derives its name. These reactions may have many different functions. Some peroxisomes use oxygen to break fatty acids down into smaller molecules that can then be transported to mitochondria,

where they are used as fuel for cellular respiration. Peroxisomes in the liver detoxify alcohol and other harmful compounds by transferring hydrogen from the poisons to oxygen. The H_2O_2 formed by peroxisome metabolism is itself toxic, but the organelle contains an enzyme that converts the H_2O_2 to water. Enclosing in the same space both the enzymes that produce hydrogen peroxide and those that dispose of this toxic compound is another example of how the cell's compartmental structure is crucial to its functions.

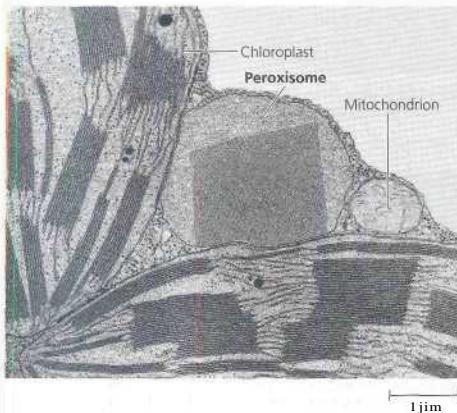

Specialized peroxisomes called glyoxysomes are found in the fat-storing tissues of plant seeds. These organelles contain enzymes that initiate the conversion of fatty acids to sugar, which the emerging seedling can use as a source of energy and carbon until it is able to produce its own sugar by photosynthesis.

Unlike lysosomes, peroxisomes do not bud from the endomembrane system. They grow larger by incorporating proteins made primarily in the cytosol, lipids made in the ER, and lipids synthesized within the peroxisome itself. Peroxisomes may increase in number by splitting in two when they reach a certain size.

Concept Check 6.5

1. Describe at least two common characteristics of chloroplasts and mitochondria.
2. Explain the characteristics of mitochondria and chloroplasts that place them in a separate category from organelles in the endomembrane system.

For suggested answers, see Appendix A.

At> Figure 6.19 Peroxisomes. Peroxisomes are roughly spherical and often have a granular or crystalline core that is thought to be a dense collection of enzyme molecules. This peroxisome is in a leaf cell. Notice its proximity to two chloroplasts and a mitochondrion. These organelles cooperate with peroxisomes in certain metabolic functions (TEM).

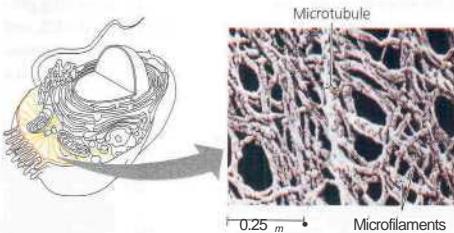

The cytoskeleton is a network of fibers that organizes structures and activities in the cell

In the early days of electron microscopy, biologists thought that the organelles of a eukaryotic cell floated freely in the cytosol. But improvements in both light microscopy and electron microscopy have revealed the cytoskeleton, a network of fibers extending throughout the cytoplasm (**Figure 6.20**). The cytoskeleton, which plays a major role in organizing the structures and activities of the cell, is composed of three types of molecular structures: microtubules, microfilaments, and intermediate filaments (**Table 6.1**).

Roles of the Cytoskeleton: Support, Motility, and Regulation

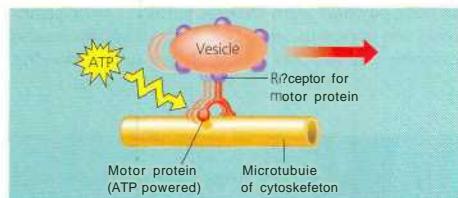

The most obvious function of the cytoskeleton is to give mechanical support to the cell and maintain its shape. This is especially important for animal cells, which lack walls. The remarkable strength and resilience of the cytoskeleton as a whole is based on its architecture. Like a geodesic dome, the cytoskeleton is stabilized by a balance between opposing forces exerted by its elements. And just as the skeleton of an animal helps fix the positions of other body parts, the cytoskeleton provides anchorage for many organelles and even cytosolic enzyme molecules. The cytoskeleton is more dynamic than an animal skeleton, however. It can be quickly dismantled in one part of the cell and reassembled in a new location, changing the shape of the cell.

The cytoskeleton is also involved in several types of cell motility (movement). The term *cell motility* encompasses both

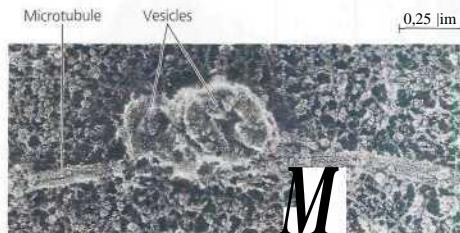

A Figure 6.20 The cytoskeleton. In this TEM, prepared by a method known as deep-etching, the thicker, hollow microtubules and the thinner, solid microfilaments are visible. A third component of the cytoskeleton, intermediate filaments, is not evident here.

changes in cell location and more limited movements of parts of the cell. Cell motility generally requires the interaction of the cytoskeleton with proteins called motor proteins. Examples of such cell motility abound. Cytoskeletal elements and motor proteins work together with plasma membrane molecules to allow whole cells to move along fibers outside the cell. Motor proteins bring about the movements of cilia and flagella by gripping microtubules within those organelles and propelling them past each other. A similar mechanism involving microfilaments causes muscle cells to contract. Inside the cell, vesicles often travel to their destinations along "monorails" provided by the cytoskeleton. For example, this is how vesicles containing neurotransmitter molecules migrate to the tips of axons, the long extensions of nerve cells that release these molecules as chemical signals to adjacent nerve cells (**Figure 6.21**). The vesicles that bud off from the ER travel to the Golgi along tracks built of cytoskeletal elements. It is the cytoskeleton that manipulates the plasma membrane to form food vacuoles during phagocytosis. Finally, the streaming of cytoplasm that circulates materials within many large plant cells is yet another kind of cellular movement brought about by components of the cytoskeleton.

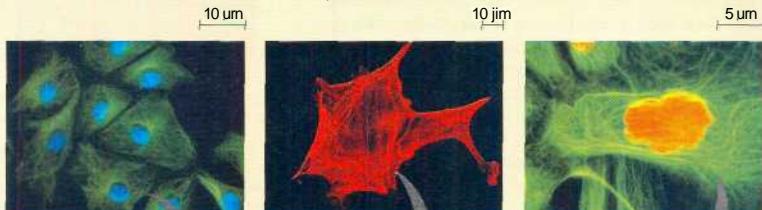

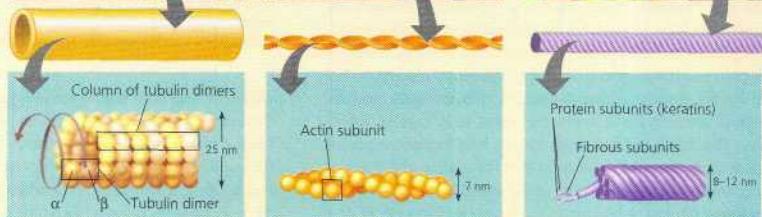

(a) Motor proteins that attach to receptors on organelles can "walk" the organelles along microtubules or, in some cases, microfilaments.

(b) Vesicles containing neurotransmitters migrate to the tips of nerve cell axons via the mechanism in (a). In this SEM of a squid giant axon, two vesicles can be seen moving along a microtubule. (A separate part of the experiment provided the evidence that they were in fact moving.)

A Figure 6.21 Motor proteins and the cytoskeleton.

Table 6.1 The Structure and Function of the Cytoskeleton

| Property | Microtubules (Tubulin Polymers) | Microfilaments (Actin Filaments) | Intermediate Filaments |
|---|--|--|--|
| Structure | Hollow tubes; wall consists of 13 columns of tubulin molecules | Two intertwined strands of actin, each a polymer of actin subunits | Fibrous proteins supercoiled into thicker cables |
| Diameter | 25 nm with 15-nm lumen | 7 nm | 8–12 nm |
| Protein subunits | Tubulin, consisting of α-tubulin and β-tubulin | Actin | One of several different proteins of the keratin family, depending on cell type |
| Main functions | Maintenance of cell shape (compression-resisting "girders") Cell motility (as in cilia or flagella) Chromosome movements in cell division Organelle movements | Maintenance of cell shape (tension-bearing elements) Changes in cell shape Muscle contraction Cytoplasmic streaming Cell motility (as in pseudopodia) Cell division (cleavage furrow formation) | Maintenance of cell shape (tension-bearing elements) Anchorage of nucleus and certain other organelles Formation of nuclear lamina |

|  | | | |

Micrographs of fibroblasts, a favorite cell type for cell biology studies. Each has been experimentally treated to fluorescently tag the structure of interest.

The most recent addition to the list of possible cytoskeletal functions is the regulation of biochemical activities in the cell. Mounting evidence suggests that the cytoskeleton can transmit mechanical forces exerted by extracellular molecules via surface proteins of the cell to its interior—and even into the nucleus. In one experiment, investigators used a micro-manipulation device to pull on certain plasma membrane proteins attached to the cytoskeleton. A video microscope captured almost instantaneous rearrangements of nucleoli and other structures in the nucleus. In this way, the transmission of

naturally occurring mechanical signals by the cytoskeleton may help regulate cell function.

Components of the Cytoskeleton

Now let's look more closely at the three main types of fibers that make up the cytoskeleton (see Table 6.1). Microtubules are the thickest of the three types; microfilaments (also called actin filaments) are the thinnest; and intermediate filaments are fibers with diameters in a middle range.

Microtubules

Microtubules are found in the cytoplasm of all eukaryotic cells. They are hollow rods measuring about 25 nm in diameter and from 200 nm to 25 μm in length. The wall of the hollow tube is constructed from a globular protein called tubulin. Each tubulin molecule is a dimer consisting of two slightly different polypeptide subunits, α -tubulin and β -tubulin. A microtubule grows in length by adding tubulin dimers to its ends. Microtubules can be disassembled and their tubulin used to build microtubules elsewhere in the cell.

Microtubules shape and support the cell and also serve as tracks along which organelles equipped with motor proteins can move (see Figure 6.21). For example, microtubules guide secretory vesicles from the Golgi apparatus to the plasma membrane. Microtubules are also responsible for the separation of chromosomes during cell division (see Chapter 12).

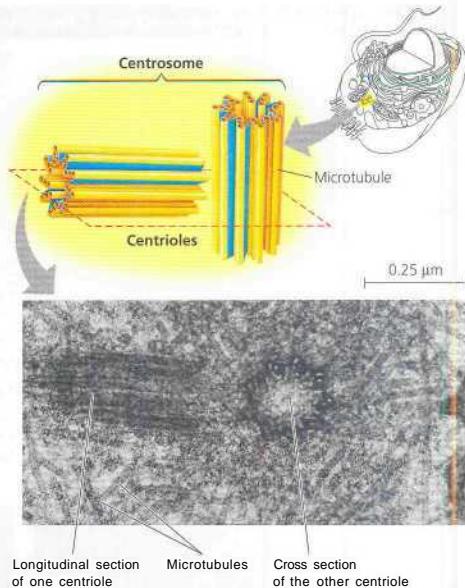

Centrosomes and Centrioles. In many cells, microtubules grow out from a centrosome, a region often located near the nucleus that is considered to be a "microtubule-organizing center." These microtubules function as compression-resisting girders of the cytoskeleton. Within the centrosome of an animal cell are a pair of centrioles, each composed of nine sets of triplet microtubules arranged in a ring (Figure 6.22). Before a cell divides, the centrioles replicate. Although centrioles may help organize microtubule assembly, they are not essential for this function in all eukaryotes; centrosomes of most plants lack centrioles, but have well-organized microtubules.

Cilia and Flagella. In eukaryotes, a specialized arrangement of microtubules is responsible for the beating of flagella (singular, *flagellum*) and cilia (singular, *cilium*), locomotor appendages that protrude from some cells. Many unicellular eukaryotic organisms are propelled through water by cilia or flagella, and the sperm of animals, algae, and some plants have flagella. When cilia or flagella extend from cells that are held in place as part of a tissue layer, they can move fluid over the surface of the tissue. For example, the ciliated lining of the windpipe sweeps mucus containing trapped debris out of the lungs (see Figure 6.4). In a woman's reproductive tract, the cilia lining the oviducts (fallopian tubes) help move an egg toward the uterus.

Cilia usually occur in large numbers on the cell surface. They are about 0.25 μm in diameter and about 2–20 μm in length. Flagella are the same diameter but longer than cilia, measuring 10–200 μm in length. Also, flagella are usually limited to just one or a few per cell.

Flagella and cilia differ in their beating patterns (Figure 6.23). A flagellum has an undulating motion that generates force in the same direction as the flagellum's axis. In contrast, cilia work more like oars, with alternating power and recovery strokes generating force in a direction perpendicular to the cilium's axis.

Though different in length, number per cell, and beating pattern, cilia and flagella share a common ultrastructure. A

A Figure 6.22 Centrosome containing a pair of centrioles.

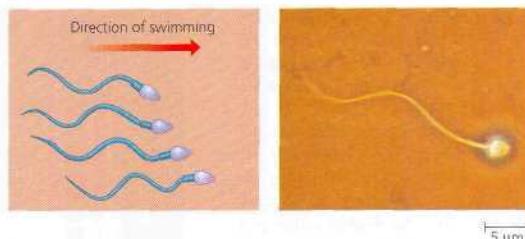

An animal cell has a pair of centrioles within its centrosome, the region near the nucleus where the cell's microtubules are initiated. The centrioles, each about 250 nm (0.25 μm) in diameter, are found at right angles to each other, and each is made up of nine sets of three microtubules. The blue portions of the drawing represent nontubulin proteins that connect the microtubule triplets (TEM).

cilium or flagellum has a core of microtubules sheathed in an extension of the plasma membrane (Figure 6.24). Nine doublets of microtubules, the members of each pair sharing part of their walls, are arranged in a ring. In the center of the ring are two single microtubules. This arrangement, referred to as the "9 + 2" pattern, is found in nearly all eukaryotic flagella and cilia. (The flagella of motile prokaryotes, discussed in Chapter 27, do not contain microtubules.) Flexible "wagon wheels" of cross-linking proteins, evenly spaced along the length of the cilium or flagellum, connect the outer doublets to each other (the wheel rim) and to the two central microtubules (the wheel spokes). Each outer doublet also has pairs of side-arms spaced along its length and reaching toward the neighboring doublet; these are motor proteins. The microtubule assembly of a cilium or flagellum is anchored in the cell by a basal body, which is structurally identical to a centriole. In fact, in many animals (including humans), the basal body of the fertilizing sperm's flagellum enters the egg and becomes a centriole.

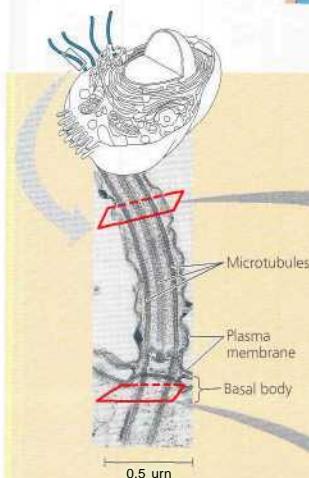

Each motor protein extending from one microtubule doublet to the next is a large protein called dynein, which is composed

▲ Figure 6.23
A comparison of the beating of flagella and cilia.

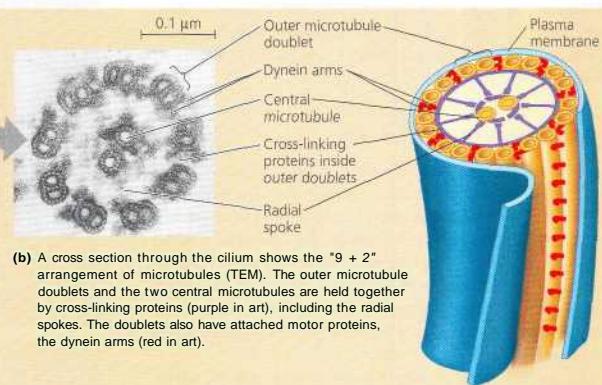

(a) Motion of flagella. A flagellum usually undulates, its snakelike motion driving a cell in the same direction as the axis of the flagellum. Propulsion of a human sperm cell is an example of flagellate locomotion (LM).

(b) Motion of cilia. Cilia have a back-and-forth motion that moves the cell in a direction perpendicular to the axis of the cilium. A dense nap of cilia, beating at a rate of about 40 to 60 strokes a second, covers this *Colpidium*, a freshwater protozoan (SEM).

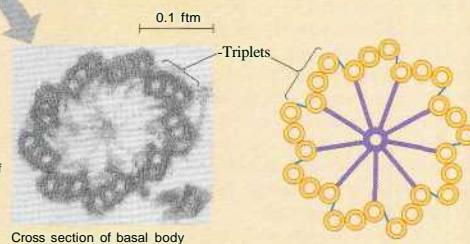

(a) A longitudinal section of a cilium shows microtubules running the length of the structure (TEM).

(b) A cross section through the "9 + 2" arrangement of microtubules (TEM). The outer microtubule doublets and the two central microtubules are held together by cross-linking proteins (purple in art), including the radial spokes. The doublets also have attached motor proteins, the dynein arms (red in art).

(c) Basal body: The nine outer doublets of a cilium or flagellum extend into the basal body, where each doublet joins another microtubule to form a ring of nine triplets. Each triplet is connected to the next by non-tubulin proteins (blue). The two central microtubules terminate above the basal body (TEM).

▲ Figure 6.24 Ultrastructure of a eukaryotic flagellum or cilium.

of several polypeptides. These dynein arms are responsible for the bending movements of cilia and flagella. A dynein arm performs a complex cycle of movements caused by changes in the conformation of the protein, with ATP providing the energy for these changes (**Figure 6.25**).

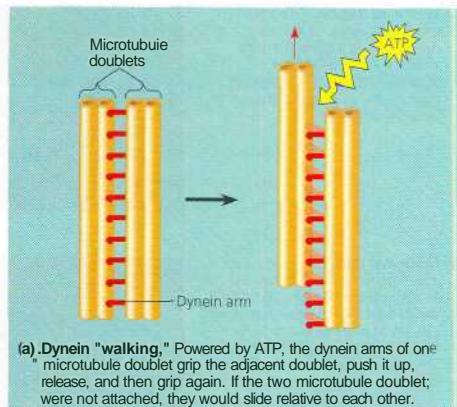

The mechanics of dynein "walking" are reminiscent of a cat climbing a tree by attaching its claws, moving its legs, releasing its front claws, and grabbing again farther up the tree. Similarly, the dynein arms of one doublet attach to an adjacent doublet and pull so that the doublets slide past each other in opposite directions. The arms then release from the other doublet and reattach a little farther along its length. Without any restraints on the movement of the microtubule doublets, one doublet would continue to "walk" along and slide past the surface of the other, elongating the cilium or flagellum rather than bending it (see Figure 6.25a). For lateral movement of a cilium or flagellum, the dynein "walking" must have something to pull against, as when the muscles in your leg pull against your bones to move your knee. In cilia and flagella, the microtubule doublets seem to be held in place by the cross-linking proteins just inside the outer doublets and by the radial spokes and other structural elements. Thus, neighboring doublets cannot slide past each other very far. Instead, the forces exerted by the dynein arms cause the doublets to curve, bending the cilium or flagellum (see Figure 6.25b and c).

Microfilaments (Actin Filaments)

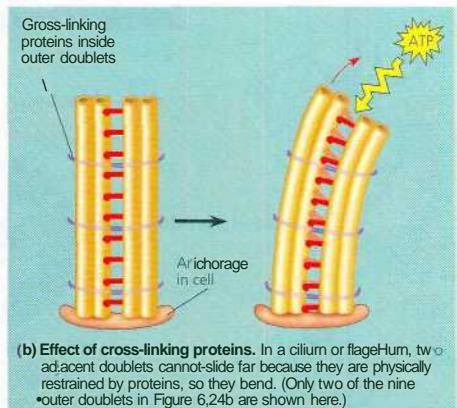

Microfilaments are solid rods about 7 nm in diameter. They are also called actin filaments, because they are built from molecules of actin, a globular protein. A microfilament is a twisted double chain of actin subunits (see Table 6.1). Besides occurring as linear filaments, microfilaments can form structural networks, due to the presence of proteins that bind along the side of an actin filament and allow a new filament to extend as a branch. Microfilaments seem to be present in all eukaryotic cells.

In contrast to the compression-resisting role of microtubules, the structural role of microfilaments in the cytoskeleton is to bear tension (pulling forces). The ability of microfilaments to form a three-dimensional network just inside the plasma membrane helps support the cell's shape. This network gives the cortex (outer cytoplasmic layer) of a cell the semisolid consistency of a gel, in contrast with the more fluid (sol) state of the interior cytoplasm. In animal cells specialized for transporting materials across the plasma membrane, such as intestinal cells, bundles of microfilaments make up the core of microvilli, the previously mentioned delicate projections that increase the cell surface area (**Figure 6.26**).

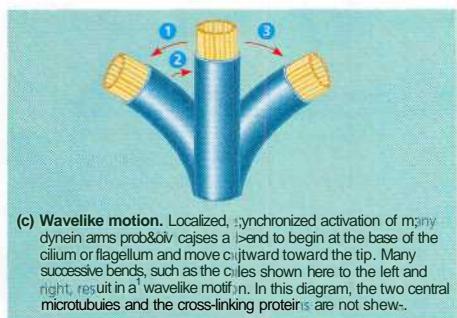

Microfilaments are well known for their role in cell motility, particularly as part of the contractile apparatus of muscle

(a) Dynein "walking." Powered by ATP, the dynein arms of one microtubule doublet grip the adjacent doublet, push it up, release, and then grip again. If the two microtubule doublets were not attached, they would slide relative to each other.

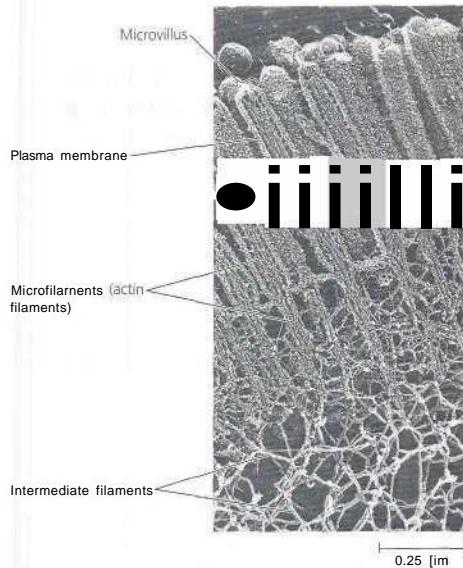

(b) Effect of cross-linking proteins. In a cilium or flagellum, two adjacent doublets cannot slide far because they are physically restrained by proteins, so they bend. (Only two of the nine outer doublets in Figure 6.24b are shown here.)

(c) Wavelike motion. Localized, synchronized activation of many dynein arms causes each cilium to begin at the base of the cilium or flagellum and move outward toward the tip. Many successive bends, such as the cilia shown here to the left and right, result in a wavelike motion. In this diagram, the two central microtubules and the cross-linking proteins are not shown.

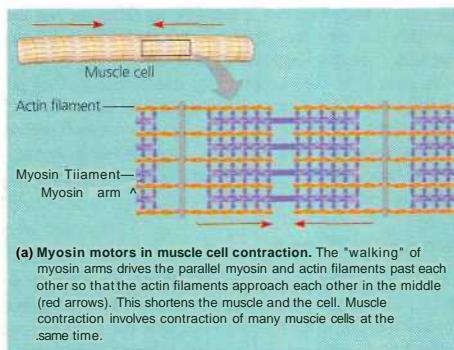

* **Figure 6.25 How dynein "walking" moves flagella and cilia.**

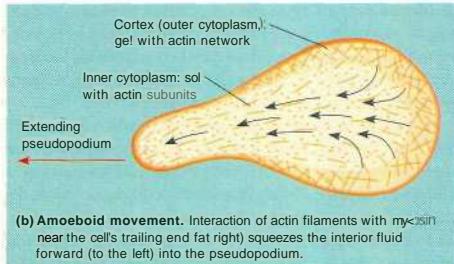

& Figure 6.26 A structural role of microfilaments. The surface area of this nutrient-absorbing intestinal cell is increased by its many microvilli (singular, microvillus), cellular extensions reinforced by bundles of microfilaments. These actin filaments are anchored to a network of intermediate filaments (TEM).

cells. Thousands of actin filaments are arranged parallel to one another along the length of a muscle cell, interdigitated with thicker filaments made of a protein called myosin (**Figure 6.27a**). Myosin acts as a motor protein by means of projections (arms) that "walk" along the actin filaments. Contraction of the muscle cell results from the actin and myosin filaments sliding past one another in this way, shortening the cell. In other kinds of cells, actin filaments are associated with myosin in miniature and less elaborate versions of the arrangement in muscle cells. These actin-myosin aggregates are responsible for localized contractions of cells. For example, a contracting belt of microfilaments forms a cleavage furrow that pinches a dividing animal cell into two daughter cells.

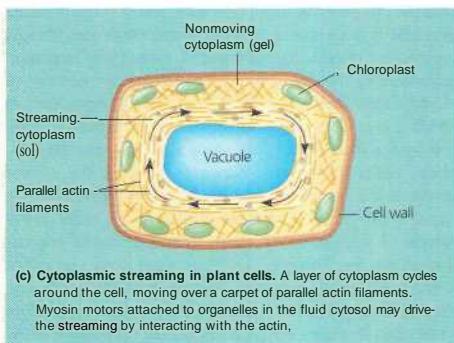

Localized contraction brought about by actin and myosin also plays a role in amoeboid movement (**Figure 6.27b**), in which a cell, such as an amoeba, for example, crawls along a surface by extending and flowing into cellular extensions called pseudopodia (from the Greek *pseudos*, false, and *pod*, foot). Pseudopodia extend and contract through the reversible assembly of actin subunits into microfilaments and of microfilaments into networks that convert cytoplasm from sol to

(a) Myosin motors in muscle cell contraction. The "walking" of myosin arms drives the parallel myosin and actin filaments past each other so that the actin filaments approach each other in the middle (red arrows). This shortens the muscle and the cell. Muscle contraction involves contraction of many muscle cells at the same time.

(b) Amoeboid movement. Interaction of actin filaments with myosin near the cell's trailing end (at right) squeezes the interior fluid forward (to the left) into the pseudopodium.

(c) Cytoplasmic streaming in plant cells. A layer of cytoplasm cycles around the cell, moving over a carpet of parallel actin filaments. Myosin motors attached to organelles in the fluid cytosol may drive the streaming by interacting with the actin.

A Figure 6.27 Microfilaments and motility. In the three examples shown in this figure, cell nuclei and most other organelles have been omitted for clarity.

gel. According to a widely accepted model, filaments near the cell's trailing end interact with myosin, causing contraction. Like squeezing on a toothpaste tube, this contraction forces the interior fluid into the pseudopodium, where the actin network has been weakened. The pseudopodium extends until

the actin reassembles into a network. Amoebas are not the only cells that move by crawling; so do many cells in the animal body, including some white blood cells.

In plant cells, both actin-myosin interactions and sol-gel transformations brought about by actin may be involved in cytoplasmic streaming, a circular flow of cytoplasm within cells (**Figure 6.27c**). This movement, which is especially common in large plant cells, speeds the distribution of materials within the cell.

Intermediate Filaments

Intermediate filaments are named for their diameter, which, at 8–12 nm, is larger than the diameter of microfilaments but smaller than that of microtubules (see Table 6.1, p. 113). Specialized for bearing tension (like microfilaments), intermediate filaments are a diverse class of cytoskeletal elements. Each type is constructed from a different molecular subunit belonging to a family of proteins whose members include the keratins. Microtubules and microfilaments, in contrast, are consistent in diameter and composition in all eukaryotic cells.

Intermediate filaments are more permanent fixtures of cells than are microfilaments and microtubules, which are often disassembled and reassembled in various parts of a cell. Even after cells die, intermediate filament networks often persist; for example, the outer layer of our skin consists of dead skin cells full of keratin proteins. Chemical treatments that remove microfilaments and microtubules from the cytoplasm of living cells leave a web of intermediate filaments that retains its original shape. Such experiments suggest that intermediate filaments are especially important in reinforcing the shape of a cell and fixing the position of certain organelles. For example, the nucleus commonly sits within a cage made of intermediate filaments, fixed in location by branches of the filaments that extend into the cytoplasm. Other intermediate filaments make up the nuclear lamina that lines the interior of the nuclear envelope (see Figure 6.10). In cases where the shape of the entire cell is correlated with function, intermediate filaments support that shape. For instance, the long extensions (axons) of nerve cells that transmit impulses are strengthened by one class of intermediate filament. Thus, the various kinds of intermediate filaments may function as the framework of the entire cytoskeleton.

Concept Check 6.6

1. Describe how the properties of microtubules, microfilaments, and intermediate filaments allow them to determine cell shape.
2. How do cilia and flagella bend?

For suggested answers, see Appendix A.

Concept 6.7

Extracellular components and connections between cells help coordinate cellular activities

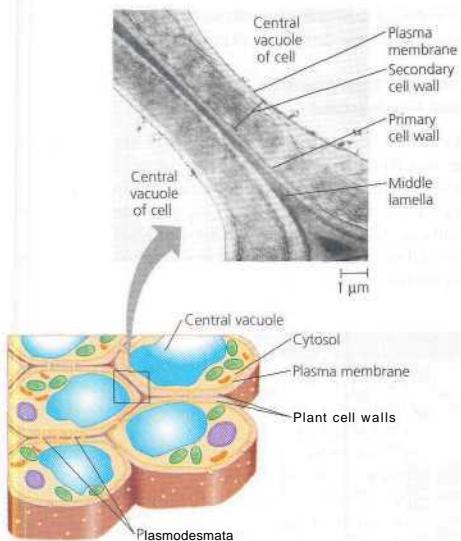

Having crisscrossed the interior of the cell to explore various organelles, we complete our tour of the cell by returning to the surface of this microscopic world, where there are additional structures with important functions. The plasma membrane is usually regarded as the boundary of the living cell, but most cells synthesize and secrete materials of one kind or another that are external to the plasma membrane. Although they are outside the cell, the study of these extracellular structures is central to cell biology because they are involved in so many cellular functions.

Cell Walls of Plants

The cell wall is an extracellular structure of plant cells that distinguishes them from animal cells. The wall protects the plant cell, maintains its shape, and prevents excessive uptake of water. On the level of the whole plant, the strong walls of specialized cells hold the plant up against the force of gravity. Prokaryotes, fungi, and some protists also have cell walls, but we will postpone discussion of them until Unit Five.

Plant cell walls are much thicker than the plasma membrane, ranging from 0.1 μm to several micrometers. The exact chemical composition of the wall varies from species to species and even from one cell type to another in the same plant, but the basic design of the wall is consistent. Microfibrils made of the polysaccharide cellulose (see Figure 5.8) are embedded in a matrix of other polysaccharides and protein. This combination of materials, strong fibers in a "ground substance" (matrix), is the same basic architectural design found in steel-reinforced concrete and in fiberglass.

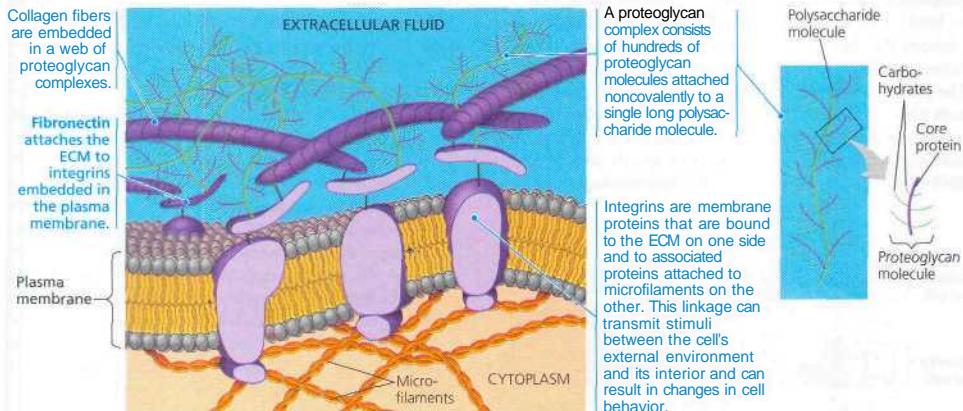

A young plant cell first secretes a relatively thin and flexible wall called the primary cell wall (**Figure 6.28**). Between primary walls of adjacent cells is the middle lamella, a thin layer rich in sticky polysaccharides called pectins. The middle lamella glues adjacent cells together (pectin is used as a thickening agent in jams and jellies). When the cell matures and stops growing, it strengthens its wall. Some plant cells do this simply by secreting hardening substances into the primary wall. Other cells add a secondary cell wall between the plasma membrane and the primary wall. The secondary wall, often deposited in several laminated layers, has a strong and durable matrix that affords the cell protection and support. Wood, for example, consists mainly of secondary walls. Plant cell walls are commonly perforated by channels between adjacent cells called plasmodesmata (see Figure 6.28), which will be discussed shortly.

iii Figure 6.28 Plant cell walls. The orientation drawing shows several cells, each with a large vacuole, a nucleus, and several chloroplasts and mitochondria. The transmission electron micrograph (TEM) shows the cell walls where two cells come together. The multilayered partition between plant cells consists of adjoining walls individually secreted by the cells.

The Extracellular Matrix (ECM) of Animal Cells

Although animal cells lack walls akin to those of plant cells, they do have an elaborate **extracellular matrix (ECM)** (Figure 6.29). The main ingredients of the ECM are glycoproteins secreted by the cells. (Recall that glycoproteins are proteins with covalently bonded carbohydrate, usually short chains of sugars.) The most abundant glycoprotein in the ECM of most animal cells is **collagen**, which forms strong fibers outside the cells. In fact, collagen accounts for about half of the total protein in the human body. The collagen fibers are embedded in a network woven from proteoglycans, which are glycoproteins of another class. A proteoglycan molecule consists of a small core protein with many carbohydrate chains covalently attached, so that it may be up to 95% carbohydrate. Large proteoglycan complexes can form when hundreds of proteoglycans become noncovalently attached to a single long polysaccharide molecule, as shown in Figure 6.29. Some cells are attached to the ECM by still other ECM glycoproteins, including **fibronectin**. Fibronectin and other ECM proteins bind to cell surface receptor proteins called integrins that are built into the plasma membrane. Integrins span the membrane and bind on their cytoplasmic side to associated proteins attached to microfilaments of the cytoskeleton. The name integrin is based on the word *integrate*: Integrins are in a position to transmit changes between the ECM and the cytoskeleton and thus to integrate changes occurring outside and inside the cell.

A. Figure 6.29 Extracellular matrix (ECM) of an animal cell. The molecular composition and structure of the ECM varies from one cell type to another. In this example, three different types of glycoproteins are present: proteoglycans, collagen, and fibronectin.

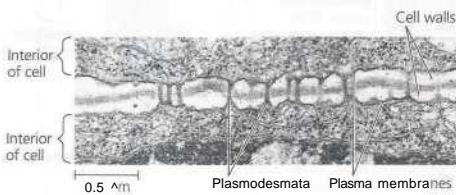

Current research on fibronectin, other ECM molecules, and integrins is revealing the influential role of the extracellular matrix in the lives of cells. By communicating with a cell through integrins, the ECM can regulate a cell's behavior. For example, some cells in a developing embryo migrate along specific pathways by matching the orientation of their microfilaments to the "grain" of fibers in the extracellular matrix. Researchers are also learning that the extracellular matrix around a cell can influence the activity of genes in the nucleus. Information about the ECM probably reaches the nucleus by a combination of mechanical and chemical signaling pathways. Mechanical signaling involves fibronectin, integrins, and microfilaments of the cytoskeleton. Changes in the cytoskeleton may in turn trigger chemical signaling pathways inside the cell, leading to changes in the set of proteins being made by the cell and therefore changes in the cell's function. In this way, the extracellular matrix of a particular tissue may help coordinate the behavior of all the cells within that tissue. Direct connections between cells also function in this coordination, as we discuss next.

Intercellular Junctions

The many cells of an animal or plant are organized into tissues, organs, and organ systems. Neighboring cells often adhere, interact, and communicate through special patches of direct physical contact.

Plants: Plasmodesmata

It might seem that the nonliving cell walls of plants would isolate cells from one another. But in fact, as shown in **Figure 6.30**, plant cell walls are perforated with channels called plasmodesmata (singular, *plasmodesma*; from the Greek *desmos*, to bind). Cytosol passes through the plasmodesmata and connects the chemical environments of adjacent cells. These connections unify most of the plant into one living continuum. The plasma membranes of adjacent cells line the channel of each plasmodesma and thus are continuous. Water and small solutes can pass freely from cell to cell, and recent experiments have shown that in certain circumstances, specific proteins and RNA molecules can also do this. The macromolecules to be

A Figure 6.30 Plasmodesmata between plant cells. The cytoplasm of one plant cell is continuous with the cytoplasm of its neighbors via plasmodesmata, channels through the cell walls (TEM).

transported to neighboring cells seem to reach the plasmodesmata by moving along fibers of the cytoskeleton.

Animals: Tight Junctions, Desmosomes, and Gap Junctions

In animals, there are three main types of intercellular junctions: *tight junctions*, *desmosomes*, and *gap junctions* (which are most like the plasmodesmata of plants). All three types are especially common in epithelial tissue, which lines the internal surfaces of the body. **Figure 6.31** uses epithelial cells of the intestinal lining to illustrate these junctions: please study this figure before moving on.

Concept Check 6.7

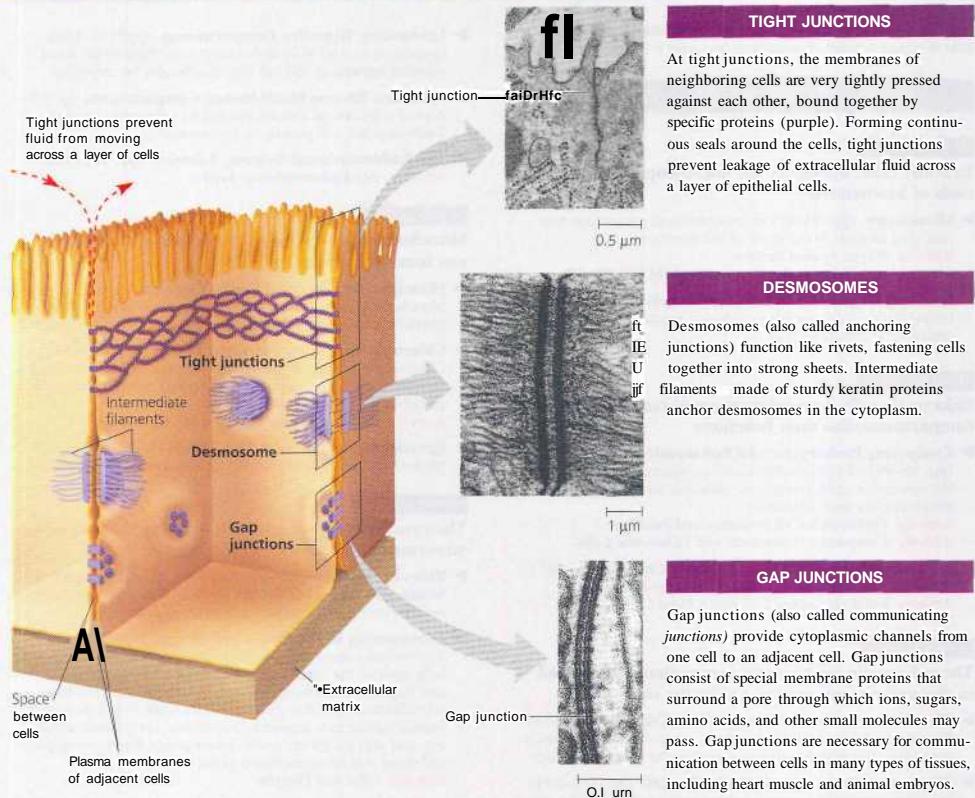

1. In what ways are the cells of multicellular plants and animals structurally different from single-celled plants or animals?
2. What characteristics of the plant cell wall and animal cell extracellular matrix allow the cells to fulfill their need to exchange matter and information with their external environment?

For suggested answers, see Appendix A.

The Cell: A Living Unit Greater Than the Sum of Its Parts

From our panoramic view of the cell's overall compartmental organization to our close-up inspection of each organelles architecture, this tour of the cell has provided many opportunities to correlate structure with function. (This would be a good time to review cell structure by returning to Figure 6.9, pp. 100 and 101.) But even as we dissect the cell, remember that none of its organelles works alone. As an example of cellular integration, consider the microscopic scene in **Figure 6.32**. The large cell is a macrophage (see Figure 6.14a). It helps defend the body against infections by ingesting bacteria (the smaller cells) into phagocytic vesicles. The macrophage crawls along a surface and reaches out to the bacteria with thin pseudopodia (called filopodia). Actin filaments interact with other elements of the cytoskeleton in these movements. After the macrophage engulfs the bacteria, they are destroyed by lysosomes. The elaborate endomembrane system produces the lysosomes. The digestive enzymes of the lysosomes and the proteins of the cytoskeleton are all made on ribosomes. And the synthesis of these proteins is programmed by genetic messages dispatched from the DNA in the nucleus. All these processes require energy, which mitochondria supply in the form of ATP. Cellular functions arise from cellular order: The cell is a living unit greater than the sum of its parts.

Exploring Intercellular Junctions in Animal Tissues

> **Figure 6.32 The emergence of cellular functions from the cooperation of many organelles.** The ability of this macrophage (brown) to recognize, apprehend, and destroy bacteria (yellow) is a coordinated activity of the whole cell. Its cytoskeleton, lysosomes, and plasma membrane are among the components that function in phagocytosis (colorized SEM).

Chapter 6 Review

QQ to the Campbell BioQgy website (www.wmpbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 6.1

To study cells, biologists use microscopes and the tools of biochemistry

- **Microscopy** (pp. 95-97) Improvements in microscopy have catalyzed progress in the study of cell structure.
Activity Metric System Review
Investigation *What Is the Size and Scale of Our World?*
- **Isolating Organelles by Cell Fractionation** (p. 97) Cell biologists can obtain pellets enriched in specific organelles by centrifuging disrupted cells.

Concept 6.2

Eukaryotic cells have internal membranes that compartmentalize their functions

- **Comparing Prokaryotic and Eukaryotic Cells** (pp. 98-99) All cells are bounded by a plasma membrane. Unlike eukaryotic cells, prokaryotic cells lack nuclei and other membrane-enclosed organelles.
Activity Prokaryotic Cell Structure and Function
Activity Comparing Prokaryotic and Eukaryotic Cells
- **A Panoramic View of the Eukaryotic Cell** (pp. 99-101) Plant and animal cells have most of the same organelles.
Activity Build an Animal Cell and a Plant Cell

Concept 6.3

The eukaryotic cell's genetic instructions are housed in the nucleus and carried out by the ribosomes

- **The Nucleus: Genetic Library of the Cell** (pp. 102-103) The nucleus houses DNA and nucleoli, where ribosomal subunits are made. Materials pass through pores in the nuclear envelope.
- **Ribosomes: Protein Factories in the Cell** (pp. 102-104) Free ribosomes in the cytosol and bound ribosomes on the outside of the ER and the nuclear envelope synthesize proteins.
Activity Role of the Nucleus and Ribosomes in Protein Synthesis

Concept 6.4

The endomembrane system regulates protein traffic and performs metabolic functions in the cell

- The membranes of the endomembrane system are connected by physical continuity or through transport vesicles (p. 104).
- **The Endoplasmic Reticulum: Biosynthetic Factory** (pp. 104-105) Smooth ER synthesizes lipids, metabolizes carbohydrates, stores calcium, and detoxifies poisons. Rough ER has bound ribosomes and produces proteins and membranes, which are distributed by transport vesicles from the ER.
- **The Golgi Apparatus: Shipping and Receiving Center** (pp. 105-107) Proteins are transported from the ER to the Golgi, where they are modified, sorted, and released in transport vesicles.

- **Lysosomes: Digestive Compartments** [pp. 107-108] Lysosomes are sacs of hydrolytic enzymes. They break down ingested substances and cell macromolecules for recycling.
- **Vacuoles: Diverse Maintenance Compartments** (p. 108) A plant cell's central vacuole functions in digestion, storage, waste disposal, cell growth, and protection.
- **The Endomembrane System: A Review** (pp. 108-109)
Activity The Endomembrane System

Concept 6.5

Mitochondria and chloroplasts change energy from one form to another

- **Mitochondria: Chemical Energy Conversion** (pp. 109-110) Mitochondria, the sites of cellular respiration, have an outer membrane and an inner membrane that is folded into cristae.
- **Chloroplasts: Capture of Light Energy** (pp. 110-111) Chloroplasts contain pigments that function in photosynthesis. Two membranes surround the fluid stroma, which contains thylakoids stacked into grana.
Activity Build a Chloroplast and a Mitochondrion
- **Peroxisomes: Oxidation** (pp. 110-111) Peroxisomes produce hydrogen peroxide (H_2O_2) and convert it to water.

Concept 6.6

The cytoskeleton is a network of fibers that organizes structures and activities in the cell

- **Roles of the Cytoskeleton: Support, Motility, and Regulation** (pp. 112-113) The cytoskeleton functions in structural support, for the cell, motility, and signal transmission.
- **Components of the Cytoskeleton** (pp. 113-118) Microtubules shape the cell, guide movement of organelles, and help separate the chromosome copies in dividing cells. Cilia and flagella are motile appendages containing microtubules. Microfilaments are thin rods built from actin; they function in muscle contraction, amoeboid movement, cytoplasmic streaming, and support for microvilli. Intermediate filaments support cell shape and fix organelles in place.
Activity Cilia and Flagella

Concept 6.7

Extracellular components and connections between cells help coordinate cellular activities

- **Cell Walls of Plants** (pp. 118-119) Plant cell walls are made of cellulose fibers embedded in other polysaccharides and protein.
- **The Extracellular Matrix (ECM) of Animal Cells** (pp. 119-120) Animal cells secrete glycoproteins that form the ECM, which functions in support, adhesion, movement, and regulation.
- **Intercellular Junctions** (pp. 120-121) Plants have plasmodesmata that pass through adjoining cell walls. Animal cells have tight junctions, desmosomes, and gap junctions.
Activity Cell Junctions
- **The Cell: A Living Unit Greater Than the Sum of Its Parts** (pp. 120-121)

TESTING YOUR KNOWLEDGE

Evolution Connection

Although the similarities among cells reveal the evolutionary unity of life, cells can differ dramatically in structure. Which aspects of cell structure best reveal their evolutionary unity? What are some examples of specialized cellular modifications?

Scientific Inquiry

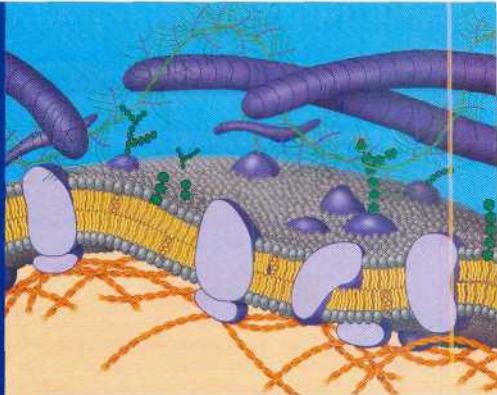

Imagine protein X, destined to go to the plasma membrane of a cell. Assume that the mRNA carrying the genetic message for protein X has already been translated by ribosomes in a cell culture. You collect the cells, break them open, and then fractionate their contents by differential centrifugation as shown in Figure 6.5. In the pellet of which fraction would you expect to find protein X? Explain your answer by describing the transit of protein X through the cell, investigation *What Is the Size and Scale of Our World?*

Science, Technology, and Society

Doctors at a California university removed a man's spleen, standard treatment for a type of leukemia. The disease did not recur. Researchers kept some of the spleen cells alive in a nutrient medium. They found that some of the cells produced a blood protein that showed promise for treating cancer and AIDS. The researchers patented the cells. The patient sued, claiming a share in profits from any products derived from his cells. The California Supreme Court ruled against the patient, stating that his suit "threatens to destroy the economic incentive to conduct important medical research." The U.S. Supreme Court agreed. Do you think the patient was treated fairly? What else would you like to know about this case that might help you make up your mind?

7

Membrane Structure and Function

A. Figure 7.1 The plasma membrane.

Key Concepts

- 7.1 Cellular membranes are fluid mosaics of lipids and proteins
- 7.2 Membrane structure results in selective permeability
- 7.3 Passive transport is diffusion of a substance across a membrane with no energy investment
- 7.4 Active transport uses energy to move solutes against their gradients
- 7.5 Bulk transport across the plasma membrane occurs by exocytosis and endocytosis

Overview

Life at the Edge

The plasma membrane is the edge of life, the boundary that separates the living cell from its nonliving surroundings. A remarkable film only about 8 nm thick—it would take over 8,000 to equal the thickness of this page—the plasma membrane controls traffic into and out of the cell it surrounds. Like all biological membranes, the plasma membrane exhibits **selective permeability**; that is, it allows some substances to cross it more easily than others. One of the earliest episodes in the evolution of life may have been the formation of a membrane that enclosed a solution different from the surrounding solution while still permitting the uptake of nutrients and elimination of waste products. This ability of the cell to discriminate in its chemical exchanges with its environment is fundamental to life, and it is the plasma membrane and its component molecules that make this selectivity possible.

In this chapter, you will learn how cellular membranes control the passage of substances. The importance of selective

permeability was highlighted when the 2003 Nobel Prize in Chemistry was awarded to Peter Agre (see the interview on pp. 92–93) and Roderick MacKinnon, two scientists who worked out how water and specific ions are transported into and out of the cell. We will concentrate on the plasma membrane, the outermost membrane of the cell, represented in **Figure 7.1**. However, the same general principles of membrane traffic also apply to the many varieties of internal membranes that partition the eukaryotic cell. To understand how membranes work, we begin by examining their architecture.

Concept 7.1

Cellular membranes are fluid mosaics of lipids and proteins

Lipids and proteins are the staple ingredients of membranes, although carbohydrates are also important. The most abundant lipids in most membranes are phospholipids. The ability of phospholipids to form membranes is inherent in their molecular structure. A phospholipid is an **amphipathic molecule**, meaning it has both a hydrophilic region and a hydrophobic region (see Figure 5.13). Other types of membrane lipids are also amphipathic. Furthermore, most of the proteins of membranes have both hydrophobic and hydrophilic regions.

How are phospholipids and proteins arranged in the membranes of cells? You encountered the currently accepted model for the arrangement of these molecules in Chapter 6 (see Figure 6.8). In this **fluid mosaic model**, the membrane is a fluid structure with a "mosaic" of various proteins embedded in or attached to a double layer (bilayer) of phospholipids. Well discuss this model in detail, starting with the story of how it was developed.

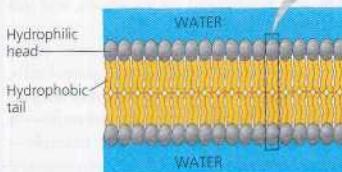

Membrane Models: Scientific Inquiry

Scientists began building molecular models of the membrane decades before membranes were first seen with the electron microscope in the 1950s. In 1915, membranes isolated from red blood cells were chemically analyzed and found to be composed of lipids and proteins. Ten years later, two Dutch scientists, E. Gorter and E. Grendel, reasoned that cell membranes must actually be phospholipid bilayers. Such a double layer of molecules could exist as a stable boundary between two aqueous compartments because the molecular arrangement shelters the hydrophobic tails of the phospholipids from water while exposing the hydrophilic heads to water (Figure 7.2).

With the conclusion that a phospholipid bilayer was the main fabric of a membrane, the next question was where to place the proteins. Although the heads of phospholipids are hydrophilic, the surface of a membrane consisting of a pure phospholipid bilayer adheres less strongly to water than does the surface of a biological membrane. Given these data, in 1935, Hugh Davson and James Danielli suggested that this difference could be accounted for if the membrane were coated on both sides with hydrophilic proteins. They proposed a sandwich model: a phospholipid bilayer between two layers of proteins.

When researchers first used electron microscopes to study cells in the 1950s, the pictures seemed to support the Davson-Danielli model. By the 1960s, the Davson-Danielli sandwich had become widely accepted as the structure not only of the plasma membrane, but of all the internal membranes of the cell. By the end of that decade, however, many cell biologists recognized two problems with the model. First, the generalization that all membranes of the cell are identical was challenged. Whereas the plasma membrane is 7–8 nm thick and has a three-layered structure in electron micrographs, the inner membrane of the mitochondrion is only 6 nm thick and looks like a row of beads. Mitochondria! membranes also have a substantially-greater percentage of proteins than do plasma membranes, and there are differences in the specific kinds of phospholipids and other lipids. In short, membranes with different functions differ in chemical composition and structure.

A second, more serious problem with the sandwich model was the placement of the proteins. Unlike proteins dissolved in the cytosol, membrane proteins are

A Figure 7.2 Phospholipid bilayer (cross section).

not very soluble in water. Membrane proteins have hydrophobic regions as well as hydrophilic regions (that is, they are amphiphatic). If such proteins were layered on the surface of the membrane, their hydrophobic parts would be in an aqueous environment.

In 1972, S. J. Singer and G. Nicolson proposed that membrane proteins are dispersed and individually inserted into the phospholipid bilayer, with only their hydrophilic regions protruding far enough from the bilayer to be exposed to water (Figure 7.3). This molecular arrangement would maximize contact of hydrophilic regions of proteins and phospholipids with water while providing their hydrophobic parts with a nonaqueous environment. According to this model, the membrane is a mosaic of protein molecules bobbing in a fluid bilayer of phospholipids.

A method of preparing cells for electron microscopy called freeze-fracture has demonstrated visually that proteins are indeed embedded in the phospholipid bilayer of the membrane. Freeze-fracture splits a membrane along the middle of the phospholipid bilayer. When the halves of the fractured membrane are viewed in the electron microscope, the interior of the bilayer appears cobblestoned, with protein particles interspersed in a smooth matrix, as in the fluid mosaic model (Figure 7.4, next page). Other kinds of evidence further support this arrangement.

Models are proposed by scientists as hypotheses, ways of organizing and explaining existing information. Replacing one model of membrane structure with another does not imply that the original model was worthless. The acceptance or rejection of a model depends on how well it fits observations and explains experimental results. A good model also makes predictions that shape future research. Models inspire experiments, and few models survive these tests without modification. New findings may make a model obsolete; even then, it may not be totally scrapped, but revised to incorporate the new observations. The fluid mosaic model is continually being refined and may one day undergo further revision.

Now let's take a closer look at membrane structure, beginning with the ability of lipids and proteins to drift laterally within the membrane.

A Figure 7.3 The fluid mosaic model for membranes.

Figure 7.4

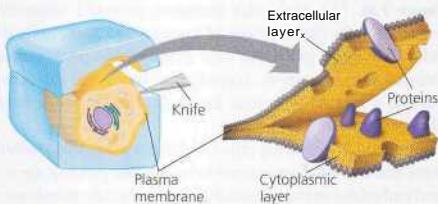

Research Method Freeze-Fracture

APPLICATION

A cell membrane can be split into its two layers, revealing the ultrastructure of the membrane's interior.

TECHNIQUE

A cell is frozen and fractured with a knife. The fracture plane often follows the hydrophobic interior of a membrane, splitting the phospholipid bilayer into two separated layers. The membrane proteins go wholly with one of the layers.

RESULTS

These SEMs show membrane proteins (the "bumps") in the two layers, demonstrating that proteins are embedded in the phospholipid bilayer.

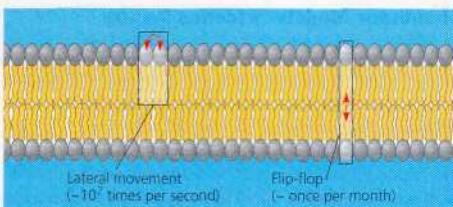

The Fluidity of Membranes

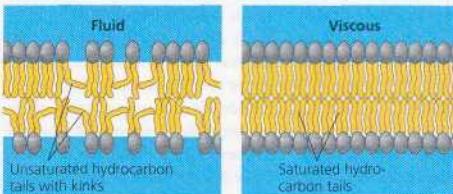

Membranes are not static sheets of molecules locked rigidly in place. A membrane is held together primarily by hydrophobic interactions, which are much weaker than covalent bonds (see Figure 5.20). Most of the lipids and some of the proteins can drift about laterally—that is, in the plane of the membrane (Figure 7.5a). It is quite rare, however, for a molecule to flip-flop transversely across the membrane, switching from one phospholipid layer to the other; to do so, the hydrophilic part of the molecule must cross the hydrophobic core of the membrane.

The lateral movement of phospholipids within the membrane is rapid. Adjacent phospholipids switch positions about 10^7 times per second, which means that a phospholipid can travel about 2 μm—the length of a typical bacterial cell—in 1 second. Proteins are much larger than lipids and move more slowly, but some membrane proteins do, in fact, drift (Figure 7.6). And some membrane proteins seem to move in a highly directed manner, perhaps driven along cytoskeletal fibers by motor proteins connected to the membrane proteins' cytoplasmic regions. However, many other membrane proteins seem to be held virtually immobile by their attachment to the cytoskeleton.

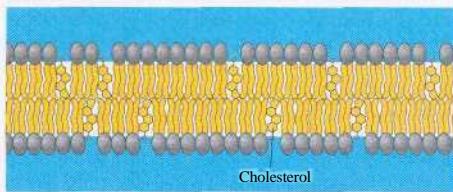

A membrane remains fluid as temperature decreases, until finally the phospholipids settle into a closely packed arrangement and the membrane solidifies, much as bacon grease

(a) Movement of phospholipids. Lipids move laterally in a membrane, but flip-flopping across the membrane is quite rare.

(b) Membrane fluidity. Unsaturated hydrocarbon tails of phospholipids have kinks that keep the molecules from packing together, enhancing membrane fluidity.

(c) Cholesterol within the animal cell membrane. Cholesterol reduces membrane fluidity at moderate temperatures by reducing phospholipid movement, but at low temperatures it hinders solidification by disrupting the regular packing of phospholipids.

A Figure 7.5 The fluidity of membranes.

forms lard when it cools. The temperature at which a membrane solidifies depends on the types of lipids it is made of. The membrane remains fluid to a lower temperature if it is rich in phospholipids with unsaturated hydrocarbon tails (see Figures 5.12 and 5.13). Because of kinks in the tails where double bonds are located, unsaturated hydrocarbons cannot pack together as closely as saturated hydrocarbons, and this makes the membrane more fluid (Figure 7.5b).

The steroid cholesterol, which is wedged between phospholipid molecules in the plasma membranes of animal cells, has different effects on membrane fluidity at different temperatures (Figure 7.5c). At relatively warm temperatures—at 37°C, the body temperature of humans, for example—cholesterol makes the membrane less fluid by restraining the movement of phospholipids. However, because cholesterol

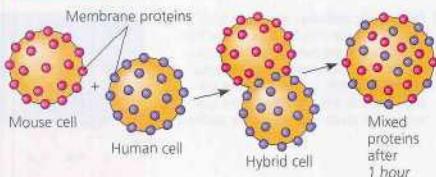

Figure 7.6

Inquiry Do membrane proteins move?

EXPERIMENT

Researchers labeled the plasma membrane proteins of a mouse cell and a human cell with two different markers and fused the cells. Using a microscope, they observed the markers on the hybrid cell.

RESULTS

CONCLUSION

The ~~ATTACHMENT~~ **ATTACHMENT** of

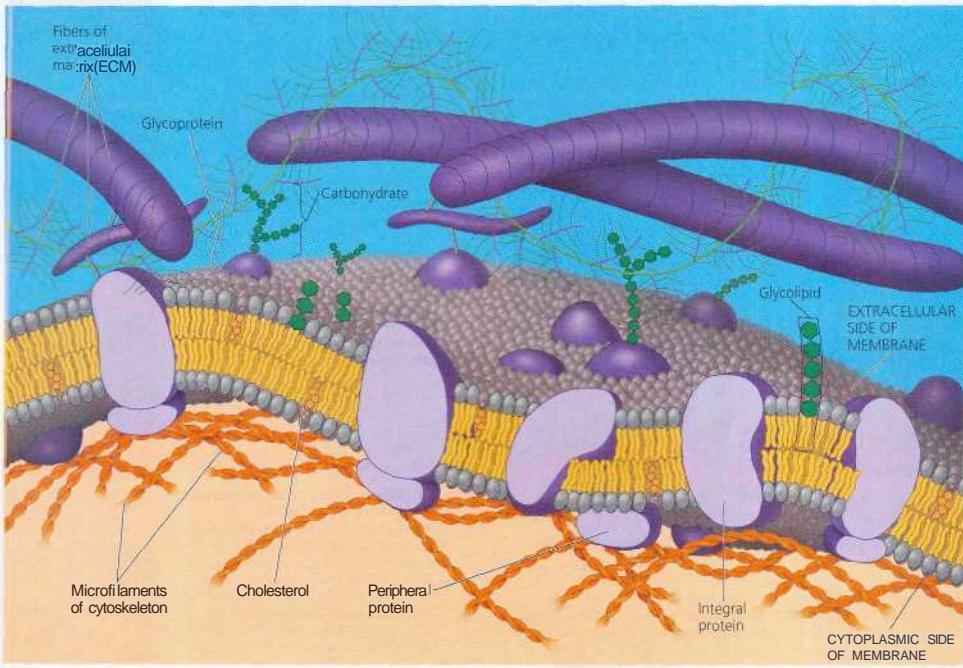

membrane proteins indicates that at least some membrane proteins move sideways within the plane of the plasma membrane.

also hinders the close packing of phospholipids, it lowers the temperature required for the membrane to solidify. Thus, cholesterol can be thought of as a "temperature buffer" for the membrane, resisting changes in membrane fluidity that can be caused by changes in temperature.

Membranes must be fluid to work properly; they are usually about as fluid as salad oil. When a membrane solidifies, its permeability changes, and enzymatic proteins in the membrane may become inactive—for example, if their activity requires them to be able to move laterally in the membrane. The lipid composition of cell membranes can change as an adjustment to changing temperature. For instance, in many plants that tolerate extreme cold, such as winter wheat, the percentage of unsaturated phospholipids increases in autumn, an adaptation that keeps the membranes from solidifying during winter.

Membrane Proteins and Their Functions

Now we come to the *mosaic* aspect of the fluid mosaic model. A membrane is a collage of different proteins embedded in the fluid matrix of the lipid bilayer (Figure 7.7). More than 50 kinds

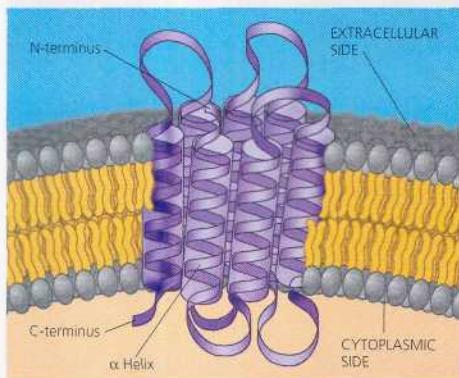

A Figure 7.7 The detailed structure of an animal cell's plasma membrane, in cross section.

of proteins have been found so far in the plasma membrane of red blood cells, for example. Phospholipids form the main fabric of the membrane, but proteins determine most of the membrane's **specific functions**. Different types of cells contain different sets of membrane proteins, and the various membranes within a cell each have a unique collection of proteins.

Notice in Figure 7.7 that there are two major populations of membrane proteins. **Integral proteins** penetrate the hydrophobic core of the lipid bilayer. Many are **transmembrane** proteins, which completely span the membrane. The hydrophobic regions of an integral protein consist of one or more stretches of nonpolar amino acids (see Figure 5.17), usually coiled into **α helices** (Figure 7.8). The hydrophilic parts of the molecule are exposed to the aqueous solutions on either side of the membrane. **Peripheral proteins** are not embedded in the lipid bilayer at all; they are appendages loosely bound to the surface of the membrane, often to the exposed parts of integral proteins (see Figure 7.7).

On the cytoplasmic side of the plasma membrane, some membrane proteins are held in place by attachment to the cytoskeleton. And on the exterior side, certain membrane proteins are attached to fibers of the extracellular matrix (see Figure 6.29; integrins are one type of integral protein). These attachments combine to give animal cells a stronger framework than the plasma membrane itself could provide.

Figure 7.9 gives an overview of six major functions performed by proteins of the plasma membrane. A single cell may

A Figure 7.8 The structure of a transmembrane protein.

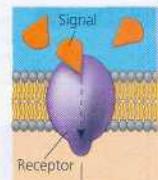

The protein shown here, bacteriorhodopsin (a bacterial transport protein), has a distinct orientation in the membrane, with the N-terminus outside the cell and the C-terminus inside. This ribbon model highlights the α -helical secondary structure of the hydrophobic parts of the protein, which lie mostly within the hydrophobic core of the membrane. The protein includes seven transmembrane helices (outlined with cylinders for emphasis). The nonhelical hydrophilic segments of the protein are in contact with the aqueous solutions on the extracellular and cytoplasmic sides of the membrane.

(a) Transport. (left) A protein that spans the membrane may provide a hydrophilic channel across the membrane that is selective for a particular solute. (right) Other transport proteins shuttle a substance from one side to the other by changing shape. Some of these proteins hydrolyze ATP as an energy source to actively pump substances across the membrane.

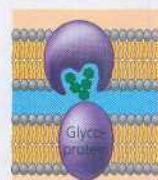

(b) Enzymatic activity. A protein built into the membrane may be an enzyme with its active site exposed to substances in the adjacent solution. In some cases, several enzymes in a membrane are organized as a team that carries out sequential steps of a metabolic pathway.

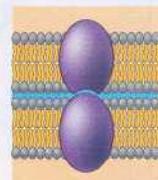

(c) Signal transduction. A membrane protein may have a binding site with a specific shape that fits the shape of a chemical messenger, such as a hormone. The external messenger (signal) may cause a conformational change in the protein (receptor) that relays the message to the inside of the cell.

(d) Cell-cell recognition. Some glycoproteins serve as identification tags that are specifically recognized by other cells.

(e) Intercellular joining. Membrane proteins of adjacent cells may hook together in various kinds of junctions, such as gap junctions or tight junctions (see Figure 6.31).

(f) Attachment to the cytoskeleton and extracellular matrix (ECM). Microfilaments or other elements of the cytoskeleton may be bonded to membrane proteins, a function that helps maintain cell shape and stabilizes the location of certain membrane proteins. Proteins that adhere to the ECM can coordinate extracellular and intracellular changes (see Figure 6.29).

A Figure 7.9 Some functions of membrane proteins. In many cases, a single protein performs some combination of these tasks.

have membrane proteins carrying out several of these functions, and a single protein may have multiple functions. Thus, the membrane is a functional mosaic as well as a structural one.

The Role of Membrane Carbohydrates in Cell-Cell Recognition

Cell-cell recognition, a cell's ability to distinguish one type of neighboring cell from another, is crucial to the functioning of an organism. It is important, for example, in the sorting of cells into tissues and organs in an animal embryo. It is also the basis for the rejection of foreign cells (including those of transplanted organs) by the immune system, an important line of defense in vertebrate animals (see Chapter 43). The way cells recognize other cells is by binding to surface molecules, often carbohydrates, on the plasma membrane (see Figure 7.9d).

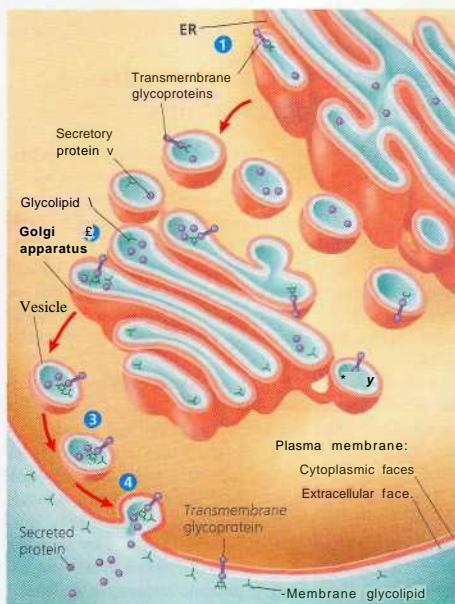

Membrane carbohydrates are usually short, branched chains of fewer than 15 sugar units. Some of these carbohydrates are covalently bonded to lipids, forming molecules called **glycolipids**. (Recall that *glyco* refers to the presence of carbohydrate.) Most, however, are covalently bonded to proteins, which are thereby glycoproteins (see Figure 7.7).

The carbohydrates on the external side of the plasma membrane vary from species to species, among individuals of the same species, and even from one cell type to another in a single individual. The diversity of the molecules and their location on the cell's surface enable membrane carbohydrates to function as markers that distinguish one cell from another. For example, the four human blood types designated A, B, AB, and O reflect variation in the carbohydrates on the surface of red blood cells.

Synthesis and Sidedness of Membranes

Membranes have distinct inside and outside faces. The two lipid layers may differ in specific lipid composition, and each protein has directional orientation in the membrane (see Figure 7.8). When a vesicle fuses with the plasma membrane, the outside layer of the vesicle becomes continuous with the cytoplasmic layer of the plasma membrane. Therefore, molecules that start out on the *inside* face of the ER end up on the *outside* face of the plasma membrane.

The process, shown in **Figure 7.10**, starts with ① the synthesis of membrane proteins and lipids in the endoplasmic reticulum. Carbohydrates (green) are added to the proteins (purple), making them glycoproteins. The carbohydrate portions may then be modified. ② Inside the Golgi apparatus, the glycoproteins undergo further carbohydrate modification, and lipids acquire carbohydrates, becoming glycolipids. ③ Transmembrane proteins (purple dumbbells), membrane glycolipids, and secretory proteins (purple spheres) are transported in vesicles to the plasma membrane. ④ There the vesicles fuse with the membrane, releasing secretory proteins from the cell. Vesicle fusion positions the carbohydrates of membrane

A Figure 7.10 Synthesis of membrane components and their orientation on the resulting membrane. The plasma membrane has distinct cytoplasmic and extracellular sides, or faces, with the extracellular face arising from the inside face of ER, Golgi, and vesicle membranes,

glycoproteins and glycolipids on the outside of the plasma membrane. Thus, the asymmetrical distribution of proteins, lipids, and their associated carbohydrates in the plasma membrane is determined as the membrane is being built by the ER and Golgi apparatus.

Concept Check 7.1

- How would you expect the saturation levels of membrane fatty acids to differ in plants adapted to cold environments and plants adapted to hot environments?
- The carbohydrates attached to some of the proteins and lipids of the plasma membrane are added as the membrane is made and refined in the ER and Golgi apparatus; the new membrane then forms transport vesicles that travel to the cell surface. On which side of the vesicle membrane are the carbohydrates?

For suggested answers, see Appendix A.

Concept 7.2

Membrane structure results in selective permeability

The biological membrane is an exquisite example of a supramolecular structure—many molecules ordered into a higher level of organization—with emergent properties beyond those of the individual molecules. The remainder of this chapter focuses on one of the most important of those properties: the ability to regulate transport across cellular boundaries, a function essential to the cells existence. We will see once again that form fits function: The fluid mosaic model helps explain how membranes regulate the cell's molecular traffic.

A steady traffic of small molecules and ions moves across the plasma membrane in both directions. Consider the chemical exchanges between a muscle cell and the extracellular fluid that bathes it. Sugars, amino acids, and other nutrients enter the cell, and metabolic waste products leave it. The cell takes in oxygen for cellular respiration and expels carbon dioxide. It also regulates its concentrations of inorganic ions, such as Na^+ , K^+ , Ca^{2+} , and Cl^- , by shuttling them one way or the other across the plasma membrane. Although traffic through the membrane is extensive, cell membranes are selectively permeable, and substances do not cross the barrier indiscriminately: The cell is able to take up many varieties of small molecules and ions and exclude others. Moreover, substances that move through the membrane do so at different rates.

The Permeability of the Lipid Bilayer

Hydrophobic (nonpolar) molecules, such as hydrocarbons, carbon dioxide, and oxygen, can dissolve in the lipid bilayer of the membrane and cross it with ease, without the aid of membrane proteins. However, the hydrophobic core of the membrane impedes the direct passage of ions and polar molecules, which are hydrophilic, through the membrane. Polar molecules such as glucose and other sugars pass only slowly through a lipid bilayer, and even water, an extremely small polar molecule, does not cross very rapidly. A charged atom or molecule and its surrounding shell of water (see Figure 3.6) find the hydrophobic layer of the membrane even more difficult to penetrate. Fortunately, the lipid bilayer is only part of the story of a membranes selective permeability. Proteins built into the membrane play key roles in regulating transport.

Transport Proteins

Cell membranes are permeable to specific ions and a variety of polar molecules. These hydrophilic substances can avoid

contact with the lipid bilayer by passing through **transport proteins** that span the membrane. Some transport protein^s, called *channel proteins*, function by having a hydrophilic channel that certain molecules or atomic ions use as a tunnel through the membrane (see Figure 7.9a, left). For example, the passage of water molecules through the membrane in certain cells is greatly facilitated by channel proteins known as aquaporins. (These were discovered in the laboratory of Peter Agre; see pp. 92–93.) Other transport proteins, called *carrier proteins*, hold onto their passengers and change shape in a way that shuttles them across the membrane (see Figure 7.9a, right). In both cases, the transport protein is specific for the substance it translocates (moves), allowing only a certain substance (or substances) to cross the membrane. For example, glucose carried in blood and needed by red blood cells for cellular activities enters these cells rapidly through specific transport proteins in the plasma membrane. This "glucose transporter" is so selective as a carrier protein that it even rejects fructose, a structural isomer of glucose.

Thus, the selective permeability of a membrane depends on both the discriminating barrier of the lipid bilayer and the specific transport proteins built into the membrane. But what determines the *direction* of traffic across a membrane? At a given time, will a particular substance enter or leave the cell? And what mechanisms actually drive molecules across membranes? We will address these questions next as we explore two modes of membrane traffic: passive transport and active transport.

Concept Check 7.2

- Two molecules that can cross a lipid bilayer without help from membrane proteins are O_2 and CO_2 . What properties allow this to occur?
- Why would water molecules need a transport protein (aquaporin) to move rapidly and in large quantities across a membrane?

For suggested answers, see Appendix A.

Concept 7.3

Passive transport is diffusion of a substance across a membrane with no energy investment

Molecules have a type of energy called thermal motion (heat). One result of thermal motion is **diffusion**, the tendency for molecules of any substance to spread out evenly into the available space. Each molecule moves randomly, yet diffusion of a

population of molecules may be directional. A good way to visualize this is to imagine a synthetic membrane separating pure water from a solution of a dye in water. Assume that this membrane has microscopic pores and is permeable to the dye molecules (**Figure 7.11a**). Each dye molecule wanders randomly, but there will be a *net* movement of the dye molecules across the membrane to the side that began as pure water. The dye molecules will continue to spread across the membrane until both solutions have equal concentrations of the dye. Once that point is reached, there will be a dynamic equilibrium, with as many dye molecules crossing the membrane each second in one direction as in the other.

We can now state a simple rule of diffusion: In the absence of other forces, a substance will diffuse from where it is more concentrated to where it is less concentrated. Put another way, any substance will diffuse down its concentration gradient. No work must be done to make this happen; diffusion is a spontaneous process. Note that each substance diffuses down its *own* concentration gradient, unaffected by the concentration differences of other substances (**Figure 7.11b**).

Much of the traffic across cell membranes occurs by diffusion. When a substance is more concentrated on one side of a membrane than on the other, there is a tendency for the substance to diffuse across the membrane down its concentration gradient (assuming that the membrane is permeable to that substance). One important example is the uptake of oxygen by a cell performing cellular respiration. Dissolved oxygen

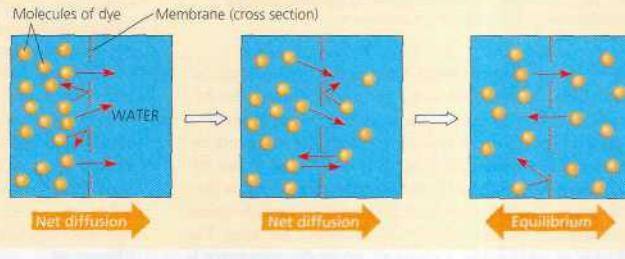

diffuses into the cell across the plasma membrane. As long as cellular respiration consumes the O₂ as it enters, diffusion into the cell will continue, because the concentration gradient favors movement in that direction.

The diffusion of a substance across a biological membrane is called passive transport because the cell does not have to expend energy to make it happen. The concentration gradient itself represents potential energy (see Chapter 2, p. 36) and drives diffusion. Remember, however, that membranes are selectively permeable and therefore have different effects on the rates of diffusion of various molecules. In the case of water, aquaporins allow water to diffuse very rapidly across the membranes of certain cells. The movement of water across the plasma membrane has important consequences for cells.

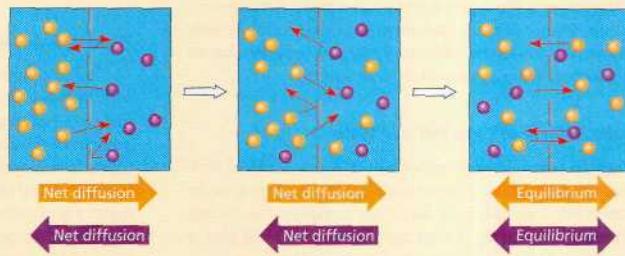

Effects of Osmosis on Water Balance

To see how two solutions with different solute concentrations interact, picture a U-shaped glass tube with a selectively permeable membrane separating two sugar solutions (**Figure 7.12**). Pores in this synthetic membrane are too small for sugar molecules to pass through but large enough for water molecules. How does this affect the water concentration? It seems logical that the solution with the higher concentration of solute would have the lower concentration of water and that water would diffuse into it from the other side for that reason. However, for a dilute solution like most biological fluids,

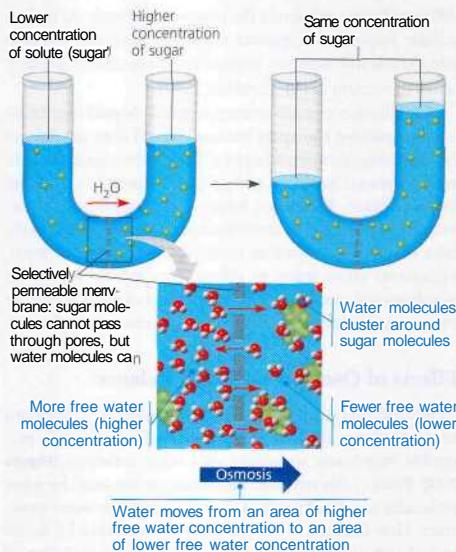

(a) Diffusion of one solute. The membrane has pores large enough for molecules of dye to pass through. Random movement of dye molecules will cause some to pass through the pores; this will happen more often on the side with more molecules. The dye diffuses from where it is more concentrated to where it is less concentrated (called diffusing down a concentration gradient). This leads to a dynamic equilibrium: The solute molecules continue to cross the membrane, but at equal rates in both directions.

(b) Diffusion of two solutes. Solutions of two different dyes are separated by a membrane that is permeable to both. Each dye diffuses down its own concentration gradient. There will be a net diffusion of the purple dye toward the left, even though the *total* solute concentration was initially greater on the left side.

A Figure 7.11 The diffusion of solutes across a membrane. Each of the large arrows under the diagrams shows the net diffusion of the dye molecules of that color.

A Figure 7.12 Osmosis. Two sugar solutions of different concentrations are separated by a selectively permeable membrane, which the solvent (water) can pass through but the solute (sugar) cannot. Water molecules move randomly and may cross through the pores in either direction, but overall, water diffuses from the solution with less concentrated solute to that with more concentrated solute. This transport of water, or osmosis, eventually equalizes the sugar concentrations on both sides of the membrane.

solutes do not affect the water concentration significantly. Instead, tight clustering of water molecules around the hydrophilic solute molecules makes some of the water unavailable to cross the membrane. It is the difference in *free* water concentration that is important. But the effect is the same: Water diffuses across the membrane from the region of lower solute concentration to that of higher solute concentration until the solute concentrations on both sides of the membrane are equal. The diffusion of water across a selectively permeable membrane is called osmosis. The movement of water across cell membranes and the balance of water between the cell and its environment are crucial to organisms. Let's now apply to living cells what we have learned about osmosis in artificial systems.

Water Balance of Cells Without Walls

When considering the behavior of a cell in a solution, both solute concentration and membrane permeability must be considered. Both factors are taken into account in the concept of tonicity, the ability of a solution to cause a cell to gain or lose water. The tonicity of a solution depends in part on its

concentration of solutes that cannot cross the membrane (nonpenetrating solutes), relative to that in the cell itself. If there are more nonpenetrating solutes in the surrounding solution, water will tend to leave the cell, and vice versa.

If a cell without a wall, such as an animal cell, is immersed in an environment that is isotonic to the cell (*iso* means "same"), there will be no *net* movement of water across the plasma membrane. Water flows across the membrane, but at the same rate in both directions. In an isotonic environment, the volume of an animal cell is stable (Figure 7.13a).

Now let's transfer the cell to a solution that is hypertonic to the cell (*hyper* means "more," in this case more nonpenetrating solutes). The cell will lose water to its environment, shrivel, and probably die. This is one reason why an increase in the salinity (saltiness) of a lake can kill the animals there—if the lake water becomes hypertonic to the animals' cells, the cells might shrivel and die. However, taking up too much water can be just as hazardous to an animal cell as losing water. If we place the cell in a solution that is hypotonic to the cell (*hypo* means "less"), water will enter the cell faster than it leaves, and the cell will swell and lyse (burst) like an overfilled water balloon.

A cell without rigid walls can tolerate neither excessive uptake nor excessive loss of water. This problem of water balance is automatically solved if such a cell lives in isotonic surroundings. Seawater is isotonic to many marine invertebrates. The cells of most terrestrial (land-dwelling) animals are bathed in an extracellular fluid that is isotonic to the cells. Animals and other organisms without rigid cell walls living in hypertonic or hypotonic environments must have special adaptations for osmoregulation, the control of water balance. For example, the protist *Paramecium* lives in pond water, which is hypotonic to the cell. *Paramecium* has a plasma membrane that is much less permeable to water than the membranes of most other cells, but this only slows the uptake of water, which continually enters the cell. *Paramecium* doesn't burst because it is also equipped with a contractile vacuole, an organelle that functions as a bilge pump to force water out of the cell as fast as it enters by osmosis (Figure 7.14). We will examine other evolutionary adaptations for osmoregulation in Chapter 44.

Water Balance of Cells with Walls

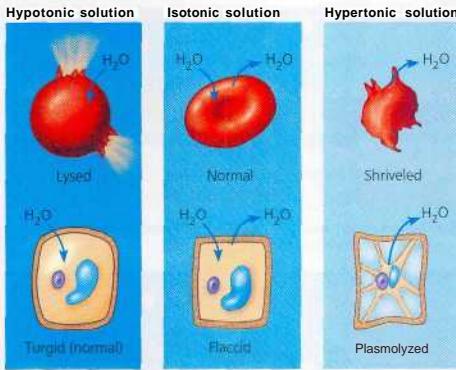

The cells of plants, prokaryotes, fungi, and some protists have walls. When such a cell is immersed in a hypotonic solution—bathed in rainwater, for example—the wall helps maintain the cell's water balance. Consider a plant cell. Like an animal cell, the plant cell swells as water enters by osmosis (Figure 7.13b). However, the elastic wall will expand only so much before it exerts a back pressure on the cell that opposes further water uptake. At this point, the cell is turgid (very firm), which is the healthy state for most plant cells. Plants that are not

fr* Figure 7.13 The water balance of living cells.

How living cells react to changes in the solute concentration of their environment depends on whether or not they have cell walls. (a) Animal cells such as this red blood cell do not have cell walls, (b) Plant cells do. (Arrows indicate net water movement since the cells were first placed in these solutions.)

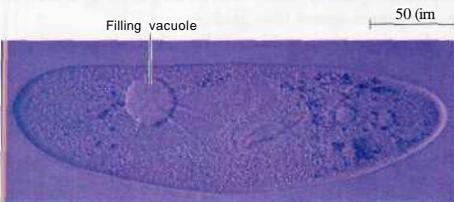

(a) Animal cell. An animal cell fares best in an isotonic environment unless it has special adaptations to offset the osmotic uptake or loss of water.

(b) Plant cell. Plant cells are turgid (firm) and generally healthiest in a hypotonic environment, where the uptake of water is eventually balanced by the elastic wall pushing back on the cell.

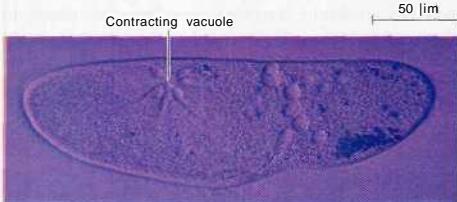

woody, such as most houseplants, depend for mechanical support on cells kept turgid by a surrounding hypotonic solution. If a plant's cells and their surroundings are isotonic, there is no net tendency for water to enter, and the cells become **flaccid** (limp).

However, a wall is of no advantage if the cell is immersed in a hypertonic environment. In this case, a plant cell, like an ani-

la) A contractile vacuole fills with fluid that enters from a system of canals radiating throughout the cytoplasm.

(b) When full, the vacuole and canals contract, expelling fluid from the cell.

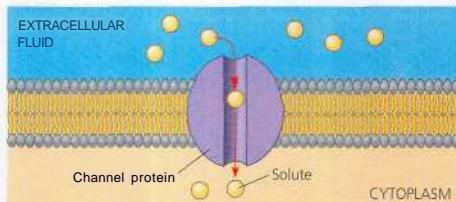

A Figure 7.14 The contractile vacuole of *Paramecium*: an evolutionary adaptation for osmoregulation. The contractile vacuole of this freshwater protist offsets osmosis by bailing water out of the cell.

imal cell, will lose water to its surroundings and shrink. As the plant cell shrivels, its plasma membrane pulls away from the wall. This phenomenon, called **plasmolysis**, causes the plant to wilt and can be lethal. The walled cells of bacteria and fungi also plasmolyze in hypertonic environments.

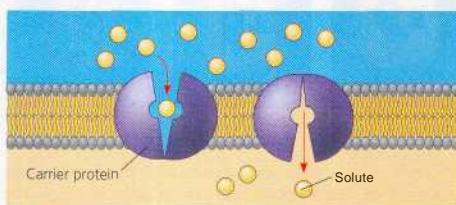

Facilitated Diffusion: Passive Transport Aided by Proteins

Lets look more closely at how water and certain hydrophilic solutes cross a membrane. As mentioned earlier, many polar molecules and ions impeded by the lipid bilayer of the membrane diffuse passively with the help of transport proteins that span the membrane. This phenomenon, is called **facilitated diffusion**. Cell biologists are still trying to learn exactly how various transport proteins facilitate diffusion. Most transport proteins are very specific: They transport only particular substances but not others.

As described earlier, the two types of transport proteins are channel proteins and carrier proteins. Channel proteins simply provide corridors that allow a specific molecule or ion to cross the membrane (**Figure 7.15a**). The hydrophilic passageways provided by these proteins allow water molecules or small ions to flow very quickly from one side of the membrane to the other. While water molecules are small enough to cross through the phospholipid bilayer, the rate of water movement by this route is relatively slow because of their polarity. Aquaporins, the water channel proteins, facilitate the massive amounts of diffusion that occur in plant cells and in animal cells such as red blood cells (see Figure 7.13). Another group of channels are **ion channels**, many of which function as gated channels; a stimulus causes them to open or close. The stimulus may be electrical or chemical; if chemical, the stimulus is a substance other than the one to be transported. For example, stimulation of a nerve cell by

(a) A channel protein (purple) has a channel through which water molecules or a specific solute can pass.

(b) A carrier protein alternates between two conformations, moving a solute across the membrane as the shape of the protein changes. The protein can transport the solute in either direction, with the net movement being down the concentration gradient of the solute.

A Figure 7.15 Two types of transport proteins that carry out facilitated diffusion. In both cases, the protein transports the solute down its concentration gradient.

certain neurotransmitter molecules opens gated channels that allow sodium ions into the cell.

Carrier proteins seem to undergo a subtle change in shape that somehow translocates the solute-binding site across the membrane (**Figure 7.15b**). These changes in shape may be triggered by the binding and release of the transported molecule.

In certain inherited diseases, specific transport systems are either defective or missing altogether. An example is cystinuria, a human disease characterized by the absence of a protein that transports cysteine and some other amino acids across the membranes of kidney cells. Kidney cells normally reabsorb these amino acids from the urine and return them to the blood, but an individual afflicted with cystinuria develops painful stones from amino acids that accumulate and crystallize in the kidneys.

Concept 7.4

Active transport uses energy to move solutes against their gradients

Despite the help of transport proteins, facilitated diffusion is still considered passive transport because the solute being transported is moving down its concentration gradient. Facilitated diffusion speeds the transport of a solute by providing an efficient passage through the membrane, but it does not alter the direction of transport. Some transport proteins, however, can move solutes against their concentration gradients, across the plasma membrane from the side where they are less concentrated to the side where they are more concentrated.

The Need for Energy in Active Transport

To pump a molecule across a membrane against its gradient requires work; the cell must expend energy. Therefore, this type of membrane traffic is called active transport. The transport proteins that move solutes against a concentration gradient are all carrier proteins, rather than channel proteins. This makes sense, because when channel proteins are open, they merely allow molecules to flow down their concentration gradient, rather than picking them up and transporting them against their gradient.

Active transport enables a cell to maintain internal concentrations of small molecules that differ from concentrations¹, in its environment. For example, compared to its surroundings, an animal cell has a much higher concentration of potassium ions and a much lower concentration of sodium ions. The plasma membrane helps maintain these steep gradients by pumping sodium out of the cell and potassium into the cell,

As in other types of cellular work, ATP supplies the energy for most active transport. One way ATP can power active transport is by transferring its terminal phosphate group directly to the transport protein. This may induce the protein to change its conformation in a manner that translocates a solute bound to the protein across the membrane. One transport system that works this way is the sodium-potassium pump, which exchanges sodium (Na^+) for potassium (K^+) across the plasma membrane of animal cells (**Figure 7.16**). **Figure 7.17** reviews the distinction between passive transport and active transport.

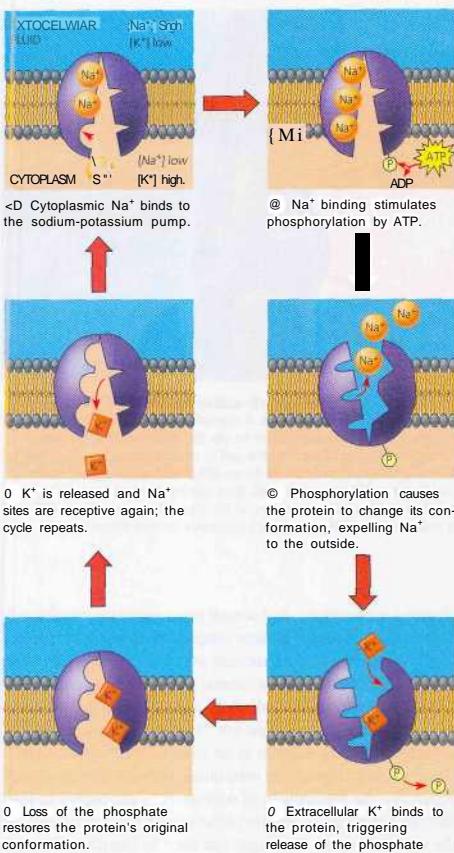

Concept Check 7.3

- If a *Paramecium* were to swim from a hypotonic environment to an isotonic one, would the activity of its contractile vacuole increase or decrease? Why?

For suggested answers, see Appendix A.

Maintenance of Membrane Potential by Ion Pumps

All cells have voltages across their plasma membranes. Voltage is electrical potential energy—a separation of opposite charges.

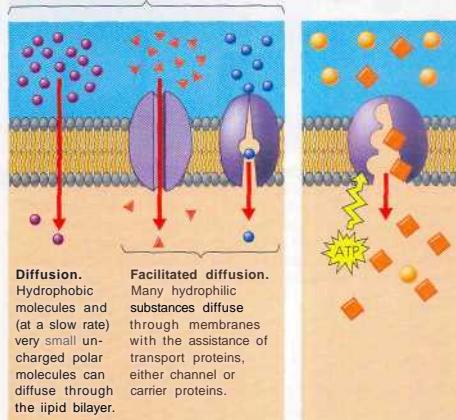

A Figure 7.16 The sodium-potassium pump: a specific case of active transport. This transport system pumps ions against steep concentration gradients: Sodium ion concentration (represented as $[Na^+]$) is high outside the cell and low inside, while potassium ion concentration ($[K^+]$) is low outside the cell and high inside. The pump oscillates between two conformational states in a pumping cycle that translocates three sodium ions out of the cell for every two potassium ions pumped into the cell. ATP powers the changes in conformation by phosphorylating the transport protein (that is, by transferring a phosphate group to the protein).

The cytoplasm of a cell is negative in charge compared to the extracellular fluid because of an unequal distribution of anions and cations on opposite sides of the membrane. The voltage across a membrane, called a **membrane potential**, ranges from

Passive transport. Substances diffuse spontaneously down their concentration gradients, crossing a membrane with no expenditure of energy by the cell. The rate of diffusion can be greatly increased by transport proteins in the membrane.

Active transport. Some transport proteins act as pumps, moving substances across a membrane against their concentration gradients. Energy for this work is usually supplied by ATP.

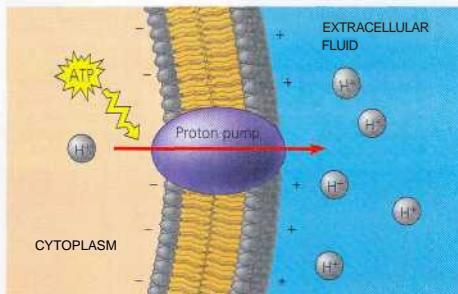

A Figure 7.17 Review: passive and active transport compared.

about -50 to -200 millivolts (mV). (The minus sign indicates that the inside of the cell is negative compared to the outside.)

The membrane potential acts like a battery, an energy source that affects the traffic of all charged substances across the membrane. Because the inside of the cell is negative compared to the outside, the membrane potential favors the passive transport of cations into the cell and anions out of the cell. Thus, *two* forces drive the diffusion of ions across a membrane: a chemical force (the ion's concentration gradient) and an electrical force (the effect of the membrane potential on the ion's movement). This combination of forces acting *on* an ion is called the electrochemical gradient. In the case of ions, we must refine our concept of passive transport: An ion does not simply diffuse down its *concentration* gradient, but diffuses down its *electrochemical* gradient. For example, the concentration of sodium ions (Na^+) inside a resting nerve cell is much lower than outside it. When the cell is stimulated, gated channels that facilitate Na^+ diffusion open. Sodium ions then "fall" down their electrochemical gradient, driven by the concentration gradient of Na^+ and by the attraction of cations to the negative side of the membrane.

Some membrane proteins that actively transport ions contribute to the membrane potential. An example is the sodium-potassium pump. Notice in Figure 7.16 that the pump does not

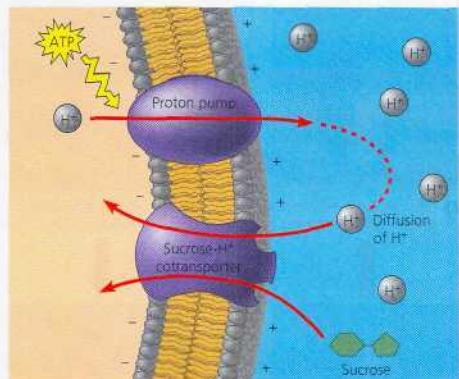

A Figure 7.18 An electrogenic pump. Proton pumps, the main electrogenic pumps of plants, fungi, and bacteria, are membrane proteins that store energy by generating voltage (charge separation) across membranes. Using ATP for power, a proton pump translocates positive charge in the form of hydrogen ions. The voltage and H⁺ concentration gradient represent a dual energy source that can drive other processes, such as the uptake of nutrients.

translocate Na⁺ and K⁺ one for one, but actually pumps three sodium ions out of the cell for every two potassium ions it pumps into the cell. With each "crank" of the pump, there is a net transfer of one positive charge from the cytoplasm to the extracellular fluid, a process that stores energy in the form of voltage. A transport protein that generates voltage across a membrane is called an electrogenic pump. The sodium-potassium pump seems to be the major electrogenic pump of animal cells. The main electrogenic pump of plants, fungi, and bacteria is a proton pump, which actively transports hydrogen ions (protons) out of the cell. The pumping of H⁺ transfers positive charge from the cytoplasm to the extracellular solution (Figure 7.18). By generating voltage across membranes, electrogenic pumps store energy that can be tapped for cellular work, including a type of membrane traffic called cotransport.

Cotransport: Coupled Transport by a Membrane Protein

A single ATP-powered pump that transports a specific solute can indirectly drive the active transport of several other solutes in a mechanism called cotransport. A substance that has been pumped across a membrane can do work as it moves back across the membrane by diffusion, analogous to water that has been pumped uphill and performs work as it flows back down. Another specialized transport protein, a cotransporter separate from the pump, can couple the "downhill" diffusion of this substance to the "uphill" transport of a second substance against its own concentration gradient. For example, a plant cell uses the gradient of hydrogen ions generated by its proton pumps to drive the active transport

A Figure 7.19 Cotransport: active transport driven by a concentration gradient. A special carrier protein such as this sucrose-H⁺ cotransporter is able to use the diffusion of H⁺ down its electrochemical gradient into the cell to drive the uptake of sucrose. The H⁺ gradient is maintained by an ATP-driven proton pump that concentrates H⁺ outside the cell, thus storing potential energy that can be used for active transport, in this case of sucrose. Thus, ATP is indirectly providing the energy necessary for cotransport.

of amino acids, sugars, and several other nutrients into the cell. One specific transport protein couples the return of hydrogen ions to the transport of sucrose into the cell (Figure 7.19). The protein can translocate sucrose into the cell against a concentration gradient, but only if the sucrose molecule travels in the company of a hydrogen ion. The hydrogen ion uses the common transport protein as an avenue to diffuse down the electrochemical gradient maintained by the proton pump. Plants use the mechanism of sucrose-H⁺ cotransport to load sucrose produced by photosynthesis into specialized cells in the veins of leaves. The sugar can then be distributed by the vascular tissue of the plant to nonphotosynthetic organs, such as roots.

What we know about cotransport proteins, osmosis, and water balance in animal cells has helped us find more effective treatments for the dehydration resulting from diarrhea, a serious problem in developing countries where intestinal parasites are prevalent. Patients are given a solution to drink containing a high concentration of glucose and salt. The solutes are taken up by transport proteins on the intestinal cell surface and passed through the cells into the blood. The resulting osmotic pressure causes a flow of water from the intestine through the intestinal cells into the blood, rehydrating the patient. Because of the specific proteins involved, both glucose and the sodium ion from salt must be present. The same principle underlies athletes' consumption of solute-rich solutions after a demanding athletic event.

Concept Check 7.4

- When nerve cells establish a voltage across their membrane with a sodium-potassium pump, does this pump use ATP or does it produce ATP? Why?
- Explain why the sodium-potassium pump in Figure 7.16 would not be considered a cotransporter.

For suggested answers, see Appendix A.

different, the events of endocytosis look like the reverse of exocytosis. A small area of the plasma membrane sinks inward to form a pocket. As the pocket deepens, it pinches in, forming a vesicle containing material that had been outside the cell. There are three types of endocytosis: phagocytosis ("cellular eating"), pinocytosis ("cellular drinking¹"), and receptor-mediated endocytosis. Please study **Figure 7.20** on page 138, which describes these processes, before going on.

Human cells use receptor-mediated endocytosis to take in cholesterol for use in the synthesis of membranes and as a precursor for the synthesis of other steroids. Cholesterol travels in the blood in particles called low-density lipoproteins (LDLs), complexes of lipids and proteins. These particles act as ligands (a general term for any molecule that binds specifically to a receptor site of another molecule) by binding to LDL receptors on membranes and then entering the cells by endocytosis. In humans with familial hypercholesterolemia, an inherited disease characterized by a very high level of cholesterol in the blood, the LDL receptor proteins are defective or missing, and the LDL particles cannot enter cells. Instead, cholesterol accumulates in the blood, where it contributes to early atherosclerosis, the buildup of lipid deposits within the walls of blood vessels, causing them to bulge inward and impede blood flow.

Vesicles not only transport substances between the cell and its surroundings but also provide a mechanism for rejuvenating or remodeling the plasma membrane. Endocytosis and exocytosis occur continually to some extent in most eukaryotic cells, and yet the amount of plasma membrane in a nongrowing cell remains fairly constant over the long run. Apparently, the addition of membrane by one process offsets the loss of membrane by the other.

Energy and cellular work have figured prominently in our study of membranes. We have seen, for example, that active transport is powered by ATP. In the next three chapters, you will learn more about how cells acquire chemical energy to do the work of life.

Concept Check 7.5

- As a cell grows, its plasma membrane expands. Does this process involve endocytosis or exocytosis? Explain.
- To send a signal, a neuron may carry out exocytosis of chemical signals that are recognized by a second neuron. In some cases, the first neuron ends the signal by taking up the signaling molecules by endocytosis. Would you expect this to occur by pinocytosis or by receptor-mediated endocytosis? Explain your reasoning.

For suggested answers, see Appendix A.

Concept 7.5

Bulk transport across the plasma membrane occurs by exocytosis and endocytosis

Water and small solutes enter and leave the cell by passing through the lipid bilayer of the plasma membrane or by being pumped or carried across the membrane by transport proteins; however, large molecules, such as proteins and polysaccharides, as well as larger particles, generally cross the membrane by a different mechanism—one involving vesicles.

Exocytosis

As we described in Chapter 6, the cell secretes macromolecules by the fusion of vesicles with the plasma membrane; this is called exocytosis. A transport vesicle that has budded from the Golgi apparatus moves along microtubules of the cytoskeleton to the plasma membrane. When the vesicle membrane and plasma membrane come into contact, the lipid molecules of the two bilayers rearrange themselves so that the two membranes fuse. The contents of the vesicle then spill to the outside of the cell, and the vesicle membrane becomes part of the plasma membrane (see Figure 7.10).

Many secretory cells use exocytosis to export their products. For example, certain cells in the pancreas manufacture the hormone insulin and secrete it into the blood by exocytosis. Another example is the neuron, or nerve cell, which uses exocytosis to release neurotransmitters that signal other neurons or muscle cells. When plant cells are making walls, exocytosis delivers proteins and certain carbohydrates from Golgi vesicles to the outside of the cell.

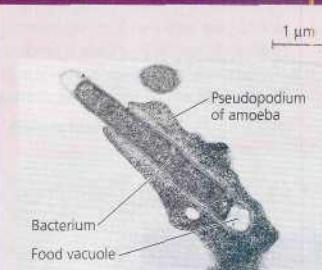

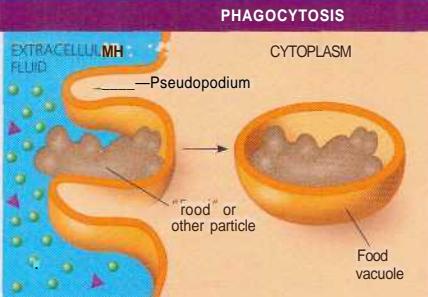

Endocytosis

In endocytosis, the cell takes in macromolecules and particulate matter by forming new vesicles from the plasma membrane. Although the proteins involved in the processes are

Figure 7.20

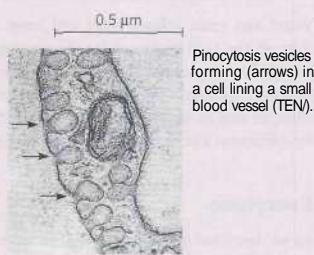

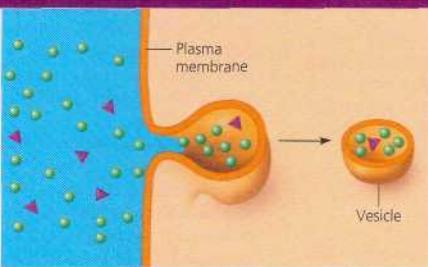

Exploring Endocytosis in Animal Cells

In **phagocytosis**, a cell engulfs a particle by wrapping pseudopodia around it and packaging it within a membrane-enclosed sac large enough to be classified as a vacuole. The particle is digested after the vacuole fuses with a lysosome containing hydrolytic enzymes.

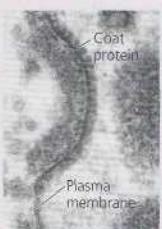

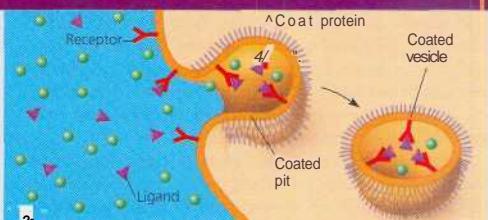

An amoeba engulfing a bacterium via phagocytosis (TEM).

In **pinocytosis**, the cell "gulps" droplets of extracellular fluid into tiny vesicles. It is not the fluid itself that is needed by the cell, but the molecules dissolved in the droplet. Because any and all included solutes are taken into the cell, pinocytosis is nonspecific in the substances it transports.

Receptor-mediated endocytosis enables the cell to acquire bulk quantities of specific substances, even though those substances may not be very concentrated in the extracellular fluid. Embedded in the membrane are proteins with specific receptor sites exposed to the extracellular fluid. The receptor proteins are usually already clustered in regions of the membrane called coated pits, which are lined on their cytoplasmic side by a fuzzy layer of coat proteins. Extracellular substances (ligands) bind to these receptors. When binding occurs, the coated pit forms a vesicle containing the ligand molecules. Notice that there are relatively more bound molecules (purple) inside the vesicle, but other molecules (green) are also present. After this ingested material is liberated from the vesicle, the receptors are recycled to the plasma membrane by the same vesicle.

RECEPTOR-MEDIATED ENDOCYTOSIS

A coated pit and a coated vesicle formed during receptor-mediated endocytosis (TEMs).

SUMMARY OF KEY CONCEPTS

Concept 7.1

Cellular membranes are fluid mosaics of lipids and proteins

- **Membrane Models: Scientific Inquiry** (pp. 125–126) The Davson–Danielli sandwich model of the membrane has been replaced by the fluid mosaic model, in which amphipathic proteins are embedded in the phospholipid bilayer.

- * **The Fluidity of Membranes** (pp. 126–127) Phospholipids and, to a lesser extent, proteins move laterally within the membrane. Cholesterol and unsaturated hydrocarbon tails in the phospholipids affect membrane fluidity.

- * **Membrane Proteins and Their Functions** (pp. 127–129) Integral proteins are embedded in the lipid bilayer; peripheral proteins are attached to the surfaces. The functions of membrane proteins include transport, enzymatic activity, signal transduction, cell-cell recognition, intercellular joining, and attachment to the cytoskeleton and extracellular matrix.

>> **The Role of Membrane Carbohydrates in Cell-Cell Recognition** (p. 129) Short chains of sugars are linked to proteins and lipids on the exterior side of the plasma membrane, where they can interact with the surface molecules of other cells.

- II* **Synthesis and Sidedness of Membranes** (p. 129) Membrane proteins and lipids are synthesized in the ER and modified in the ER and Golgi apparatus. The inside and outside faces of the membrane differ in composition.

Activity *Membrane Structure*

Concept 7.2

Membrane structure results in selective permeability

- I* A cell must exchange small molecules and ions with its surroundings, a process controlled by the plasma membrane (p. 130).

- > **The Permeability of the Lipid Bilayer** (p. 130) Hydrophobic substances are soluble in lipid and pass through membranes rapidly.

- **Transport Proteins** (p. 130) Polar molecules and ions generally require specific transport proteins to help them cross.

Activity *Selective Permeability of Membranes*

Concept 7.3

Passive transport is diffusion of a substance across a membrane with no energy investment

- Diffusion is the spontaneous movement of a substance down its concentration gradient (pp. 130–131).

Activity *Diffusion*

- **Effects of Osmosis on Water Balance** (pp. 131–133)

Water flows across a membrane from the side where solute is less concentrated (hypotonic) to the side where solute is more concentrated (hypertonic). If the concentrations are equal (isotonic), no net osmosis occurs. Cell survival depends on

balancing water uptake and loss. Cells lacking walls (as in animals and some protists) are isotonic with their environments or have adaptations for osmoregulation. Plants, prokaryotes, fungi, and some protists have elastic cell walls, so the cells don't burst in a hypertonic environment.

Activity *Osmosis and Water Balance in Cells*

Investigation *How Do Salt Concentrations Affect Cells?*

► Facilitated Diffusion: Passive Transport Aided by Proteins

(pp. 133–134) In facilitated diffusion, a transport protein speeds the movement of water or a solute across a membrane down its concentration gradient.

Activity *Facilitated Diffusion*

Concept 7.4

Active transport uses energy to move solutes against their gradients

- **The Need for Energy in Active Transport** (pp. 134–135) Specific membrane proteins use energy, usually in the form of ATP, to do the work of active transport.

Activity *Active Transport*

- **Maintenance of Membrane Potential by Ion Pumps** (pp. 134–136) Ions can have both a concentration (chemical) gradient and an electrical gradient (voltage). These forces combine in the electrochemical gradient, which determines the net direction of ionic diffusion. Electrogenic pumps, such as sodium-potassium pumps and proton pumps, are transport proteins that contribute to electrochemical gradients.

- **Cotransport: Coupled Transport by a Membrane Protein** (p. 136) One solute's "downhill" diffusion drives the others "uphill" transport.

Concept 7.5

Bulk transport across the plasma membrane occurs by exocytosis and endocytosis

- **Exocytosis** (p. 137) In exocytosis, transport vesicles migrate to the plasma membrane, fuse with it, and release their contents.

- **Endocytosis** (pp. 137–138) In endocytosis, molecules enter cells within vesicles pinched inward from the plasma membrane. The three types of endocytosis are phagocytosis, pinocytosis, and receptor-mediated endocytosis.

Activity *Exocytosis and Endocytosis*

TESTING YOUR KNOWLEDGE

Evolution Connection

Paramecium and other protists that live in hypotonic environments have cell membrane adaptations that slow osmotic water uptake, while those living in isotonic environments have more permeable cell membranes. What water regulation adaptations would you expect to have evolved in protists living in hypertonic habitats such as Great Salt Lake? How about those living in habitats where salt concentration fluctuates?

Scientific Inquiry

An experiment is designed to study the mechanism of sucrose uptake by plant cells. Cells are immersed in a sucrose solution, and the pH of the solution is monitored with a pH meter. Samples of the cells are taken at intervals, and the sucrose in the sampled cells is measured. The measurements show that sucrose uptake by the cells correlates with a rise in the pH of the surrounding solution. The magnitude of the pH change is proportional to the starting concentration of sucrose in the extracellular solution. A metabolic poison known to block the ability of cells to regenerate ATP is found to inhibit the pH changes in the extracellular solution. Propose a hypothesis accounting for these results. Suggest an additional experiment to test your hypothesis.

Investigation *How Do Salt Concentrations Affect Cells?*

Science, Technology, and Society

Extensive irrigation in arid regions causes salts to accumulate in the soil. (The water contains low concentrations of salts, but when the water evaporates from the fields, the salts are left behind to concentrate in the soil.) Based on what you have learned about water balance in plant cells, explain why increasing soil salinity (saltiness) has an adverse effect on agriculture. Suggest some ways to minimize this damage. What costs are attached to your solutions?

An Introduction to Metabolism

A Figure 8.1 Bioluminescence by a fungus.

(Key Concepts)

- 8.1 An organism's metabolism transforms matter and energy, subject to the laws of thermodynamics
- 8.2 The free-energy change of a reaction tells us whether the reaction occurs spontaneously
- 8.3 ATP powers cellular work by coupling exergonic reactions to endergonic reactions
- 8.4 Enzymes speed up metabolic reactions by lowering energy barriers
- 8.5 Regulation of enzyme activity helps control metabolism

Overview

The Energy of Life

The living cell is a chemical factory in miniature, where thousands of reactions occur within a microscopic space. Sugars can be converted to amino acids that are linked together into proteins when needed, and proteins are dismantled into amino acids that can be converted to sugars when food is digested. Small molecules are assembled into polymers, which may be hydrolyzed later as the needs of the cell change. In multicellular organisms, many cells export chemical products that are used in other parts of the organism. The process known as cellular respiration drives the cellular economy by extracting the energy stored in sugars and other fuels. Cells apply this energy to perform various types of work, such as the transport of solutes across the plasma membrane, which we discussed in Chapter 7. In a more exotic example, cells of the fungus in **Figure 8.1** convert the energy stored in certain organic molecules to light, a process called bioluminescence. (The glow may attract insects that benefit the fungus by dispersing its spores.) Bioluminescence and all other metabolic

activities carried out by a cell are precisely coordinated and controlled, in its complexity its efficiency its integration, and its responsiveness to subtle changes, the cell is peerless as a chemical factory. The concepts of metabolism that you learn in this chapter will help you understand how matter and energy flow during life's processes and how that flow is regulated.

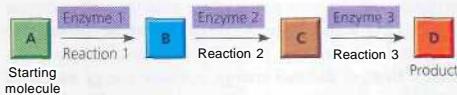

Concept 8.1

All organism's metabolism transforms matter and energy, subject to the laws of thermodynamics

The totality of an organism's chemical reactions is called **metabolism** (from the Greek *metabole*, change). Metabolism is an emergent property of life that arises from interactions between molecules within the orderly environment of the cell.

Organization of the Chemistry of Life into Metabolic Pathways

We can picture a cell's metabolism as an elaborate road map of the thousands of chemical reactions that occur in a cell, arranged as intersecting metabolic pathways. A **metabolic pathway** begins with a specific molecule, which is then altered in a series of defined steps, resulting in a certain product. Each step of the pathway is catalyzed by a specific enzyme:

Analogous to the red, yellow, and green stoplights that control the flow of traffic, mechanisms that regulate enzymes balance metabolic supply and demand, averting deficits or surpluses of important cellular molecules.

Metabolism as a whole manages the material and energy resources of the cell. Some metabolic pathways release energy by breaking down complex molecules to simpler compounds. These degradative processes are called **catabolic pathways**, or breakdown pathways. A major pathway of catabolism is cellular respiration, in which the sugar glucose and other organic fuels are broken down in the presence of oxygen to carbon dioxide and water. (Pathways can have more than one starting molecule and/or product.) Energy that was stored in the organic molecules becomes available to do the work of the cell, such as ciliary beating or membrane transport. **Anabolic pathways**, in contrast, consume energy to build complicated molecules from simpler ones; they are sometimes called biosynthetic pathways. An example of anabolism is the synthesis of a protein from amino acids. Catabolic and anabolic pathways are the "downhill" and "uphill" avenues of the metabolic map. Energy released from the downhill reactions of catabolism can be stored and then used to drive the uphill reactions of the anabolic pathways.

In this chapter, we will focus on the mechanisms common to metabolic pathways. Because energy is fundamental to all metabolic processes, a basic knowledge of energy is necessary to understand how the living cell works. Although we will use some nonliving examples to study energy, keep in mind that the concepts demonstrated by these examples also apply to **bioenergetics**, the study of how organisms manage their energy resources.

Forms of Energy

Energy is the capacity to cause change. In everyday life, energy is important because some forms of energy can be used to do work—that is, to move matter against opposing forces, such as gravity and friction. Put another way energy is the ability to rearrange a collection of matter. For example, you expend energy to turn the pages of this book, and your cells expend energy in transporting certain substances across membranes. Energy exists in various forms, and the work of life depends on the ability of cells to transform energy from one type into another.

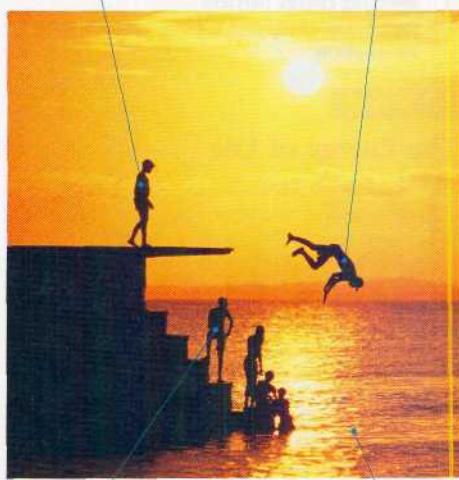

Energy can be associated with the relative motion of objects; this energy is called **kinetic energy**. Moving objects can perform work by imparting motion to other matter: A pool player uses the motion of the cue stick to push the cue ball, which in turn moves the other balls; water gushing over a dam turns turbines; and the contraction of leg muscles pushes bicycle pedals. Light is also a type of energy that can be harnessed to perform work, such as powering photosynthesis in green plants. **Heat, or thermal energy**, is kinetic energy associated with the random movement of atoms or molecules.

An object not presently moving may still possess energy. Energy that is not kinetic is called **potential energy**; it is energy that matter possesses because of its location or structure. Water behind a dam, for instance, stores energy because of its altitude above sea level. Molecules store energy because of the arrangement of their atoms. **Chemical energy** is a term used by biologists to refer to the potential energy available for release in a chemical reaction. Recall that catabolic pathways release energy by breaking down complex molecules. Biologists say that these complex molecules, such as glucose, are high in chemical energy. During a catabolic reaction, atoms are rearranged and energy is released, resulting in lower-energy breakdown products. This transformation also occurs, for example, in the engine of a car when the hydrocarbons of gasoline react explosively with oxygen, releasing the energy that pushes the pistons and producing exhaust. Although less explosive, a similar reaction of food molecules with oxygen provides chemical energy in biological systems, producing carbon dioxide and water as waste products. It is the structures and biochemical pathways of cells that enable them to release chemical energy from food molecules, powering life processes.

How is energy converted from one form to another? Consider the divers in **Figure 8.2**. The young man climbing the

On the platform, a diver has more potential energy.

Diving converts potential energy to kinetic energy.

Climbing up converts kinetic energy of muscle movement to potential energy.

In the water, a diver has less potential energy.

A **Figure 8.2 Transformations between kinetic and potential energy.**

steps to the diving platform is releasing chemical energy from the food he ate for lunch and using some of that energy to perform the work of climbing. The kinetic energy of muscle movement is thus being transformed into potential energy owing to his increasing height above the water. The young man diving is converting his potential energy to kinetic energy, which is then transferred to the water as he enters it. A small amount of energy is lost as heat due to friction.

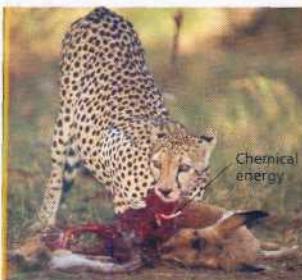

Now let's go back one step and consider the original source of the organic food molecules that provided the necessary chemical energy for the divers to climb the steps. This chemical energy was itself derived from light energy by plants during photosynthesis. Organisms are energy transformers.

The Laws of Energy Transformation

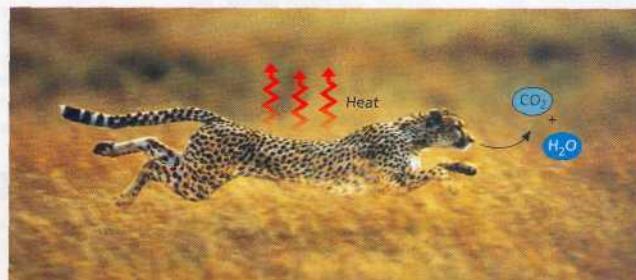

The study of the energy transformations that occur in a collection of matter is called thermodynamics. Scientists use the word system to denote the matter under study; they refer to the rest of the universe—everything outside the system—as the surroundings. A *closed system*, such as that approximated by liquid in a thermos bottle, is isolated from its surroundings. In an *open system*, energy (and often matter) can be transferred between the system and its surroundings. Organisms are open systems. They absorb energy—for instance, light energy or chemical energy in the form of organic molecules—and release heat and metabolic waste products, such as carbon dioxide, to the surroundings. Two laws of thermodynamics govern energy transformations in organisms and all other collections of matter.

ATIC First Law of Thermodynamics

According to the first law of thermodynamics, the energy of the universe is constant. *Energy can be transferred and*

(a) First law of thermodynamics: Energy can be transferred or transformed but neither created nor destroyed. For example, the chemical (potential) energy in food will be converted to the kinetic energy of the cheetah's movement in (b).

(b) Second law of thermodynamics: Every energy transfer or transformation increases the disorder (entropy) of the universe. For example, disorder is added to the cheetah's surroundings in the form of heat and the small molecules that are the by-products of metabolism.

A **Figure 8.3** The two laws of thermodynamics.

transformed, but it cannot be created or destroyed. The first law is also known as the principle of conservation of energy. The electric company does not make energy, but merely converts it to a form that is convenient to use. By converting sunlight to chemical energy, a green plant acts as an energy transformer, not an energy producer.

The cheetah in **Figure 8.3a** will convert the chemical energy of the organic molecules in its food to kinetic and other forms of energy as it carries out biological processes. What happens to this energy after it has performed work? The second law helps to answer this question.

The Second Law of Thermodynamics

If energy cannot be destroyed, why can't organisms simply recycle their energy over and over again? It turns out that during every energy transfer or transformation, some energy becomes unusable energy, unavailable to do work. In most energy transformations, more usable forms of energy are at least partly converted to heat, which is the energy associated with the random motion of atoms or molecules. Only a small fraction of the chemical energy from the food in **Figure 8.3a** is transformed into the motion of the cheetah shown in **Figure 8.3b**; most is lost as heat, which dissipates rapidly through the surroundings.

In the process of carrying out chemical reactions that perform various kinds of work, living cells unavoidably convert organized forms of energy to heat. A system can put heat to work only when there is a temperature difference that results in the heat flowing from a warmer location to a cooler one. If temperature is uniform, as it is in a living cell, then the only use for heat energy generated during a chemical reaction is to warm a body of matter, such as the organism. (This can make a room crowded with people uncomfortably

warm, as each person is carrying out a multitude of chemical reactions!)

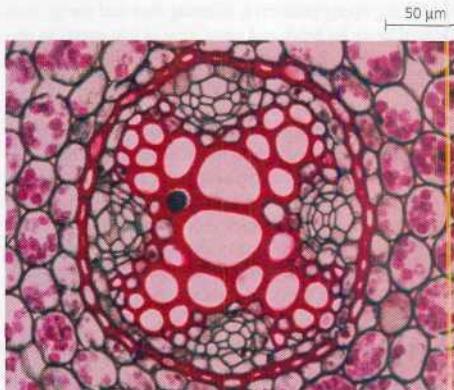

A logical consequence of the loss of usable energy during energy transfer or transformation is that each such event makes the universe more disordered. Scientists use a quantity called entropy as a measure of disorder, or randomness. The more randomly arranged a collection of matter is, the greater its entropy. We can now state the second law of thermodynamics as follows: *Every energy transfer or transformation increases the entropy of the universe.* Although order can increase locally, there is an unstoppable trend toward randomization of the universe as a whole.

In many cases, increased entropy is evident in the physical disintegration of a system's organized structure. For example, you can observe increasing entropy in the gradual decay of an unmaintained building. Much of the increasing entropy of the universe is less apparent, however, because it appears as increasing amounts of heat and less ordered forms of matter. As the cheetah in Figure 8.3b converts chemical energy to kinetic energy, it is also increasing the disorder of its surroundings by producing heat and the small molecules that are the breakdown products of food.

The concept of entropy helps us understand why certain processes occur. It turns out that for a process to occur on its own, without outside help (an input of energy), it must increase the entropy of the universe. Let's first agree to use the word *spontaneous* for a process that can occur without an input of energy. Note that as we're using it here, the word *spontaneous* does not imply that such a process would occur quickly. Some spontaneous processes may be virtually instantaneous, such as an explosion, while others may be much slower, such as the rusting of an old car over time. A process that cannot occur on its own is said to be *nonspontaneous*; it will happen only if energy is added to the system. We know from experience that certain events occur spontaneously and others do not. For instance, we know that water flows downhill spontaneously, but moves uphill only with an input of energy, for instance when a machine pumps the water against gravity. In fact, another way to state the second law is: *For a process to occur spontaneously, it must increase the entropy of the universe.*

Biological Order and Disorder

Living systems increase the entropy of their surroundings, as predicted by thermodynamic law. It is true that cells create ordered structures from less organized starting materials. For example, amino acids are ordered into the specific sequences of polypeptide chains. At the organismal level, **Figure 8.4** shows the extremely symmetrical anatomy of a plant's root, formed by biological processes from simpler starting materials. However, an organism also takes in organized forms of matter and energy from the surroundings and replaces them with less ordered forms. For example, an animal obtains starch,

A Figure 8.4 Order as a characteristic of life. Order is evident in the detailed anatomy of this root tissue from a buttercup plant (LM cross section). As open systems, organisms can increase their order as long as the order of their surroundings decreases.

proteins, and other complex molecules from the food it eats. As catabolic pathways break these molecules down, the animal releases carbon dioxide and water—small molecules that store less chemical energy than the food did. The depletion of chemical energy is accounted for by heat generated during metabolism. On a larger scale, energy flows into an ecosystem in the form of light and leaves in the form of heat.

During the early history of life, complex organisms evolved from simpler ancestors. For example, we can trace the ancestry of the plant kingdom to much simpler organisms called green algae. However, this increase in organization over time in no way violates the second law. The entropy of a particular system, such as an organism, may actually decrease, so long as the total entropy of the *universe*—the system plus its surroundings—increases. Thus, organisms are islands of low entropy in an increasingly random universe. The evolution of biological order is perfectly consistent with the laws of thermodynamics.

Concept Check 8.1

- How does the second law of thermodynamics help explain the diffusion of a substance across a membrane?
- What is the relationship between energy and work?
- Describe the forms of energy found in an apple as it grows on a tree, then falls and is digested by someone who eats it.

For suggested answers, see Appendix A.

Concept 8.2

The free-energy change of a reaction tells us whether the reaction occurs spontaneously

*T*he laws of thermodynamics that we've just discussed apply to the universe as a whole. As biologists, we want to understand the chemical reactions of life—for example, to know which reactions occur spontaneously and which ones require some input of energy from outside. But how can we know this without assessing the energy and entropy changes in the entire universe for each separate reaction?

Tree-Energy Change, AG

Recall that the universe is really equivalent to "the system" plus "the surroundings." In 1878, J. Willard Gibbs, a professor at Yale, defined a very useful function called the Gibbs free energy of a system (without considering its surroundings), symbolized by the letter G. We'll refer to the Gibbs free energy simply as free energy. **Free energy** measures the portion of a system's energy that can perform work when temperature and pressure are uniform throughout the system, as in a living cell. Let's consider how we determine the free energy change that occurs when a system changes—for example, during a chemical reaction.

The change in free energy, AG, can be calculated for any specific chemical reaction with the following formula:

$$AG = AH - TAS$$

This formula uses only properties of the system (the reaction **itself**; AH symbolizes the change in the system's *enthalpy* (in biological systems, equivalent to total energy); AS is the change in the system's entropy; and T is the absolute temperature in Kelvin (K) units ($K = ^\circ C + 273$; see Appendix B).

Once we know the value of AG for a process, we can use it to predict whether the process will be spontaneous (that is, whether it will run without an outside input of energy). A century of experiments has shown that only processes with a negative AG are spontaneous. For a process to occur spontaneously, therefore, the system must either give up enthalpy (H must decrease), give up order (TS must increase), or both: When the changes in H and TS are tallied, AG must have a negative value ($AG < 0$). This means that every spontaneous process decreases the system's free energy. Processes that have a positive or zero AG are never spontaneous.

This information is immensely interesting to biologists, for it gives us the power to predict which kinds of change can happen without help. Such spontaneous changes can be harnessed to perform work. This principle is **very** important in the study

of metabolism, where a major goal is to determine which reactions can supply energy to do work in the living cell.

Free Energy, Stability, and Equilibrium

As we saw in the previous section, when a process occurs spontaneously in a system, we can be sure that AG is negative. Another way to think of AG is to realize that it represents the difference between the free energy of the final state and the free energy of the initial state:

$$AG = G_{final} - G_{initial}$$

Thus, AG can only be negative when the process involves a loss of free energy during the change from initial state to final state. Because it has less free energy, the system in its final state is less likely to change and is therefore more stable than it was previously.

We can think of free energy as a measure of a system's instability—its tendency to change to a more stable state. Unstable systems (higher G) tend to change in such a way that they become more stable (lower G). For example, a diver on top of a platform is less stable than when floating in the water, a drop of concentrated dye is less stable than when the dye is spread randomly through the liquid, and a sugar molecule is less stable than the simpler molecules into which it can be broken (Figure 8.5, on the next page). Unless something prevents it, each of these systems will move toward greater stability: The diver falls, the solution becomes uniformly colored, and the sugar molecule is broken down.

Another term for a state of maximum stability is *equilibrium*, which you learned about in Chapter 2 in connection with chemical reactions. There is an important relationship between free energy and equilibrium, including chemical equilibrium. Recall that most chemical reactions are reversible and proceed to a point at which the forward and backward reactions occur at the same rate. The reaction is then said to be at chemical equilibrium, and [there is no further net change in the relative concentration of products and reactants.

As a reaction proceeds toward equilibrium, the free energy of the mixture of reactants and products decreases. Free energy increases when a reaction is somehow pushed away from equilibrium, perhaps by removing some of the products (and thus changing their concentration relative to that of the reactants). For a system at equilibrium, G is at its lowest possible value in that system. We can think of the equilibrium state as an energy valley. Any small change from the equilibrium position will have a positive AG and will not be spontaneous. For this reason, systems never spontaneously move away from equilibrium. Because a system at equilibrium cannot spontaneously change, it can do no work. A process is spontaneous and can perform work only when it is moving toward equilibrium.

- More free energy (higher G)
- Less stable
- Greater work capacity

- in a spontaneous change
- The free energy of the system decreases ($\Delta G < 0$)
 - The system becomes more stable
 - The released free energy can be harnessed to do work

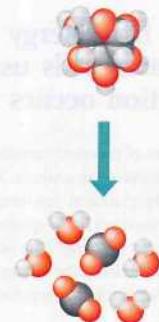

- » Less free energy (lower G)
- More stable
 - Less work capacity

(a) Gravitational motion. Objects move spontaneously from a higher altitude to a lower one.

(b) Diffusion. Molecules in a drop of dye diffuse until they are randomly dispersed.

(c) Chemical reaction. In a cell, *B* sugar molecule is broken down into simpler molecules.

A Figure 8.5 The relationship of free energy to stability, work capacity, and spontaneous change. Unstable systems (top diagrams) are rich in free energy, or *G*. They have a tendency to change spontaneously to a more stable state (bottom), and it is possible to harness this "downhill" change to perform work.

Free Energy and Metabolism

We can now apply the free-energy concept more specifically to the chemistry of life's processes.

Exergonic and Endergonic Reactions in Metabolism

Based on their free-energy changes, chemical reactions can be classified as either exergonic ("energy outward") or endergonic ("energy inward"). An exergonic reaction proceeds with a net release of free energy (Figure 8.6a). Because the chemical mixture loses free energy (*G* decreases), ΔG is negative for an exergonic reaction. Using ΔG as a standard for spontaneity, exergonic reactions are those that occur spontaneously. (Remember, the word *spontaneous* does not imply that a reaction will occur instantaneously, or even rapidly.) The magnitude of ΔG for an exergonic reaction represents the maximum amount of work the reaction can perform.* The greater the decrease in free energy, the greater the amount of work that can be done.

We can use the overall reaction for cellular respiration as an example:

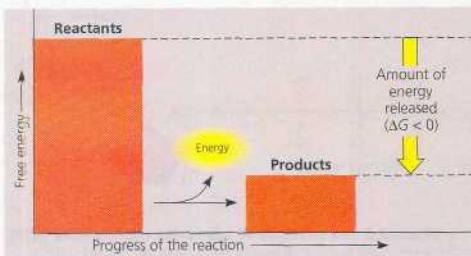

$$\Delta G = -686 \text{ kcal/mol} (-2,870 \text{ kJ/mol})$$

* The word maximum qualifies this statement, because some of the free energy is released as heat and cannot do work. Therefore, ΔG represents a theoretical upper limit of available energy.

For each mole (180 g) of glucose broken down by respiration under what are called "standard conditions" (1 M of each reactant and product, 25°C, pH 7), 686 kcal (2,870 kJ) of energy are made available for work. Because energy must be conserved, the chemical products of respiration store 686 kcal less free energy per mole than the reactants. The products are, in a sense, the spent exhaust of a process that tapped the free energy stored in the sugar molecules.

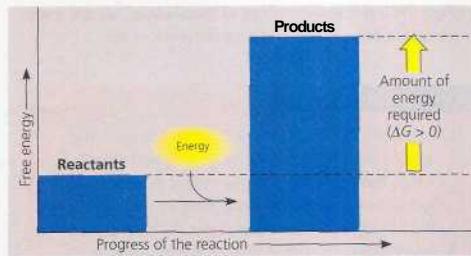

An endergonic reaction is one that absorbs free energy from its surroundings (Figure 8.6b). Because this kind of reaction essentially stores free energy in molecules (*G* increases), ΔG is positive. Such reactions are nonspontaneous, and the magnitude of ΔG is the quantity of energy required to drive the reaction. If a chemical process is exergonic (downhill) in one direction, then the reverse process is endergonic (uphill). A reversible process cannot be downhill in both directions. If $\Delta G = -686 \text{ kcal/mol}$ for respiration, which converts sugar to carbon dioxide and water, then the reverse process—the conversion of carbon dioxide and water to sugar—must be strongly endergonic, with $\Delta G = +686 \text{ kcal/mol}$. Such a reaction would never happen by itself.

How, then, do plants make the sugar that all the living world consumes for energy? They get the required energy—686 kcal to make a mole of sugar—from the environment by capturing light and converting its energy to chemical energy. Next, in a long series of exergonic steps, they gradually spend that chemical energy to assemble sugar molecules.

(a) Exergonic reaction: energy released

A Figure 8.6 Free energy changes (ΔG) in exergonic and endergonic reactions.

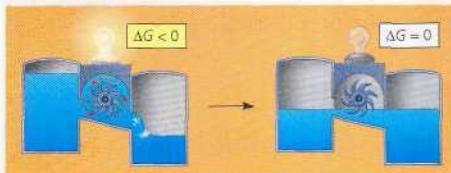

(b) Endergonic reaction: energy required

Equilibrium and Metabolism

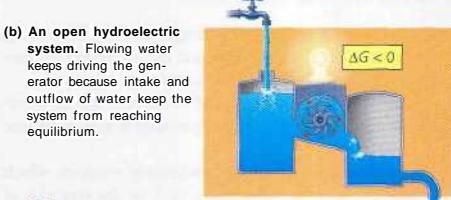

Reactions in a closed system eventually reach equilibrium, and can then do no work, as illustrated by the closed hydroelectric system in Figure 8.7a. The chemical reactions of metabolism are reversible, and they, too, would reach equilibrium if they occurred in the isolation of a test tube. Because systems at equilibrium are at a minimum of G and can do no work, a cell that has reached metabolic equilibrium is dead! The fact that metabolism as a whole is never at equilibrium is one of the defining features of life.

Like most systems, a cell in our body is not in equilibrium. The constant flow of materials in and out of the cell keeps the metabolic pathways from ever reaching equilibrium, and the cell continues to do work throughout its life. This principle is illustrated by the open (and more realistic) hydroelectric system in Figure 8.7b. However, unlike this simple single-step system, a catabolic pathway in a cell releases free energy in a series of reactions. An example is cellular respiration, illustrated by analogy in Figure 8.7c. Some of the reversible reactions of respiration are constantly "pulled" in one direction—that is, they are kept out of equilibrium. The key to maintaining this lack of equilibrium is that the product of one reaction does not accumulate, but instead becomes a reactant in the next step; finally, waste products are expelled from the cell. The overall sequence of reactions is kept going by the huge free-energy difference between glucose at the top of the energy "hill" and carbon dioxide and water at the "downhill" end. As long as our cells have a steady supply of glucose or other fuels and oxygen and are able to expel waste products to the surroundings, their metabolic pathways never reach equilibrium and can continue to do the work of life.

We see once again how important it is to think of organisms as open systems. Sunlight provides a daily source of free energy for an ecosystem's plants and other photosynthetic organisms. Animals and other nonphotosynthetic organisms in an ecosystem must have a source of free energy in the form of the organic products of photosynthesis. Now that we have

(a) A closed hydroelectric system. Water flowing downhill turns a turbine that drives a generator providing electricity to a light bulb, but only until the system reaches equilibrium.

(b) An open hydroelectric system. Flowing water keeps driving the generator because intake and outflow of water keep the system from reaching equilibrium.

(c) A multistep open hydroelectric system. Cellular respiration is analogous to this system: Glucose is broken down in a series of exergonic reactions that power the work of the cell. The product of each reaction becomes the reactant for the next, so no reaction reaches equilibrium.

A Figure 8.7 Equilibrium and work in closed and open systems.

applied the free-energy concept to metabolism, we are ready to see how a cell actually performs the work of life.

Concept Check 8.2

1. Cellular respiration uses glucose, which has a high level of free energy and releases CO_2 and water, which have low levels of free energy. Is respiration spontaneous or not? Is it exergonic or endergonic? What happens to the energy released from glucose?
2. A key process in metabolism is the transport of H^+ ions across a membrane to create a concentration gradient. In some conditions, H^+ ions flow back across the membrane and come to equal concentrations on each side. In which conditions can the H^+ ions perform work in this system?

For suggested answers, see Appendix A.

Concept 8.3

ATP powers cellular work by coupling exergonic reactions to endergonic reactions

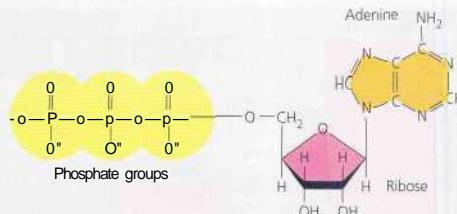

A cell does three main kinds of work:

- *Mechanical work*, such as the beating of cilia (see Chapter 6), the contraction of muscle cells, and the movement of chromosomes during cellular reproduction
- *Transport work*, the pumping of substances across membranes against the direction of spontaneous movement (see Chapter 7)
- *Chemical work*, the pushing of endergonic reactions, which would not occur spontaneously, such as the synthesis of polymers from monomers (the focus of this chapter, and Chapters 9 and 10)

A key feature in the way cells manage their energy resources to do this work is energy coupling, the use of an exergonic process to drive an endergonic one. ATP is responsible for mediating most energy coupling in cells, and in most cases it acts as the immediate source of energy that powers cellular work.

The Structure and Hydrolysis of ATP

ATP (adenosine triphosphate) was introduced in Chapter 4 when we discussed the phosphate group as a functional group. Here we will look more closely at the structure of this molecule. ATP contains the sugar ribose, with the nitrogenous base adenine and a chain of three phosphate groups bonded to it (Figure 8.8).

A Figure 8.8 The structure of adenosine triphosphate (ATP). In the cell, most hydroxyl groups of phosphates are ionized ($-O^-$).

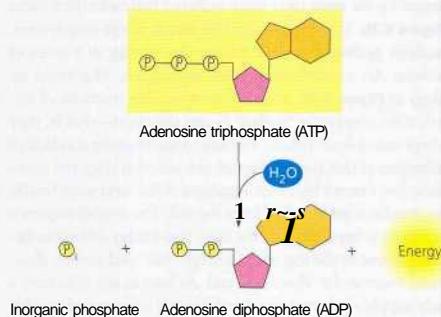

The bonds between the phosphate groups of ATP's tail can be broken by hydrolysis. When the terminal phosphate bond is broken, a molecule of inorganic phosphate (abbreviated O_i throughout this book) leaves the ATP, which becomes adenosine diphosphate, or ADP (Figure 8.9). The reaction is exergonic and under standard conditions releases 7.3 kcal of energy per mole of ATP hydrolyzed:

$$\Delta G = -7.3 \text{ kcal/mol} (-30.5 \text{ kJ/mol}) \text{ (standard conditions)*}$$

The free-energy change for many different reactions has been measured in the laboratory under standard conditions. If the ΔG of an endergonic reaction is less than the amount of energy released by ATP hydrolysis, then the two reactions can be coupled so that, overall, the coupled reactions are exergonic (Figure 8.10).

Because their hydrolysis releases energy, the phosphate bonds of ATP are sometimes referred to as high-energy phosphate

A Figure 8.9 The hydrolysis of ATP. The hydrolysis of ATP yields inorganic phosphate (O_i) and ADP.

* In the cell, the conditions do not conform to standard conditions, owing in large part to reactant and product concentrations that differ from 1 M. For example, when ATP hydrolysis occurs under cellular conditions, the actual ΔG is about -13 kcal/mol, 78% greater than the energy released by ATP hydrolysis under standard conditions.

bends, but the term is misleading. The phosphate bonds of ATP are not unusually strong bonds, as "high-energy" may imply; rather, the molecule itself has high energy in relation to that of the products (ADP and Pi). The release of energy during the hydrolysis of ATP comes from the chemical change to a state of lower free energy, not from the phosphate bonds themselves.

ATP is useful to the cell because the energy it releases on hydrolyzing a phosphate group is somewhat greater than the energy most other molecules could deliver. But why does this hydrolysis release so much energy? If we reexamine the ATP molecule in Figure 8.8, we can see that all three phosphate groups are negatively charged. These like charges are crowded together, and their mutual repulsion contributes to the instability of this region of the ATP molecule. The triphosphate tail of ATP is the chemical equivalent of a compressed spring.

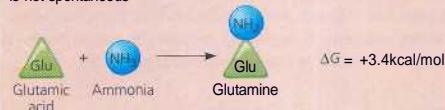

How ATP Performs Work

When ATP is hydrolyzed in a test tube, the release of free energy merely heats the surrounding water. In an organism, this same generation of heat can sometimes be beneficial. For instance, the process of shivering uses ATP hydrolysis during muscle contraction to generate heat and warm the body. In most cases in the cell, however, the generation of heat alone would be an inefficient (and potentially dangerous) use of a valuable energy resource.

Instead, with the help of specific enzymes, the cell is able to couple the energy of ATP hydrolysis directly to endergonic processes by transferring a phosphate group from ATP to some other molecule, such as the reactant. The recipient of the phosphate group is then said to be phosphorylated. The key to coupling exergonic and endergonic reactions is the formation of this phosphorylated intermediate, which is more reactive (less stable) than the original unphosphorylated molecule.

The three types of cellular work—mechanical, transport, and chemical—are nearly always powered by the hydrolysis of ATP (Figure 8.11). In each case, a phosphate group is transferred from ATP to some other molecule, and this phosphorylated molecule undergoes a change that performs work. An example is the synthesis of the amino acid glutamine from glutamic acid (another amino acid)

Endergonic reaction: ΔG is positive, reaction is not spontaneous

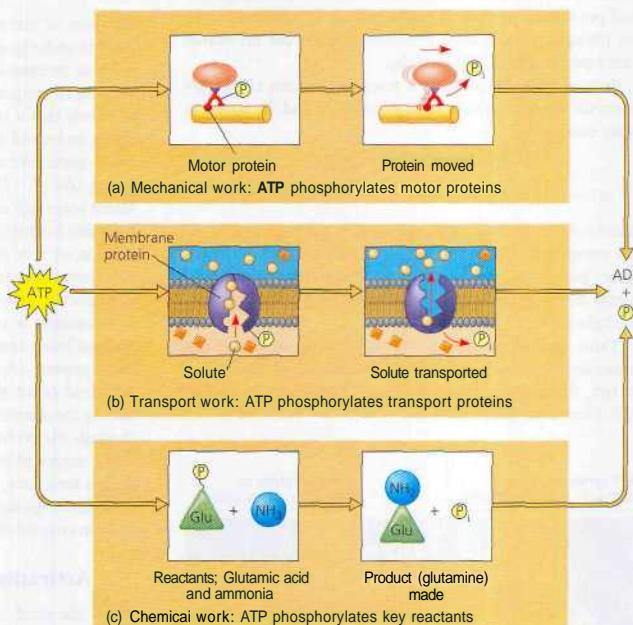

Exergonic reaction: ΔG is negative, reaction is spontaneous

Coupled reactions: Overall ΔG is negative; Together, reactions are spontaneous

$$\Delta G = -3.9 \text{ kcal/mol}$$

A Figure 8.10 Energy coupling using ATP hydrolysis. In this example, the exergonic process of ATP hydrolysis is used to drive an endergonic process—the synthesis of the amino acid glutamine from glutamic acid and ammonia.

A Figure 8.11 How ATP drives cellular work Phosphate group transfer is the mechanism responsible for most types of cellular work. For example, (a) ATP drives mechanical work by phosphorylating motor proteins, such as the ones that move organelles along cytoskeletal "tracks" in the cell. ATP also (b) drives active transport by phosphorylating certain membrane proteins. And ATP (c) drives chemical work by phosphorylating key reactants, in this case glutamic acid that is then converted to glutamine. The phosphorylated molecules lose the phosphate groups as work is performed, leaving ADP and inorganic phosphate (Pi) as products. Cellular respiration replenishes the ATP supply by powering the phosphorylation of ADP, as we will see in the next chapter.

and ammonia (see Figure 8.11c). First, ATP phosphorylates glutamic acid (Glu), making it a less stable phosphorylated intermediate. Second, ammonia displaces the phosphate group, forming glutamine (Glu—NH₂). Because the overall process is exergonic, it occurs spontaneously (see Figure 8.10).

The Regeneration of ATP

An organism at work uses ATP continuously, but ATP is a renewable resource that can be regenerated by the addition of phosphate to ADP (Figure 8.12). The free energy required to phosphorylate ADP comes from exergonic breakdown reactions (catabolism) in the cell. This shuttling of inorganic phosphate and energy is called the ATP cycle, and it couples the cell's energy-yielding (exergonic) processes to the energy-consuming (endergonic) ones. The ATP cycle moves at an astonishing pace. For example, a working muscle cell recycles its entire pool of ATP in less than a minute. That turnover represents 10 million molecules of ATP consumed and regenerated per second per cell. If ATP could not be regenerated by the phosphorylation of ADP, humans would use up nearly their body weight in ATP each day.

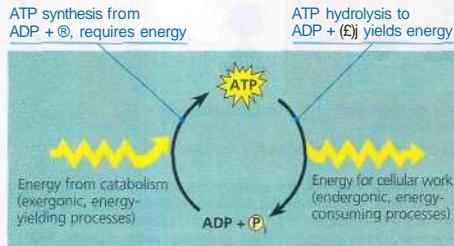

Because both directions of a reversible process cannot go downhill, the regeneration of ATP from ADP and (P)ⁱ is necessarily endergonic:

$\Delta G = +7.3 \text{ kcal/mol}$ (+30.5 kJ/mol) (standard conditions)

Because ATP formation from ADP and (P)ⁱ is not spontaneous, free energy must be spent to make it occur. Catabolic (exergonic) pathways, especially cellular respiration, provide the energy for the endergonic process of making ATP. Plants also use light energy to produce ATP.

Thus, the ATP cycle is a turnstile through which energy passes during its transfer from catabolic to anabolic pathways. In fact, the chemical potential energy temporarily stored in ATP drives most cellular work.

A Figure 8.12 The ATP cycle. Energy released by breakdown reactions (catabolism) in the cell is used to phosphorylate ADP, regenerating ATP. Energy stored in ATP drives most cellular work.

Concept Check 8.3

- In most cases, how does ATP transfer energy from exergonic to endergonic processes in the cell?
- Which of the following groups has more free energy; glutamic acid + ammonia + ATP, or glutamine + ADP + (P)ⁱ? Explain your answer.

For suggested answers, see Appendix A.

Concept 8.4

Enzymes speed up metabolic reactions by lowering energy barriers

The laws of thermodynamics tell us what will and will not happen under given conditions but say nothing about the rate of these processes. A spontaneous chemical reaction occurs without any requirement for outside energy, but it may occur so slowly that it is imperceptible. For example, even though the hydrolysis of sucrose (table sugar) to glucose and fructose is exergonic, occurring spontaneously with a release of free energy ($\Delta G = -7 \text{ kcal/mol}$), a solution of sucrose dissolved in sterile water will sit for years at room temperature with no appreciable hydrolysis. However, if we add a small amount of a catalyst, such as the enzyme sucrase, to the solution, then all the sucrose may be hydrolyzed within seconds (Figure 8.13); How does an enzyme do this?

A catalyst is a chemical agent that speeds up a reaction without being consumed by the reaction; an enzyme is a catalytic protein. (Another class of biological catalysts, made of RNA and called ribozymes, is discussed in Chapters 17 and 26.) In the absence of regulation by enzymes, chemical traffic through the pathways of metabolism would become hopelessly congested because many chemical reactions would take such a long time. In the next two sections, we will see what impedes a spontaneous reaction from occurring faster and how an enzyme changes the situation.

The Activation Energy Barrier

Every chemical reaction between molecules involves bond breaking and bond forming. For example, the hydrolysis of sucrose involves breaking the bond between glucose and fructose and one of the bonds of a water molecule, and then forming two new bonds, as shown in Figure 8.13. Changing one molecule into another generally involves contorting the starting molecule into a highly unstable state before the reaction can proceed. This contortion can be compared to a metal

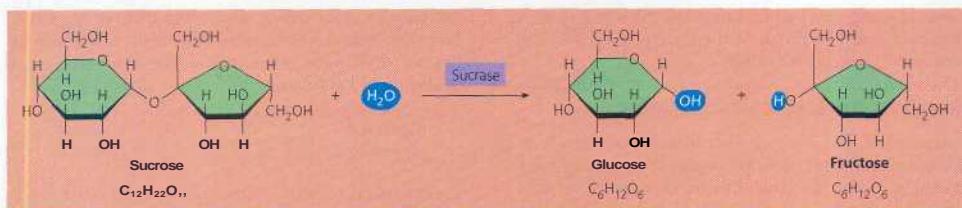

Figure 8.13 Example of an enzyme-catalyzed reaction: hydrolysis of sucrose by sucrase.

key ring when you bend it and pry it open to add a new key. The key ring is highly unstable in its opened form but returns to a stable state once the key is threaded all the way onto the ring. To reach the contorted state where bonds can change, reactant molecules must absorb energy from their surroundings. When the new bonds of the product molecules form, energy is released as heat, and the molecules return to stable shapes with lower energy.

The initial investment of energy for starting a reaction—the energy required to contort the reactant molecules so the bonds can change—is known as the **free energy of activation**, or **activation energy**, abbreviated E_A in this book. We can think of activation energy as the amount of energy needed to push the reactants over an energy barrier, or hill, so that the "downhill" part of the reaction can begin. **Figure 8.14** graphs the energy changes for a hypothetical exergonic reaction that swaps portions of two reactant molecules:

The energizing, or activation, of the reactants is represented by the uphill portion of the graph, with the free-energy content of the reactant molecules increasing. At the summit, the reactants are in an unstable condition known as the *transition state*: They are activated, and the breaking and making of bonds can occur. The bond-forming phase of the reaction corresponds to the downhill part of the curve, which shows the loss of free energy by the molecules.

Activation energy is often supplied in the form of heat that the reactant molecules absorb from the surroundings. The bonds of the reactants break only when the molecules have absorbed enough energy to become unstable and are therefore more reactive (in the transition state at the peak of the curve in Figure 8.14). The absorption of thermal energy increases the speed of the reactant molecules, so they collide more often and more forcefully. Also, thermal agitation of the atoms in the molecules makes the bonds more likely to break. As the molecules settle into their new, more stable bonding arrangements, energy is released to the surroundings. If the reaction is exergonic, E_A will be repaid with dividends, as the formation of new bonds releases more energy than was invested in the breaking of old bonds.

The reactants AB and CD must absorb enough energy from the surroundings to reach the unstable transition state, where bonds can break.

Bonds break and new bonds form, releasing energy to the surroundings.

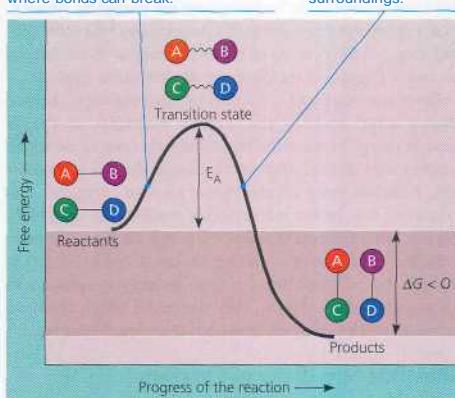

Figure 8.14 Energy profile of an exergonic reaction.

The "molecules" are hypothetical, with A, B, C, and D representing portions of the molecules. Thermodynamically, this is an exergonic reaction, with a negative ΔG , and the reaction occurs spontaneously. However, the activation energy (E_A) provides a barrier that determines the rate of the reaction.

The reaction shown in Figure 8.14 is exergonic and occurs spontaneously. However, the activation energy provides a barrier that determines the rate of the reaction. The reactants must absorb enough energy to reach the top of the activation energy barrier before the reaction can occur. For some reactions, E_A is modest enough that even at room temperature there is sufficient thermal energy for many of the reactants to reach the transition state in a short time. In most cases, however, E_A is so high and the transition state is reached so rarely that the reaction will hardly proceed at all. In these cases, the reaction will occur at a noticeable rate only if the reactants are heated. The spark plugs in an automobile engine energize the gasoline-oxygen mixture so that the molecules reach the transition state and react; only then can there be the explosive

release of energy that pushes the pistons. Without a spark, a mixture of gasoline hydrocarbons and oxygen will not react because the EA barrier is too high.

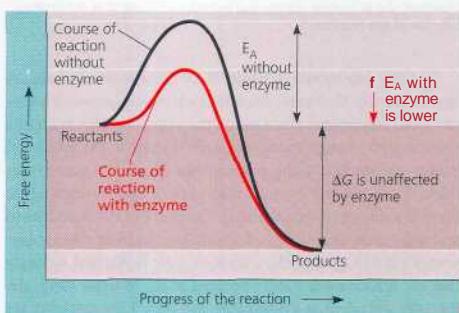

How Enzymes Lower the E_A Barrier

Proteins, DNA, and other complex molecules of the cell are rich in free energy and have the potential to decompose spontaneously; that is, the laws of thermodynamics favor their breakdown. These molecules persist only because at temperatures typical for cells, few molecules can make it over the hump of activation energy. However, the barriers for selected reactions must occasionally be surmounted for cells to carry out the processes necessary for life. Heat speeds a reaction by allowing reactants to attain the transition state more often, but this solution would be inappropriate for biological systems. First, high temperature denatures proteins and kills cells. Second, heat would speed up *all* reactions, not just those that are necessary. Organisms therefore use an alternative: catalysis.

An enzyme catalyzes a reaction by lowering the E_A barrier (**Figure 8.15**), enabling the reactant molecules to absorb enough energy to reach the transition state even at moderate temperatures. An enzyme cannot change the AC for a reaction; it cannot make an endergonic reaction exergonic. Enzymes can only hasten reactions that would occur eventually anyway, but this function makes it possible for the cell to have a dynamic metabolism, routing chemical traffic smoothly through the cell. And because enzymes are very selective in the reactions they catalyze, they determine which chemical processes will be going on in the cell at any particular time.

Substrate Specificity of Enzymes

The reactant an enzyme acts on is referred to as the enzyme's substrate. The enzyme binds to its substrate (or substrates, when there are two or more reactants), forming an enzyme-

A Figure 8.15 The effect of enzymes on reaction rate. Without affecting the free-energy change (ΔG) for a reaction, an enzyme speeds the reaction by reducing its activation energy (E_A).

substrate complex. While enzyme and substrate are joined, the catalytic action of the enzyme converts the substrate to the product (or products) of the reaction. The overall process can be summarized as follows:

For example, the enzyme sucrase (most enzyme names end in -ase) catalyzes the hydrolysis of the disaccharide sucrose into its two monosaccharides, glucose and fructose (see Figure 8.13):

The reaction catalyzed by each enzyme is very specific; an enzyme can recognize its specific substrate even among closely related compounds, such as isomers. For instance, sucrase will act only on sucrose and will not bind to other disaccharids, such as maltose. What accounts for this molecular recognition? Recall that enzymes are proteins, and proteins are macromolecules with unique three-dimensional conformations. The specificity of an enzyme results from its shape, which is a consequence of its amino acid sequence.

Only a restricted region of the enzyme molecule actually binds to the substrate. This region, called the active site, is typically a pocket or groove on the surface of the protein (**Figure 8.16a**). Usually, the active site is formed by only a few of the enzyme's amino acids, with the rest of the protein molecule providing a framework that determines the configuration of the active site. The specificity of an enzyme is attributed to a compatible fit between the shape of its active site and the shape of the substrate. The active site, however, is not a rigid receptacle for the substrate. As the substrate enters the active site, interactions between its chemical groups and those on the amino acids of the protein cause the enzyme to change its shape slightly so that the active site fits even more snugly around the substrate (**Figure 8.16b**). This induced fit is like a clasping handshake. Induced fit brings chemical groups of the active site into positions that enhance their ability to catalyze the chemical reaction.

Catalysis in the Enzyme's Active Site

In an enzymatic reaction, the substrate binds to the active site (**Figure 8.17**). In most cases, the substrate is held in the active site by weak interactions, such as hydrogen bonds and ionic bonds. Side chains (R groups) of a few of the amino acids that make up the active site catalyze the conversion of substrate to product, and the product departs from the active site. The enzyme is then free to take another substrate molecule into its active site. The entire cycle happens so fast that a single enzyme molecule typically acts on about a thousand substrate molecules per second. Some enzymes are much faster. Enzymes, like other catalysts, emerge from the reaction in their original form. There-

- Figure 8.16 Induced fit between an enzyme and its substrate. (a) In this computer graphic model, the active site of this enzyme (hexokinase, shown in blue) forms a groove on its surface. Its substrate is glucose (red). (b) When the substrate enters the active site, it induces a change in the shape of the protein. This change allows more weak bonds to form, causing the active site to embrace the substrate and hold it in place.

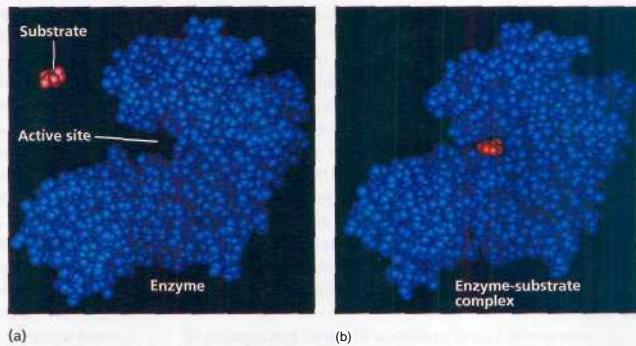

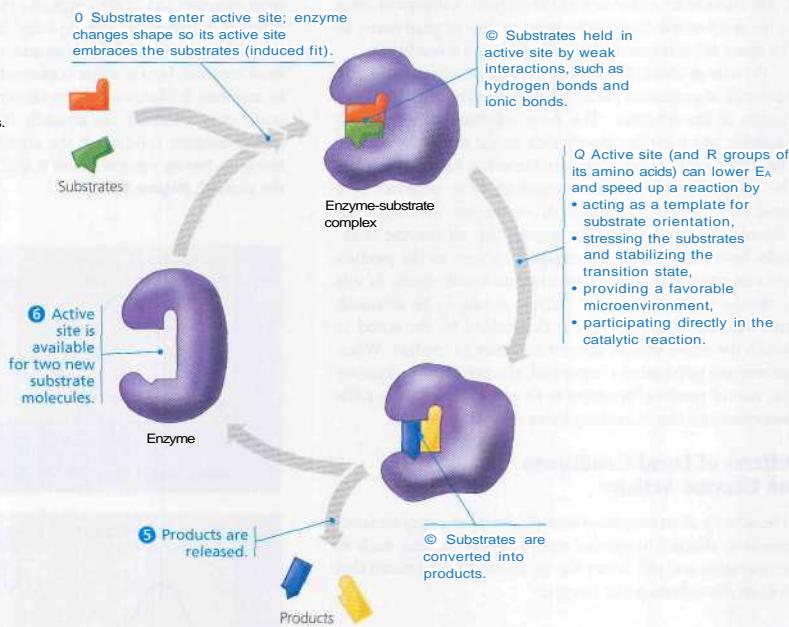

Figure 8.17 The active site and catalytic cycle of an enzyme. An enzyme can convert one or more reactant molecules to one or more product molecules. The enzyme shown here converts two substrate molecules to two product molecules.

lore, very small amounts of enzyme can have a huge metabolic impact by functioning over and over again in catalytic cycles.

Most metabolic reactions are reversible, and an enzyme can catalyze both the forward and the reverse reactions. Which reaction prevails depends mainly on the relative concentrations of reactants and products. The enzyme always catalyzes the reaction in the direction of equilibrium.

Enzymes use a variety of mechanisms that lower activation energy and speed up a reaction (see Figure 8.17, step ③). First, in reactions involving two or more reactants, the active site provides a template for the substrates to come together in the proper orientation for a reaction to occur between them. Second, as the active site of an enzyme clutches the bound substrates, the enzyme may stretch the substrate molecules

toward their transition-state conformation, stressing and bending critical chemical bonds that must be broken during the reaction. Because E^\ddagger is proportional to the difficulty of breaking the bonds, distorting the substrate makes it approach the transition state and thus reduces the amount of free energy that must be absorbed to achieve a transition state.

Third, the active site may also provide a microenvironment that is more conducive to a particular type of reaction than the solution itself would be without the enzyme. For example, if the active site has amino acids with acidic side chains (R groups), the active site may be a pocket of low pH in an otherwise neutral cell. In such cases, an acidic amino acid may facilitate H⁺ transfer to the substrate as a key step in catalyzing the reaction.

A fourth mechanism of catalysis is the direct participation of the active site in the chemical reaction. Sometimes this process even involves brief covalent bonding between the substrate and a side chain of an amino acid of the enzyme. Subsequent steps of the reaction restore the side chains to their original states, so the active site is the same after the reaction as it was before.

The rate at which a particular amount of enzyme converts substrate to product is partly a function of the initial concentration of the substrate: The more substrate molecules are available, the more frequently they access the active sites of the enzyme molecules. However, there is a limit to how fast the reaction can be pushed by adding more substrate to a fixed concentration of enzyme. At some point, the concentration of substrate will be high enough that all enzyme molecules have their active sites engaged. As soon as the product exits an active site, another substrate molecule enters. At this substrate concentration, the enzyme is said to be *saturated*, and the rate of the reaction is determined by the speed at which the active site can convert substrate to product. When an enzyme population is saturated, the only way to increase the rate of product formation is to add more enzyme. Cells sometimes do this by making more enzyme molecules.

Effects of Local Conditions on Enzyme Activity

The activity of an enzyme—how efficiently the enzyme functions—is affected by general environmental factors, such as temperature and pH. It can also be affected by chemicals that specifically influence that enzyme.

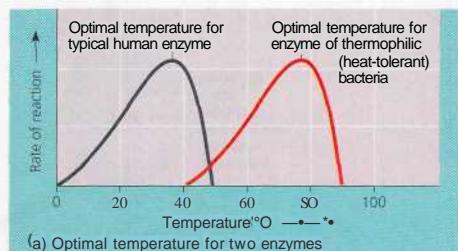

Effects of Temperature and pH

Recall from Chapter 5 that the three-dimensional structures of proteins are sensitive to their environment. As a consequence, each enzyme works better under some conditions than under others, because these *optimal conditions* favor the most active conformation for the enzyme molecule.

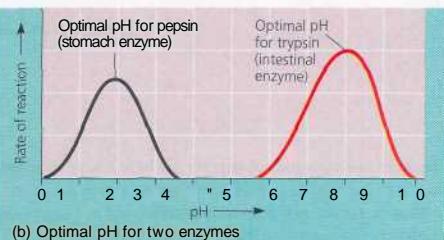

Temperature and pH are environmental factors important in the activity of an enzyme. Up to a point, the rate of an

enzymatic reaction increases with increasing temperature, partly because substrates collide with active sites more frequently when the molecules move rapidly. Above that temperature, however, the speed of the enzymatic reaction drops sharply. The thermal agitation of the enzyme molecule disrupts the hydrogen bonds, ionic bonds, and other weak interactions that stabilize the active conformation, and the protein molecule eventually denatures. Each enzyme has an optimal temperature at which its reaction rate is greatest. Without denaturing the enzyme, this temperature allows the greatest number of molecular collisions and the fastest conversion of the reactants to product molecules. Most human enzymes have optimal temperatures of about 35–40°C (close to human body temperature). Bacteria that live in hot springs contain enzymes with optimal temperatures of 70°C or higher (Figure 8.18a).

just as each enzyme has an optimal temperature, it also has a pH at which it is most active. The optimal pH values for most enzymes fall in the range of pH 6–8, but there are exceptions. For example, pepsin, a digestive enzyme in the stomach, works best at pH 2. Such an acidic environment denature most enzymes, but the active conformation of pepsin is adapted to maintain its functional three-dimensional structure in the acidic environment of the stomach. In contrast, trypsin, a digestive enzyme residing in the alkaline environment of the intestine, has an optimal pH of 8 and would be denatured in the stomach (Figure 8.18b).

(a) Optimal temperature for two enzymes

(b) Optimal pH for two enzymes

A Figure 8.18 Environmental factors affecting enzyme activity. Each enzyme has an optimal (a) temperature and (b) pH that favor the most active conformation of the protein molecule.

Cofactors

Many enzymes require nonprotein helpers for catalytic activity. These adjuncts, called cofactors, may be bound tightly to the enzyme as permanent residents, or they may bind loosely and reversibly along with the substrate. The cofactors of some enzymes are inorganic, such as the metal atoms zinc, iron, and copper in ionic form. If the cofactor is an organic molecule, it is more specifically called a coenzyme. Most vitamins are coenzymes or raw materials from which coenzymes are made. Cofactors function in various ways, but in all cases where they are used, they perform a crucial function in catalysis. You'll encounter examples of cofactors later in the book.

Enzyme Inhibitors

Certain chemicals selectively inhibit the action of specific enzymes, and we have learned a lot about enzyme function by studying the effects of these molecules. If the inhibitor attaches to the enzyme by covalent bonds, inhibition is usually irreversible.

Many enzyme inhibitors, however, bind to the enzyme by weak bonds, in which case inhibition is reversible. Some reversible inhibitors resemble the normal substrate molecule and compete for admission into the active site (**Figure 8.19a** and **b**). These mimics, called competitive inhibitors, reduce the productivity of enzymes by blocking substrates from entering active sites. This kind of inhibition can be overcome by increasing the concentration of substrate so that as active sites become available, more substrate molecules than inhibitor molecules are around to gain entry to the sites.

In contrast, noncompetitive inhibitors do not directly compete with the substrate to bind to the enzyme at the active site (**Figure 8.19c**). Instead, they impede enzymatic reactions by binding to another part of the enzyme. This interaction causes the enzyme molecule to change its shape, rendering the active site less effective at catalyzing the conversion of substrate to product.

Toxins and poisons are often irreversible enzyme inhibitors. An example is sarin, a nerve gas that caused the death of several people and injury to many others when it was released by terrorists in the Tokyo subway in 1995. This small molecule binds covalently to the R group on the amino acid serine, which is found in the active site of acetylcholinesterase, an enzyme important in the nervous system. Other examples include the pesticides DDT and parathion, inhibitors of key enzymes in the nervous system. Finally, many antibiotics are inhibitors of specific enzymes in bacteria. For instance, penicillin blocks the active site of an enzyme that many bacteria use to make their cell walls.

Citing enzyme inhibitors that are metabolic poisons may give the impression that enzyme inhibition is generally abnormal and harmful. In fact, molecules naturally present in the cell often regulate enzyme activity by acting as inhibitors.

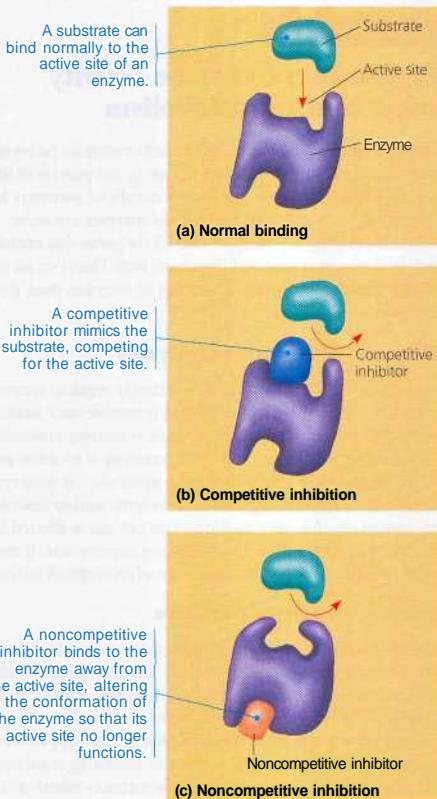

Figure 8.19 Inhibition of enzyme activity.

Such regulation—selective inhibition—is essential to the control of cellular metabolism, as we discuss next.

Concept Check 8.4

1. Many spontaneous reactions occur very slowly. Why don't all spontaneous reactions occur instantly?
2. Describe why enzymes act only on very specific substrates.
3. Malonate is a competitive inhibitor of the enzyme succinate dehydrogenase. Describe how malonate would prevent the enzyme from acting on its normal substrate succinate.

For suggested answers, see Appendix A.

Concept 8.5

Regulation of enzyme activity helps control metabolism

Chemical chaos would result if all of a cell's metabolic pathways were operating simultaneously. Intrinsic to the process of life is a cell's ability to tightly regulate its metabolic pathways by controlling when and where its various enzymes are active. It does this either by switching on and off the genes that encode specific enzymes (as we will discuss in Unit Three) or, as we discuss here, by regulating the activity of enzymes once they are made.

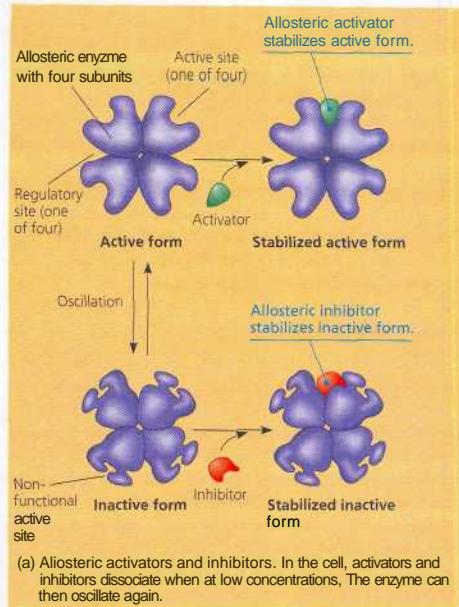

Allosteric Regulation of Enzymes

In many cases, the molecules that naturally regulate enzyme activity in a cell behave something like reversible noncompetitive inhibitors (see Figure 8.19c). These regulatory molecules change an enzyme's shape and the functioning of its active site by binding to a site elsewhere on the molecule, via noncovalent bonds. Allosteric regulation is the term used to describe any case in which a protein's function at one site is affected by the binding of a regulatory molecule to a separate site. It may result in either inhibition or stimulation of an enzyme's activity.

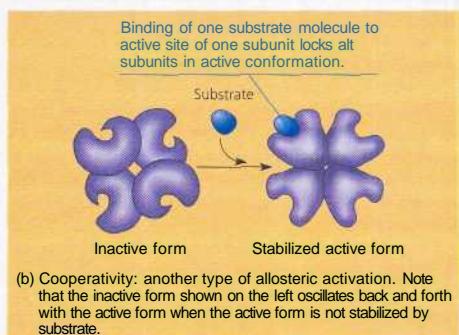

Allosteric Activation and Inhibition

Most allosterically regulated enzymes are constructed from two or more polypeptide chains, or subunits (Figure 8.20). Each subunit has its own active site. The entire complex oscillates between two conformational states, one catalytically active and the other inactive (Figure 8.20a). In the simplest case of allosteric regulation, an activating or inhibiting regulator's molecule binds to a regulatory site (sometimes called an allosteric site), often located where subunits join. The binding of an *activator* to a regulatory site stabilizes the conformation that has functional active sites, whereas the binding of an *inhibitor* stabilizes the inactive form of the enzyme. The subunits of an allosteric enzyme fit together in such a way that a conformational change in one subunit is transmitted to all others. Through this interaction of subunits, a single activator or inhibitor molecule that binds to one regulatory site will affect the active sites of all subunits.

Fluctuating concentrations of regulators can cause a sophisticated pattern of response in the activity of cellular enzymes. The products of ATP hydrolysis (ADP and Pi), for example, play a major role in balancing the flow of traffic between anabolic and catabolic pathways by their effects on key enzymes. For example, ATP binds to several catabolic enzymes allosterically, lowering their affinity for substrate and thus inhibiting their activity. ADP however, functions as an activator of the same enzymes. This is logical because a major function of catabolism is to regenerate ATP if ATP production lags behind its

(a) Allosteric activators and inhibitors. In the cell, activators and inhibitors dissociate when at low concentrations. The enzyme can then oscillate again.

(b) Cooperativity: another type of allosteric activation. Note that the inactive form shown on the left oscillates back and forth with the active form when the active form is not stabilized by substrate.

A Figure 8.20 Allosteric regulation of enzyme activity.

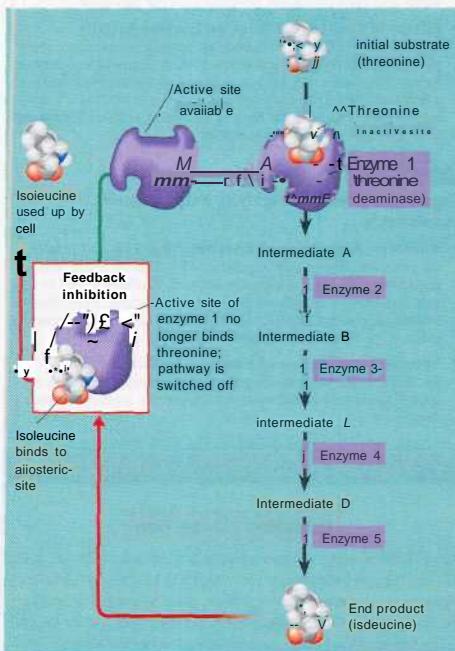

use, ADP accumulates and activates these key enzymes that speed up catabolism, producing more ATP. If the supply of ATP exceeds demand, then catabolism slows down as ATP molecules accumulate and bind these same enzymes, inhibiting them. ATP, ADP and other related molecules also affect key enzymes in anabolic pathways. In this way, allosteric enzymes control the rates of key reactions in metabolic pathways.

In another kind of allosteric activation, a substrate molecule binding to one active site may stimulate the catalytic powers

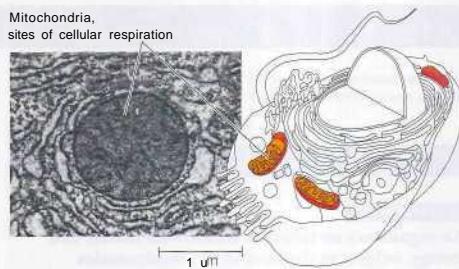

of a multi-subunit enzyme by affecting the other active sites (**Figure 8.20b**). If an enzyme has two or more subunits, a substrate molecule causing induced fit in one subunit can trigger the same favorable conformational change in all the other subunits of the enzyme. Called cooperativity, this mechanism amplifies the response of enzymes to substrates: One substrate molecule primes an enzyme to accept additional substrate molecules more readily.

Feedback Inhibition

When ATP allosterically inhibits an enzyme in an ATP-generating pathway, the result is feedback inhibition, a common method of metabolic control. In feedback inhibition, a metabolic pathway is switched off by the inhibitory binding of its end product to an enzyme that acts early in the pathway. **Figure 8.21** shows an example of this control mechanism operating on an anabolic pathway. Some cells use this pathway of five steps to synthesize the amino acid isoleucine from threonine, another amino acid. As isoleucine accumulates, it slows down its own synthesis by allosterically inhibiting the enzyme for the very first step of the pathway. Feedback inhibi-

A Figure 8.21 Feedback inhibition in isoleucine synthesis.

A Figure 8.22 Organelles and structural order in metabolism. Organelles such as these mitochondria (TEM) contain enzymes that carry out specific functions, in this case cellular respiration.

bition thereby prevents the cell from wasting chemical resources by synthesizing more isoleucine than is necessary.

Specific Localization of Enzymes Within the Cell

The cell is not just a bag of chemicals with thousands of different kinds of enzymes and substrates in a random mix. Structures within the cell help bring order to metabolic pathways. In some cases, a team of enzymes for several steps of a metabolic pathway is assembled into a multienzyme complex. The arrangement controls and speeds up the sequence of reactions, as the product from the first enzyme becomes the substrate for an adjacent enzyme in the complex, and so on, until the end product is released. Some enzymes and enzyme complexes have fixed locations within the cell, and act as structural components of particular membranes. Others are in solution within specific membrane-enclosed eukaryotic organelles, each with its own internal chemical environment. For example, in eukaryotic cells, the enzymes for cellular respiration reside in specific locations within mitochondria. (**Figure 8.22**).

In this chapter we have learned that metabolism, the intersecting set of chemical pathways characteristic of life, is a choreographed interplay of thousands of different kinds of cellular molecules. In the next chapter we explore cellular respiration, the major catabolic pathway that breaks down organic molecules, releasing energy for the crucial processes of life.

SUMMARY OF KEY CONCEPTS

Concept 8.1

An organism's metabolism transforms matter and energy, subject to the laws of thermodynamics

- **Organization of the Chemistry of Life into Metabolic Pathways** (pp. 141–142) Metabolism is the collection of chemical reactions that occur in an organism. Aided by enzymes, it follows intersecting pathways, which may be catabolic (breaking down molecules, releasing energy) or anabolic (building molecules, consuming energy).
- **Forms of Energy** (pp. 142–143) Energy is the capacity to cause change; some forms of energy do work by moving matter. Kinetic energy is associated with motion. Potential energy is stored in the location or structure of matter and includes chemical energy stored in molecular structure.
- **The Laws of Energy Transformation** (pp. 143–144) The first law, conservation of energy, states that energy cannot be created or destroyed; only transferred or transformed. The second law states that spontaneous changes, those requiring no outside input of energy, increase the entropy (disorder) of the universe.
Activity Energy Transformations

Concept 8.2

The free-energy change of a reaction tells us whether the reaction occurs spontaneously

- **Free-Energy Change, ΔG** (p. 145) A living system's free energy is energy that can do work under cellular conditions. The change in free energy (ΔG) during a biological process is related directly to enthalpy change (ΔH) and to the change in entropy (ΔS): $\Delta G = \Delta H - \Delta S \cdot T$.
- **Free Energy, Stability, and Equilibrium** (pp. 145–146) Organisms live at the expense of free energy. During a spontaneous change, free energy decreases and the stability of a system increases. At maximum stability, the system is at equilibrium.
- **Free Energy and Metabolism** (pp. 146–148) In an exergonic (spontaneous) chemical reaction, the products have less free energy than the reactants ($- \Delta G$). Endergonic (nonspontaneous) reactions require an input of energy ($+ \Delta G$). The addition of starting materials and the removal of end products prevent metabolism from reaching equilibrium.

Concept 8.3

ATP powers cellular work by coupling exergonic reactions to endergonic reactions

- **The Structure and Hydrolysis of ATP** (pp. 148–149) ATP is the cell's energy shuttle. Release of its terminal phosphate group produces ADP, inorganic phosphate, and free energy
Activity The Structure of ATP
- **How ATP Performs Work** (pp. 149–150) ATP drives endergonic reactions by phosphorylation, the transfer of a phosphate

group to specific reactants, making them more reactive. In this way, cells can carry out work, such as movement and anabolism.

Activity Chemical Reactions and ATP

- **The Regeneration of ATP** (p. 150) Catabolic pathways drive the regeneration of ATP from ADP and phosphate.

Concept 8.4

Enzymes speed up metabolic reactions by lowering energy barriers

- **The Activation Energy Barrier** (pp. 150–152) In a chemical reaction, the energy necessary to break the bonds of the reactants is the activation energy, E_A .
- **How Enzymes Lower the E_A Barrier** (p. 152) Enzymes, which are proteins, are biological catalysts. They speed up reactions by lowering the activation energy barrier.
- **Substrate Specificity of Enzymes** (p. 152) Each type of enzyme has a unique active site that combines specifically with its substrate, the reactant molecule on which it acts. The enzyme changes shape slightly when it binds the substrate (induced fit).
Activity How Enzymes Work
- **Catalysis in the Enzyme's Active Site** (pp. 152–154) The active site can lower an E_A barrier by orienting substrates correctly, straining their bonds, providing a favorable microenvironment, and even covalently bonding with the substrate.

- **Effects of Local Conditions on Enzyme Activity** (pp. 154–155) Each enzyme has an optimal temperature and pH. Inhibitors reduce enzyme function. A competitive inhibitor binds to the active site, while a noncompetitive inhibitor binds to a different site on the enzyme.

Investigation How Is the Rate of Enzyme Catalysis Measured? Biology Labs On-Line EnzymeLab

Concept 8.5

Regulation of enzyme activity helps control metabolism

- **Allosteric Regulation of Enzymes** (pp. 156–157) Many enzymes are allosterically regulated: They change shape when regulatory molecules, either activators or inhibitors, bind to specific regulatory sites, affecting enzymatic function. If feedback inhibition, the end product of a metabolic pathway) allosterically inhibits the enzyme for an earlier step in the pathway
- **Specific Localization of Enzymes Within the Cell** (p. 157) Some enzymes are grouped into complexes, some are incorporated into membranes, and others are contained inside organelles.

TESTING YOUR KNOWLEDGE

Evolution Connection

A recent revival of the anti-evolutionary "argument from design" holds that biochemical pathways are too complex to have evolved, because all intermediate steps in a given pathway must be present to produce the final product. Critique this argument. How could you use the existing diversity of metabolic pathways that produce the same or similar products to support your case?

Scientific Inquiry

A researcher has developed an assay to measure the activity of an important enzyme present in liver cells being grown in culture. She adds the enzyme's substrate to a dish of cells, then measures the appearance of reaction products. The results are graphed as the amount of product on the y-axis versus time on the x-axis. The researcher notes four sections of the graph. For a short period of time, no products appeared (section A). Then (section B) the reaction rate was quite high (the slope of the line was steep). After some time, the reaction slowed down considerably (section C), although, products continued to appear (the line was not flat). Still later, the reaction resumed its original rapid rate (section D). Draw the graph, and propose a model to explain the molecular events underlying this interesting reaction profile.

Investigation How Is the Rate of Enzyme Catalysis Measured?
Biology Labs On-Line EnzymeLab

Science, Technology, and Society

The EPA is evaluating the safety of the most commonly used organophosphate insecticides (organic compounds containing phosphate groups). Organophosphates typically interfere with nerve transmission by inhibiting the enzymes that degrade the transmitter molecules diffusing from one neuron to another. Noxious insects are not uniquely¹ susceptible; humans and other vertebrates can be affected as well. Thus, the use of organophosphate pesticides creates some health risks. As a consumer, what level of risk are you willing to accept in exchange for an abundant and affordable food supply? What other facts would you like to know before you defend your opinion?

9 Cellular Respiration

Harvesting Chemical Energy

A Figure 9.1 This giant panda is consuming fuel to power the work of life.

Key Concepts

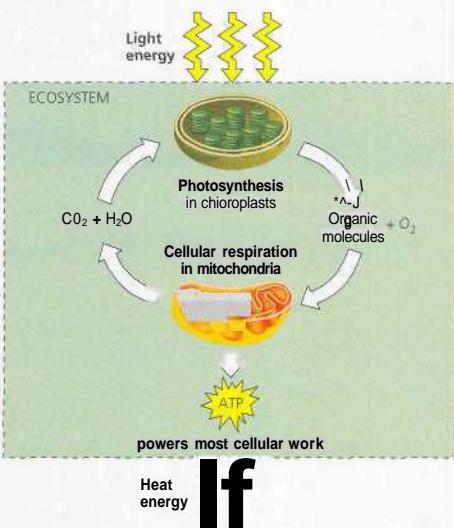

- 9.1 Catabolic pathways yield energy by oxidizing organic fuels
- 9.2 Glycolysis harvests chemical energy by oxidizing glucose to pyruvate
- 9.3 The citric acid cycle completes the energy-yielding oxidation of organic molecules
- 9.4 During oxidative phosphorylation, chemiosmosis couples electron transport to ATP synthesis

- 9.6 Glycolysis and the citric acid cycle connect to many other metabolic pathways

Overview

Life Is Work

Living cells require transfusions of energy from outside sources to perform their many tasks—for example, assembling polymers, pumping substances across membranes, moving, and reproducing. The giant panda in **Figure 9.1** obtains energy for its cells by eating plants; some animals feed on other organisms that eat plants. The energy stored in the organic molecules of food ultimately comes from the sun. Energy flows into an ecosystem as sunlight and leaves as heat (**Figure 9.2**). In contrast, the chemical elements essential to life are recycled. Photosynthesis generates oxygen and organic molecules used by the mitochondria of eukaryotes (including plants and algae) as fuel for cellular respiration. Respiration breaks this fuel down, generating ATP. The waste products of respiration, carbon dioxide and water, are the raw materials for photosynthesis. In this chapter, we con-

sider how cells harvest the chemical energy stored in organic molecules and use it to generate ATP, the molecule that drives most cellular work. After presenting some basics about respiration, we will focus on the three key pathways of respiration: glycolysis, the citric acid cycle, and oxidative phosphorylation.

A Figure 9.2 Energy flow and chemical recycling in ecosystems. Energy flows into an ecosystem as sunlight and ultimately leaves as heat, while the chemical elements essential to life are recycled.

Concept 9.1

Catabolic pathways yield energy by oxidizing organic fuels

In this section, we consider several processes that are central to cellular respiration and related pathways.

Catabolic Pathways and Production of ATP

Organic compounds store energy in their arrangement of atoms. With the help of enzymes, a cell systematically degrades complex organic molecules that are rich in potential energy to simpler waste products that have less energy. Some of the energy taken out of chemical storage can be used to do work; the rest is dissipated as heat. As you learned in Chapter 8, metabolic pathways that release stored energy by breaking down complex molecules are called catabolic pathways. One catabolic process, fermentation, is a partial degradation of sugars that occurs without the use of oxygen. However, the most prevalent and efficient catabolic pathway is cellular respiration, in which oxygen is consumed as a reactant along with the organic fuel. In eukaryotic cells, mitochondria house most of the metabolic equipment for cellular respiration.

Although very different in mechanism, respiration is in principle similar to the combustion of gasoline in an automobile engine after oxygen is mixed with the fuel (hydrocarbons). Food provides the fuel for respiration, and the exhaust is carbon dioxide and water. The overall process can be summarized as follows:

Although carbohydrates, fats, and proteins can all be processed and consumed as fuel, it is helpful to learn the steps of cellular respiration by tracking the degradation of the sugar glucose ($\text{C}_6\text{H}_{12}\text{O}_6$), the fuel that cells most often use:

This breakdown of glucose is exergonic, having a free-energy change of -686 kcal ($-2,870 \text{ kJ}$) per mole of glucose decomposed ($\Delta G = -686 \text{ kcal/mol}$). Recall that a negative ΔG indicates that the products of the chemical process store less energy than the reactants and that the reaction can happen spontaneously—in other words, without an input of energy.

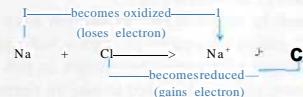

Catabolic pathways do not directly move flagella, pump solutes across membranes, polymerize monomers, or perform other cellular work. Catabolism is linked to work by a chemical drive shaft—ATP, which you learned about in Chapter 8. To keep working, the cell must regenerate its supply of ATP from ADP and Pi (see Figure 8.11). To understand how cellular respiration accomplishes this, let's examine the fundamental chemical processes known as oxidation and reduction.

Redox Reactions: Oxidation and Reduction

Why do the catabolic pathways that decompose glucose and other organic fuels yield energy? The answer is based on the transfer of electrons during the chemical reactions. The relocation of electrons releases energy stored in organic molecules, and this energy ultimately is used to synthesize ATP.

The Principle of Redox

In many chemical reactions, there is a transfer of one or more electrons (e^-) from one reactant to another. These electron transfers are called oxidation-reduction reactions, or redox reactions for short. In a redox reaction, the loss of electrons from one substance is called oxidation, and the addition of electrons to another substance is known as reduction. (Note that *adding* electrons is called *reduction*; negatively charged electrons added to an atom *reduce* the amount of positive charge of that atom.) To take a simple, nonbiological example, consider the reaction between the elements sodium (Na) and chlorine (Cl) that forms table salt:

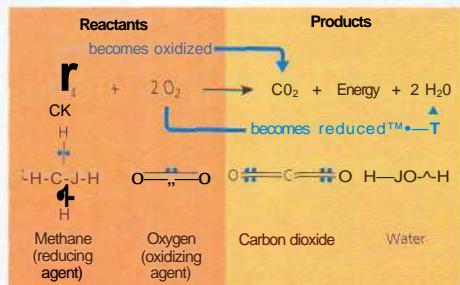

We could generalize a redox reaction this way:

In the generalized reaction, substance X, the electron donor, is called the reducing agent; it reduces Y, which accepts the donated electron. Substance Y, the electron acceptor, is the oxidizing agent; it oxidizes X by removing its electron. Because an electron transfer requires both a donor and an acceptor oxidation and reduction always go together.

Not all redox reactions involve the complete transfer of electrons from one substance to another; some change the degree of electron sharing in covalent bonds. The reaction between methane and oxygen, shown in Figure 9.3 on the next page, is an example. As explained in Chapter 2, the covalent electrons in methane are shared nearly equally between the bonded atoms because carbon and hydrogen have about the same affinity for valence electrons; they are about equally electronegative. But when methane reacts with oxygen, forming carbon dioxide, electrons end up farther away from the carbon atom and closer to their new covalent partners, the oxygen atoms, which are very electronegative. In effect, the carbon atom has "partially lost" its shared electrons; thus, methane has been oxidized.

Now let's examine the fate of the reactant O_2 . The two atoms of the oxygen molecule (O_2) share their electrons equally. But when oxygen reacts with the hydrogen from methane, forming water, the electrons of the covalent bonds are drawn closer to

• **Figure 9.3** Methane combustion as an energy-yielding redox reaction. The reaction releases energy to the surroundings because the electrons lose potential energy when they end up closer to electronegative atoms such as oxygen.

the oxygen (see Figure 9.3). In effect, each oxygen atom has partially "gained" electrons, and so the oxygen molecule will be reduced. Because oxygen is so electronegative, it is one of the most potent of all oxidizing agents.

Energy must be added to pull an electron away from an atom, **just** as energy is required to push a ball uphill. The more electronegative the atom (the stronger its pull on electrons), the more energy is required to take an electron away from it. An electron loses potential energy when it shifts from a less electronegative atom toward a more electronegative one, just as a ball loses potential energy when it rolls downhill. A redox reaction that relocates electrons closer to oxygen, such as the burning of methane, therefore releases chemical energy that can be put to work.

Oxidation of Organic Fuel Molecules During Cellular Respiration

The oxidation of methane by oxygen is the main combustion reaction that occurs at the burner of a gas stove. The combustion of gasoline in an automobile engine is also a redox reaction; the energy released pushes the pistons. But the energy-yielding redox process of greatest interest here is respiration: the oxidation of glucose and other molecules in food. Examine again the summary equation for cellular respiration, but this time think of it as a redox process:

As in the combustion of methane or gasoline, the fuel (glucose) is oxidized and oxygen is reduced. The electrons lose potential energy along the way, and energy is released.

In general, organic molecules that have an abundance of hydrogen are excellent fuels because their bonds are a source of "hilltop" electrons, whose energy may be released as these

electrons "fall" down an energy gradient when they are transferred to oxygen. The summary equation for respiration indicates that hydrogen is transferred from glucose to oxygen. But the important point, not visible in the summary equation, is that the status of electrons changes as hydrogen is transferred to oxygen, liberating energy (ΔG is negative). By oxidizing glucose, respiration liberates stored energy from glucose and makes it available for ATP synthesis.

The main energy foods, carbohydrates and fats, are reservoirs of electrons associated with hydrogen. Only the barrier of activation energy holds back the flood of electrons to a lower energy state (see Figure 8.14)- Without this barrier, a food substance like glucose would combine almost instantaneously with O_2 . When we supply the activation energy by igniting glucose, it burns in air, releasing 686 kcal (2,870 kJ) of heat per mole of glucose (about 180 g). Body temperature is not high enough to initiate burning, of course. Instead, if you swallow some glucose, enzymes in your cells will lower the barrier of activation energy, allowing the sugar to be oxidized in a series of steps.

Stepwise Energy Harvest via NAD^+ and the Electron Transport Chain

If energy is released from a fuel all at once, it cannot be harnessed efficiently for constructive work. For example, if a gasoline tank explodes, it cannot drive a car very far. Cellular respiration does not oxidize glucose in a single explosive step either. Rather, glucose and other organic fuels are broken down in a series of steps, each *one* catalyzed by an enzyme. At key steps, electrons are stripped from the glucose. As is often the case in oxidation reactions, each electron travels with a proton—thus, as a hydrogen atom. The hydrogen atoms are not transferred directly to oxygen, but instead are usually passed first to a coenzyme called NAD^+ (nicotinamide adenine dinucleotide, a derivative of the vitamin niacin). As an electron acceptor, NAD^{+} functions as an oxidizing agent during respiration.

How does NAD^+ trap electrons from glucose and other organic molecules? Enzymes called dehydrogenases remove a pair of hydrogen atoms (two electrons and two protons) from the substrate (a sugar, for example), thereby oxidizing it. The enzyme delivers the two electrons along with *one* proton to its coenzyme, NAD^+ (Figure 9.4). The other proton is released as a hydrogen ion (H^+) into the surrounding solution:

By receiving two negatively charged electrons but only one positively charged proton, NAD^+ has its charge neutralized when it is reduced to NADH. The name NADH shows the hydrogen that has been received in the reaction. NAD^+ is the most versa-

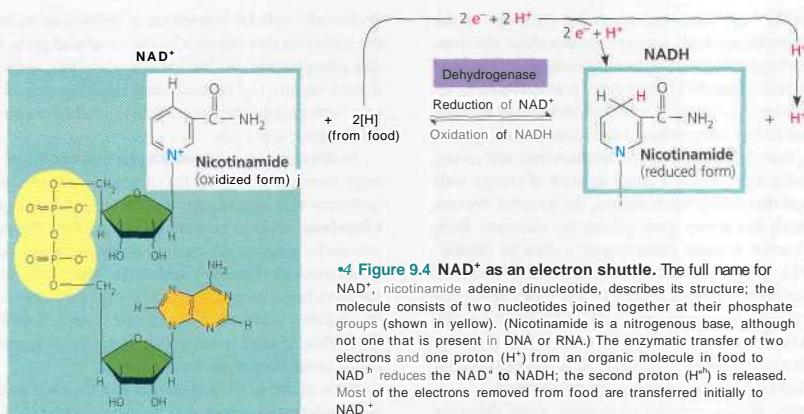

Figure 9.4 NAD⁺ as an electron shuttle. The full name for NAD⁺, nicotinamide adenine dinucleotide, describes its structure; the molecule consists of two nucleotides joined together at their phosphate groups (shown in yellow). (Nicotinamide is a nitrogenous base, although not one that is present in DNA or RNA.) The enzymatic transfer of two electrons and one proton (H^+) from an organic molecule in food to NAD⁺ reduces the NAD⁺ to NADH; the second proton (H^+) is released. Most of the electrons removed from food are transferred initially to NAD⁺.

tile electron acceptor in cellular respiration and functions in several of the redox steps during the breakdown of sugar.

Electrons lose very little of their potential energy when they are transferred from food to NAD⁺. Each NADH molecule formed during respiration represents stored energy that can be tapped to make ATP when the electrons complete their "fall" down an energy gradient from NADH to oxygen.

How do electrons that are extracted from food and stored by NADH finally reach oxygen? It will help to compare the redox chemistry of cellular respiration to a much simpler reaction: the reaction between hydrogen and oxygen to form water (Figure 9.5a). Mix H₂ and O₂, provide a spark for activation

energy, and the gases combine explosively. The explosion represents a release of energy as the electrons of hydrogen fall closer to the electronegative oxygen atoms. Cellular respiration also brings hydrogen and oxygen together to form water, but there are two important differences. First, in cellular respiration, the hydrogen that reacts with oxygen is derived from organic molecules rather than H₂. Second, respiration uses an electron transport chain to break the fall of electrons to oxygen into several energy-releasing steps instead of one explosive reaction (Figure 9.5b). The transport chain consists of a number of molecules, mostly proteins, built into the inner membrane of a mitochondrion. Electrons removed from food are shuttled

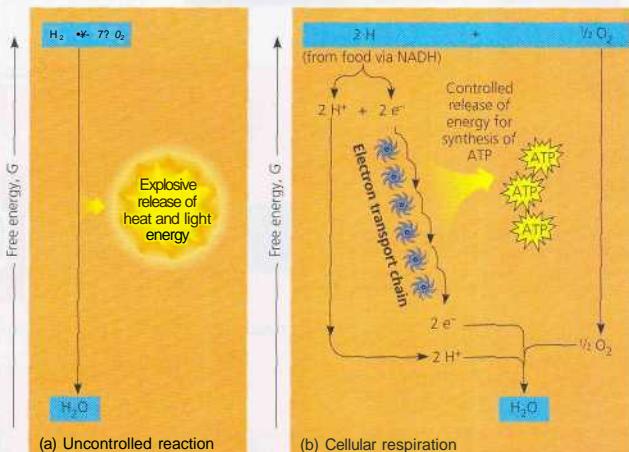

Figure 9.5 An introduction to electron transport chains. (a) The uncontrolled exergonic reaction of hydrogen with oxygen to form water releases a large amount of energy in the form of heat and light; an explosion. (b) In cellular respiration, the same reaction occurs in stages: An electron transport chain breaks the "fall" of electrons in this reaction into a series of smaller steps and stores some of the released energy in a form that can be used to make ATP. (The rest of the energy is released as heat.)

by NADH to the "top," higher-energy end of the chain. At the "bottom," lower-energy end, oxygen captures these electrons along with hydrogen nuclei (H^+), forming water.

Electron transfer from NADH to oxygen is an exergonic reaction with a free-energy change of -53 kcal/mol (-222 kJ/mol). Instead of this energy being released and wasted in a single explosive step, electrons cascade down the chain from one carrier molecule to the next, losing a small amount of energy with each step until they finally reach oxygen, the terminal electron acceptor, which has a very great affinity for electrons. Each "downhill" carrier is more electronegative than its "uphill" neighbor, with oxygen at the bottom of the chain. Thus, the electrons removed from food by NAD^+ fall down an energy gradient in the electron transport chain to a far more stable location in the electronegative oxygen atom. Put another way, oxygen pulls electrons down the chain in an energy-yielding tumble analogous to gravity pulling objects downhill.

In summary during cellular respiration, most electrons travel the following "downhill" route: food \rightarrow $NADH \rightarrow$ electron transport chain \rightarrow oxygen. Later in this chapter, you will learn more about how the cell uses the energy released from this exergonic electron fall to regenerate its supply of ATP.

Now that we have covered the basic redox mechanisms of cellular respiration, let's look at the entire process.

The Stages of Cellular Respiration: A Preview

Respiration is a cumulative function of three metabolic stages:

1. Glycolysis (color-coded light blue throughout the chapter)
2. The citric acid cycle (color-coded salmon)
3. Oxidative phosphorylation: electron transport and chemiosmosis (color-coded violet)

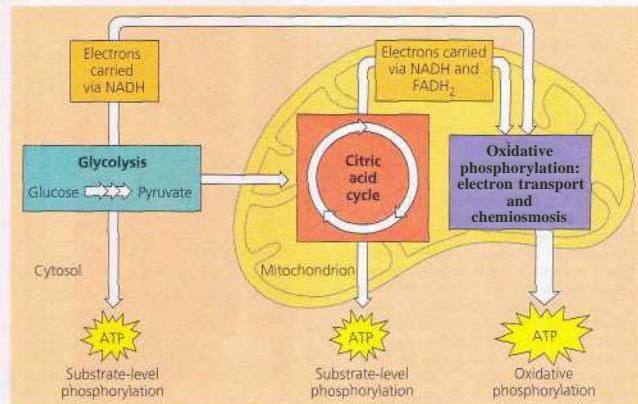

Technically, cellular respiration is defined as including only the processes that require O_2 : the citric acid cycle and oxidative phosphorylation. We include glycolysis, even though it doesn't require O_2 , because most respiring cells deriving energy from glucose use this process to produce starting material for the citric acid cycle.

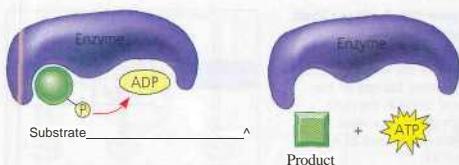

As diagrammed in **Figure 9.6**, the first two stages of cellular respiration, glycolysis and the citric acid cycle, are the catabolic pathways that decompose glucose and other organic fuels. **Glycolysis**, which occurs in the cytosol, begins the degradation process by breaking glucose into two molecules of a compound called pyruvate. The **citric acid cycle**, which takes place within the mitochondrial matrix, completes the breakdown of glucose by oxidizing a derivative of pyruvate to carbon dioxide. Thus, the carbon dioxide produced by respiration represents fragments of oxidized organic molecules.

Some of the steps of glycolysis and the citric acid cycle are redox reactions in which dehydrogenase enzymes transfer electrons from substrates to NAD^+ , forming NADH. In the third stage of respiration, the electron transport chain accepts electrons from the breakdown products of the first two stages (most often via NADH) and passes these electrons from one molecule to another. At the end of the chain, the electrons are combined with molecular oxygen and hydrogen ions (H^+), forming water (see Figure 9.5b). The energy released at each step of the chain is stored in a form the mitochondrion can use to make ATP. This mode of ATP synthesis is called **oxidative phosphorylation** because it is powered by the redox reactions of the electron transport chain.

The inner membrane of the mitochondrion is the site of electron transport and chemiosmosis, the processes that together constitute oxidative phosphorylation. Oxidative phosphorylation accounts for almost 90% of the ATP generated by

>> Figure 9.6 An overview of cellular respiration. During glycolysis, each glucose molecule is broken down into two molecules of the compound pyruvate. The pyruvate enters the mitochondrion, where the citric acid cycle oxidizes it to carbon dioxide. NADH and a similar coenzyme called $FADH_2$ transfer electrons derived from glucose to electron transport chains, which are built into the inner mitochondrial membrane. During oxidative phosphorylation, electron transport chains convert the chemical energy to a form used for ATP synthesis in the process called chemiosmosis.

A Figure 9.7 Substrate-level phosphorylation. Some ATP is made by direct enzymatic transfer of a phosphate group from an organic substrate to ADP.

respiration. A smaller amount of ATP is formed directly in a few reactions of glycolysis and the citric acid cycle by a mechanism called substrate-level phosphorylation (Figure 9.7). This mode of ATP synthesis occurs when an enzyme transfers a phosphate group from a substrate molecule to ADP, rather than adding an inorganic phosphate to ADP as in oxidative phosphorylation. "Substrate molecule" here refers to an organic molecule generated during the catabolism of glucose.

For each molecule of glucose degraded to carbon dioxide and water by respiration, the cell makes up to about 38 molecules of ATP, each with 7.3 kcal/mol of free energy. Respiration cashes in the large denomination of energy banked in a single molecule of glucose (686 kcal/mol) for the small change of many molecules of ATP, which is more practical for the cell to spend on its work.

This preview has introduced how glycolysis, the citric acid cycle, and oxidative phosphorylation fit into the overall process of cellular respiration. We are now ready to take a closer look at each of these three stages of respiration.

Concept Check 9.1

- In the following redox reaction, which compound is oxidized and which is reduced?

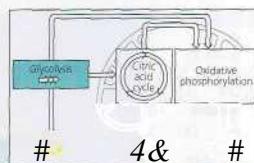

For suggested answers, see Appendix A.

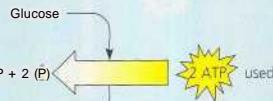

Concept 9.2

Glycolysis harvests chemical energy by oxidizing glucose to pyruvate

The word *glycolysis* means "splitting of sugar," and that is exactly what happens during this pathway. Glucose, a six-carbon sugar, is split into two three-carbon sugars. These smaller sugars are then oxidized and their remaining atoms rearranged to form two molecules of pyruvate. (Pyruvate is the ionized form of pyruvic acid.)

Energy investment phase

Energy payoff phase

Net

A Figure 9.8 The energy input and output of glycolysis.

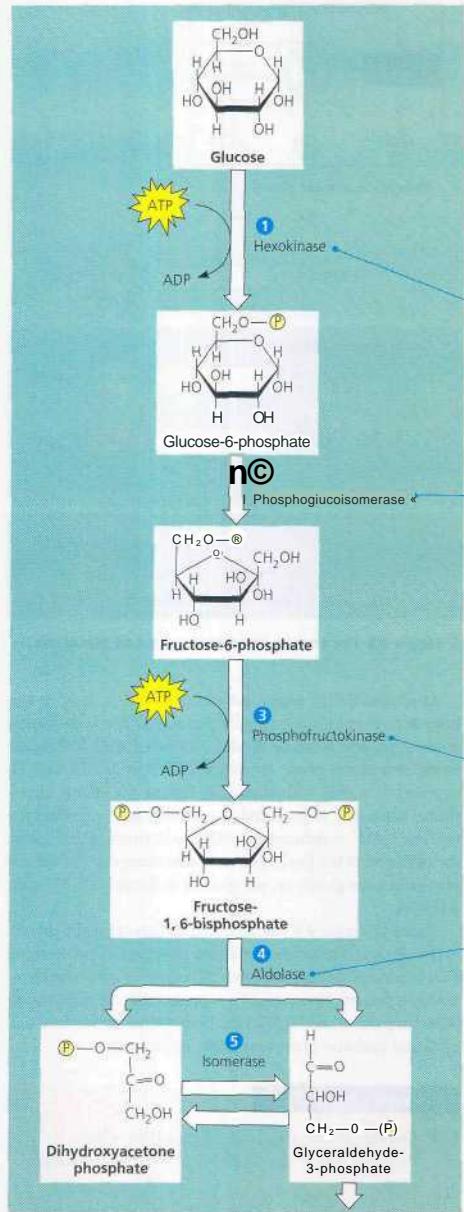

As summarized in Figure 9.8 and described in detail in Figure 9.9, on the next two pages, the pathway of glycolysis consists of ten steps, which can be divided into two phases. During the energy investment phase, the cell actually spends ATP. This investment is repaid with dividends during the energy payoff phase, when ATP is produced by substrate-level phosphorylation and NAD⁺ is reduced to NADH by electrons released from the oxidation of the food (glucose in this example). The net energy yield from glycolysis, per glucose molecule, is 2 ATP plus 2 NADH.

Notice in Figure 9.9 that all of the carbon originally present in glucose is accounted for in the two molecules of pyruvate; no CO₂ is released during glycolysis. Glycolysis occurs whether or not O₂ is present. However, if O₂ is present, the chemical energy stored in pyruvate and NADH can be extracted by the citric acid cycle and oxidative phosphorylation, respectively.

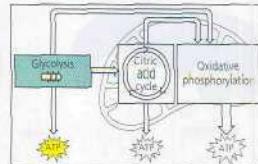

Concept Check 9.2

- During the redox reaction in glycolysis, which molecule acts as the oxidizing agent? The reducing agent?

For suggested answers, see Appendix A.

V Figure 9.9 A closer look at glycolysis. The orientation diagram at the right relates glycolysis to the whole process of respiration. Do not let the chemical detail in the main diagram block your view of glycolysis as a source of ATP and NADH.

ENERGY INVESTMENT PHASE

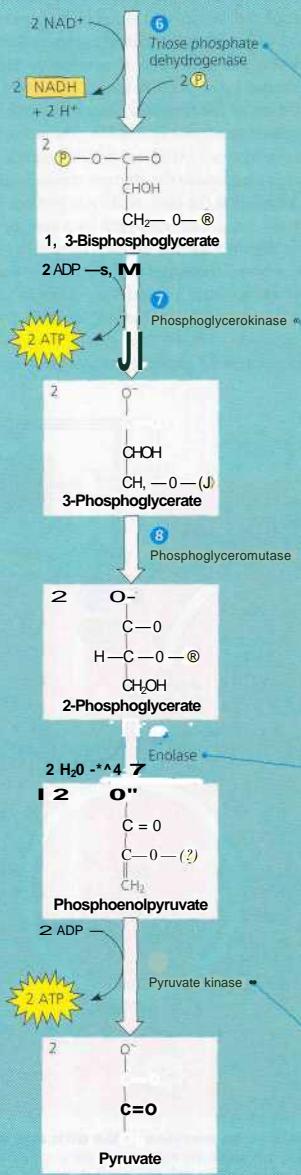

Q Glucose enters the cell and is phosphorylated by the enzyme hexokinase, which transfers a phosphate group from ATP to the sugar. The charge of the phosphate group traps the sugar in the cell because the plasma membrane is impermeable to ions. Phosphorylation also makes glucose more chemically reactive. In this diagram, the transfer of a phosphate group or pair of electrons from one reactant to another is indicated by coupled arrows: 'n1'

J 0 Glucose-6-phosphate is rearranged to convert it to its isomer, I fructose-6-phosphate.

© This enzyme transfers a phosphate group from ATP to the sugar, investing another molecule of ATP in glycolysis. So far, 2 ATP have been used. With phosphate groups on its opposite ends, the sugar is now ready to be split in half. This is a key step for regulation of glycolysis; phosphofructokinase is allosterically regulated by ATP and its products.

© This is the reaction from which glycolysis gets its name. The enzyme cleaves the sugar molecule into two different three-carbon sugars: dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. These two sugars are isomers of each other.

© Isomerase catalyzes the reversible conversion between the two three-carbon sugars. This reaction never reaches equilibrium in the cell because the next enzyme in glycolysis uses only glyceraldehyde-3-phosphate as its substrate (and not dihydroxyacetone phosphate). This pulls the equilibrium in the direction of glyceraldehyde-3-phosphate, which is removed as fast as it forms. Thus, the net result of steps 4 and 5 is cleavage of a six-carbon sugar into two molecules of glyceraldehyde-3-phosphate; this will progress through the remaining steps of glycolysis.

ENERGY PAYOFF PHASE

O This enzyme catalyzes two sequential reactions while it holds glyceraldehyde-3-phosphate in its active site. First, the sugar is oxidized by the transfer of electrons and H⁺ to NAD⁺, forming NADH (a redox reaction). This reaction is very exergonic, and the enzyme uses the released energy to attach a phosphate group to the oxidized substrate, making a product of very high potential energy. The source of the phosphates is the pool of inorganic phosphate ions that are always present in the cytosol. Notice that the coefficient 2 precedes all molecules in the energy payoff phase; these steps occur after glucose is split into two three-carbon sugars (step 4).

O Glycolysis produces some ATP by substrate-level phosphorylation. The phosphate group added in the previous step is transferred to ADP in an exergonic reaction. For each glucose molecule that began glycolysis, step 7 produces 2 ATP, since every product after the sugar-splitting step (step 4) is doubled. Recall that 2 ATP debt was invested to get sugar ready for splitting; this ATP debt has now been repaid. Glucose has been converted to 3-phosphoglycerate, which is not a sugar. The carbonyl group that characterizes a sugar has been oxidized to a carboxyl group ($-\text{COO}^-$), the hallmark of an organic acid. The sugar was oxidized in step 6, and now the energy made available by that oxidation has been used to make ATP.

Q Next, this enzyme relocates the remaining phosphate group. This step prepares the substrate for the next reaction.

Q This enzyme causes a double bond to form in the substrate by extracting a water molecule, yielding phosphoenolpyruvate (PEP). The electrons of the substrate are rearranged in such a way that the remaining phosphate bond becomes very unstable, preparing the substrate for the next reaction.

(E) The last reaction of glycolysis produces more ATP by transferring the phosphate group from PEP to ADP, a second example of substrate-level phosphorylation. Since this step occurs twice for each glucose molecule, 2 ATP are produced. Overall, glycolysis has used 2 ATP in the energy investment phase (steps 1 and 3) and produced 4 ATP in the energy payoff phase (steps 7 and 10), for a net gain of 2 ATP. Glycolysis has repaid the ATP investment with 100% interest. Additional energy was stored by step 6 in NADH, which can be used to make ATP by oxidative phosphorylation if oxygen is present. Glucose has been broken down and oxidized to two molecules of pyruvate, the end product of the glycolytic pathway. If oxygen is present, the chemical energy in pyruvate can be extracted by the citric acid cycle.

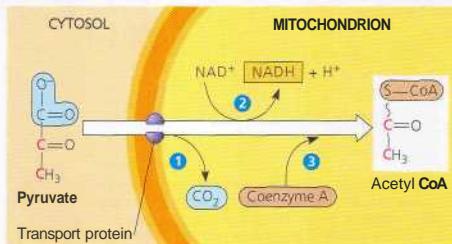

Concept 9.3

The citric acid cycle completes the energy-yielding oxidation of organic molecules

Glycolysis releases less than a quarter of the chemical energy stored in glucose; most of the energy remains stockpiled in the two molecules of pyruvate. If molecular oxygen is present, the pyruvate enters the mitochondrion, where the enzymes of the citric acid cycle complete the oxidation of the organic fuel.

Upon entering the mitochondrion via active transport, pyruvate is first converted to a compound called acetyl coenzyme A, or acetyl CoA (Figure 9.10). This step, the junction between glycolysis and the citric acid cycle, is accomplished by a multi-enzyme complex that catalyzes three reactions: ① Pyruvate's carboxyl group (—COO^-), which is already fully oxidized and thus has little chemical energy, is removed and given off as a molecule of CO_2 . (This is the first step in which CO_2 is released during respiration.) ② The remaining two-carbon fragment is oxidized, forming a compound named acetate (the ionized form of acetic acid). An enzyme transfers the extracted electrons to NAD^+ , storing energy in the form of NADH . ③ Finally, coenzyme A, a sulfur-containing compound derived from a B vitamin, is attached to the acetate by an unstable bond that makes the acetyl group (the attached acetate) very reactive. The product of this chemical grooming, acetyl CoA, is now ready to feed its acetyl group into the citric acid cycle for further oxidation.

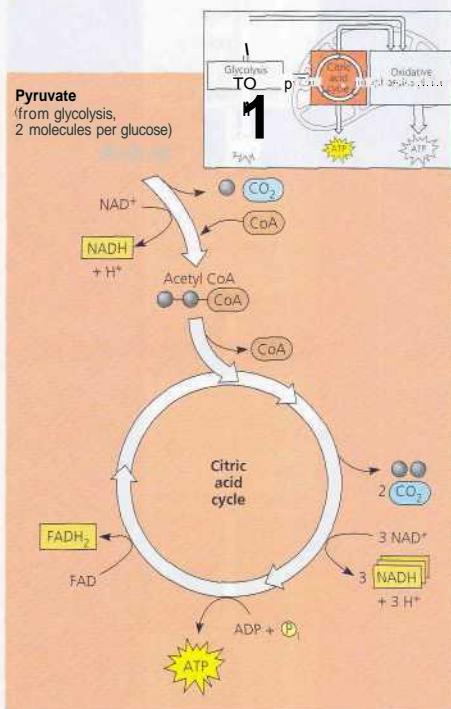

The citric acid cycle is also called the tricarboxylic acid cycle or the Krebs cycle, the latter honoring Hans Krebs, the German-British scientist who was largely responsible for elucidating the pathway in the 1930s. The cycle functions as a metabolic furnace

A Figure 9.10 Conversion of pyruvate to acetyl CoA, the junction between glycolysis and the citric acid cycle.
Because pyruvate is a charged molecule, it must enter the mitochondrion via active transport, with the help of a transport protein. Next, a complex of several enzymes (the pyruvate dehydrogenase complex) catalyzes the three numbered steps, which are described in the text. The acetyl group of acetyl CoA will enter the citric acid cycle. The CO_2 molecule will diffuse out of the cell.

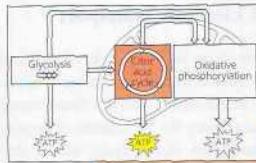

that oxidizes organic fuel derived from pyruvate. Figure 9.11 summarizes the inputs and outputs as pyruvate is broken down to 3 CO_2 molecules, including the molecule of CO_2 released during the conversion of pyruvate to acetyl CoA. The cycle generates 1 ATP per turn by substrate-level phosphorylation, but most of the chemical energy is transferred to NAD^{14} and the related coenzyme FAD during the redox reactions. The reduced coenzymes, NADH and FADH_2 , shuttle their cargo of high-energy electrons to the electron transport chain.

Now let's look at the citric acid cycle in more detail. The cycle has eight steps, each catalyzed by a specific enzyme. You can see in Figure 9.12 that for each turn of the citric acid cycle, two carbons (red) enter in the relatively reduced form of an acetyl group (step 1), and two different carbons (blue) leave in the completely oxidized form of CO_2 (steps 3 and 4). The acetyl group of acetyl CoA joins the cycle by combining with the compound oxaloacetate, forming citrate (step 1).

A Figure 9.11 An overview of the citric acid cycle.

To calculate the inputs and outputs on a per-glucose basis, multiply by 2, because each glucose molecule is split during glycolysis into two pyruvate molecules,

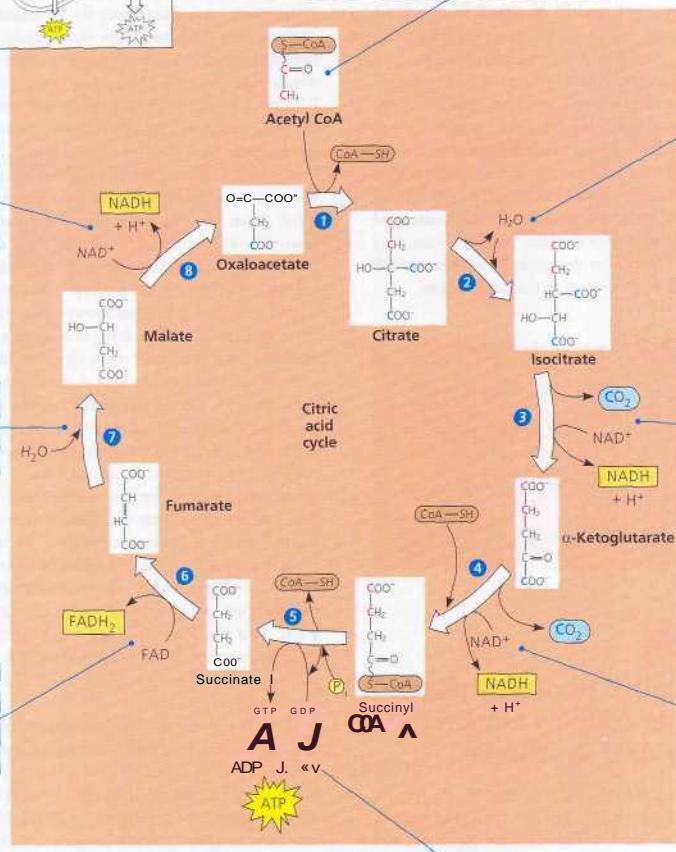

O Acetyl CoA adds its two-carbon acetyl group to oxaloacetate, producing citrate.

i§ The substrate is oxidized, reducing NAD⁺ to NADH and regenerating oxaloacetate.

ii Addition of a water molecule rearranges bonds in the substrate.

iii Two hydrogens are transferred to FAD, forming FADH₂ and oxidizing succinate.

Q Citrate is converted to its isomer, isocitrate, by removal of one water molecule and addition of another.

Q Citrate loses a CO₂ molecule, and the resulting compound is oxidized, reducing NAD⁺ to NADH.

Q Another CO₂ is lost, and the resulting compound is oxidized, reducing NAD⁺ to NADH. The remaining molecule is then attached to coenzyme A by an unstable bond.

Q CoA is displaced by a phosphate group, which is transferred to GDP, forming GTP, and then to ADP, forming ATP (substrate-level phosphorylation).

4 Figure 9.12 A closer look at the citric acid cycle. In the chemical structures, red type traces the fate of the two carbon atoms that enter the cycle via acetyl CoA (step 1), and blue type indicates the two carbons that exit the cycle as CO₂ in steps 3 and 4. (The red labeling only goes through step 5, but you can continue to trace the fate of those carbons.) Notice that

the carbon atoms that enter the cycle from acetyl CoA do not leave the cycle in the same turn. They remain in the cycle, occupying a different location in the molecules on their next turn after another acetyl group is added. As a consequence, the oxaloacetate that is regenerated at step 8 is composed of different carbon atoms each time around. All the citric

acid cycle enzymes are located in the mitochondrial matrix except for the enzyme that catalyzes step 6, which resides in the inner mitochondrial membrane. Carboxylic acids are represented in their ionized forms, as —COO⁻, because the ionized forms prevail at the pH within the mitochondrion. For example, citrate is the ionized form of citric acid.

(Citrate is the ionized form of citric acid, for which the citric acid cycle is named.) The next seven steps decompose the citrate back to oxaloacetate. It is this regeneration of oxaloacetate that makes this process a *cycle*.

For each acetyl group that enters the cycle, 3 NAD⁺ are reduced to NADH (steps 3, 4, and 8). In step 6, electrons are transferred not to NAD⁺, but to a different electron acceptor, FAD (flavin adenine dinucleotide, derived from riboflavin, a B vitamin). Step 5 in the citric acid cycle forms a GTP molecule directly by substrate-level phosphorylation, similar to the ATP-generating steps of glycolysis. This GTP is then used to synthesize an ATP, the only ATP generated directly by the citric acid cycle. Most of the ATP output of respiration results from oxidative phosphorylation, when the NADH and FADH₂ produced by the citric acid cycle relay the electrons extracted from food to the electron transport chain. In the process, they supply the necessary energy for the phosphorylation of ADP to ATP. We will explore this process in the next section.

Concept Check 9.3

1. In which molecules is most of the energy from the citric acid cycle's redox reactions conserved? How will these molecules convert their energy to a form that can be used to make ATP?
2. What cellular processes produce the carbon dioxide that you exhale?

For suggested answers, see Appendix A.

Concept 9.4

During oxidative phosphorylation, chemiosmosis couples electron transport to ATP synthesis

Our main objective in this chapter is to learn how cells harvest the energy of food to make ATP. But the metabolic components of respiration we have dissected so far, glycolysis and the citric acid cycle, produce only 4 ATP molecules per glucose molecule, all by substrate-level phosphorylation: 2 net ATP from glycolysis and 2 ATP from the citric acid cycle. At this point, molecules of NADH (and FADH₂) account for most of the energy extracted from the food. These electron escorts link glycolysis and the citric acid cycle to the machinery of oxidative phosphorylation, which uses energy released by the electron transport chain to power ATP synthesis. In this section, you will learn first how the electron transport chain works, then how the inner membrane of the mitochondrion couples electron flow down the chain to ATP synthesis.

The Pathway of Electron Transport

The electron transport chain is a collection of molecules embedded in the inner membrane of the mitochondrion. The folding of the inner membrane to form cristae increases its surface area, providing space for thousands of copies of the chain in each mitochondrion. (Once again, we see that structure fits function.) Most components of the chain are proteins, which exist in multiprotein complexes numbered I through IV. Tightly bound to these proteins are *prosthetic groups*, nonprotein components essential for the catalytic functions of certain enzymes.

Figure 9.13 shows the sequence of electron carriers in the electron transport chain and the drop in free energy as electrons travel down the chain. During electron transport along the chain, electron carriers alternate between reduced and oxidized states as they accept and donate electrons. Each component of the chain becomes reduced when it accepts electrons from its "uphill" neighbor, which has a lower affinity for electrons (is less electronegative). It then returns to its oxidized form as it passes electrons to its "downhill," more electronegative neighbor.

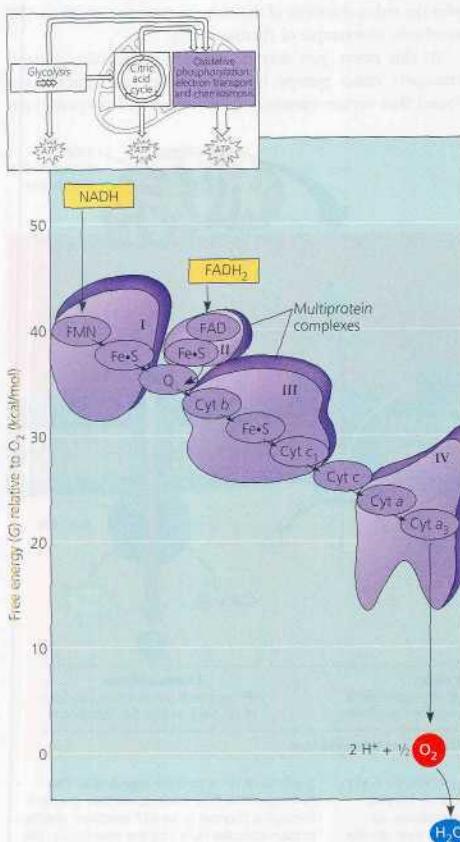

Now let's take a closer look at the electron transport chain in Figure 9.13. Electrons removed from food by NAD⁺, during glycolysis and the citric acid cycle, are transferred from NADH to the first molecule of the electron transport chain. This molecule is a flavoprotein, so named because it has a prosthetic group called flavin mononucleotide (FMN in complex I). In the next redox reaction, the flavoprotein returns to its oxidized form as it passes electrons to an iron-sulfur protein (Fe²⁺S in complex I), one of a family of proteins with both iron and sulfur tightly bound. The iron-sulfur protein then passes the electrons to a compound called ubiquinone (Q in Figure Q.I3). This electron carrier is a small hydrophobic molecule, the only member of the electron transport chain that is not a protein. Ubiquinone is mobile within the membrane rather than residing in a particular complex.

Most of the remaining electron carriers between ubiquinone and oxygen are proteins called cytochromes. Their prosthetic group, called a heme group, has an iron atom that accepts and donates electrons. (It is similar to the heme group in hemoglobin, the protein of red blood cells, except that the iron in hemoglobin carries oxygen, not electrons.) The electron transport chain has several types of cytochromes, each a different protein with a slightly different electron-carrying heme group. The last cytochrome of the chain, cyt a_3 , passes its electrons to oxygen, which is very electronegative. Each oxygen atom also picks up a pair of hydrogen ions from the aqueous solution, forming water.

Another source of electrons for the transport chain is FADH₂, the other reduced product of the citric acid cycle. Notice in Figure 9.13 that FADH₂ adds its electrons to the electron transport chain at complex II, at a lower *energy* level than NADH does. Consequently, the electron transport chain

provides about one-third less energy for ATP synthesis when the electron donor is FADH₂ rather than NADH.

The electron transport chain makes no ATP directly. Its function is to ease the fall of electrons from food to oxygen, breaking a large free-energy drop into a series of smaller steps that release energy in manageable amounts. How does the mitochondrion couple this electron transport and energy release to ATP synthesis? The answer is a mechanism called chemiosmosis.

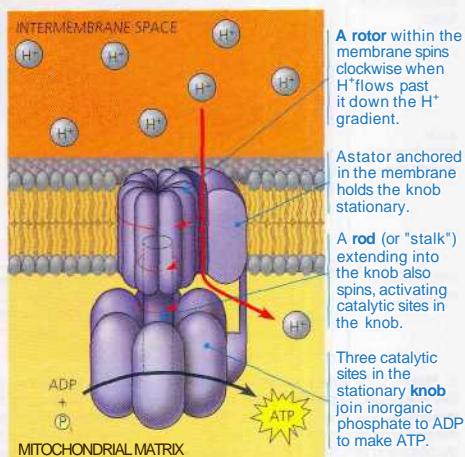

A Figure 9.13 Free-energy change during electron transport. The overall energy drop (ΔG) for electrons traveling from NADH to oxygen is 53 kcal/mol, but this "fall" is broken up into a series of smaller steps by the electron transport chain. (An oxygen atom is represented here as $V_2 O_2$ to emphasize that the electron transport chain reduces molecular oxygen, O_2 , not individual oxygen atoms. For every 2 NADH molecules, 1 O_2 molecule is reduced to 2 H_2O .)

Chemiosmosis: The Energy-Coupling Mechanism

Populating the inner membrane of the mitochondrion are many copies of a protein complex called **ATP synthase**, the enzyme that actually makes ATP from ADP and inorganic phosphate (Figure 9.14). ATP synthase works like an ion pump running in reverse. Recall from Chapter 7 that ion pumps use ATP as an energy source to transport ions against their gradients. In the reverse of that process, ATP synthase uses the energy of an existing ion gradient to power ATP synthesis. The ion gradient that drives phosphorylation is a proton (**hydrogen** ion) gradient; that is, the power source for the ATP synthase is a difference in the concentration of H^+ on opposite sides of the inner mitochondrial membrane. (We can also think of this gradient as a difference in pH, since pH is a measure of H^+ concentration.) This process, in which energy stored in the form of a hydrogen ion gradient across a membrane is used to drive cellular work such as the synthesis of ATP, is called **chemiosmosis** (from the Greek *osmos*, push). We have previously used the word osmosis in discussing water transport, but here it refers to the flow of H^+ across a membrane.

From studying the **structure** of ATP synthase, scientists have learned how the flow of H^+ through this large enzyme powers ATP generation. ATP synthase is a multisubunit complex with

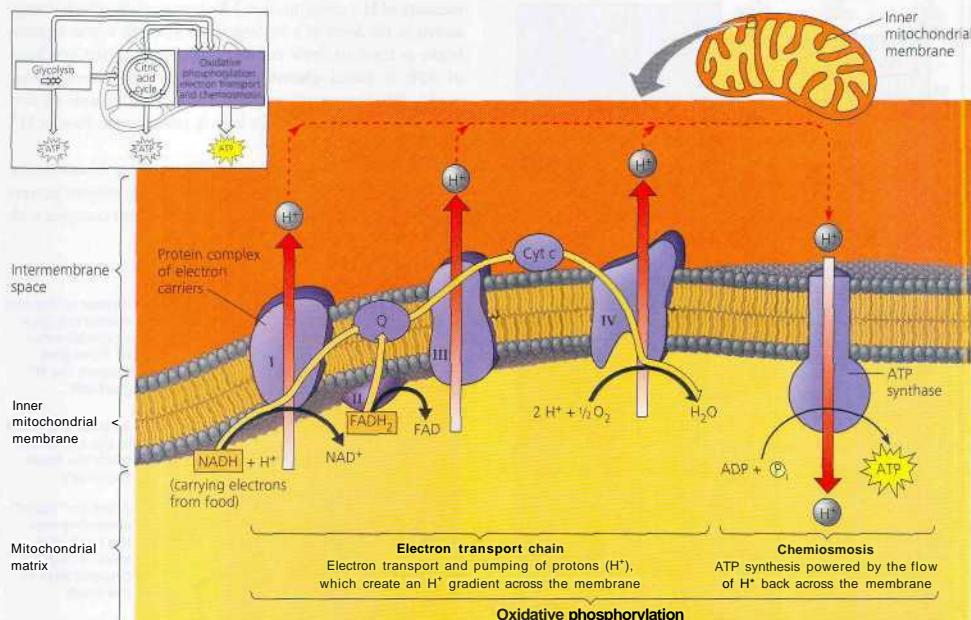

A Figure 9.14 ATP synthase, a molecular mill. The ATP synthase protein complex functions as a mill, powered by the flow of hydrogen ions. This complex resides in mitochondrial and chloroplast membranes of eukaryotes and in the plasma membranes of prokaryotes. Each of the four parts of ATP synthase consists of a number of polypeptide subunits.

four main parts, each made up of multiple polypeptides (see Figure 9.14): a rotor in the inner mitochondrial membrane; a knob that protrudes into the mitochondrial matrix; an internal rod extending from the rotor into the knob; and a stator, anchored next to the rotor, that holds the knob stationary: Hydrogen ions flow down a narrow space between the stator and rotor, causing the rotor and its attached rod to rotate, much as a rushing stream turns a waterwheel. The spinning rod causes conformational changes in the stationary knob, activating three catalytic sites in the subunits that make up the knob, such that ADP and inorganic phosphate combine to make ATP.

So how does the inner mitochondrial membrane generate and maintain the H⁺ gradient that drives ATP synthesis in the ATP synthase protein complex? Creating the H⁺ gradient is the function of the electron transport chain, which is shown

in its mitochondrial location in **Figure 9.15**. The chain is an energy converter that uses the exergonic flow of electrons to pump H⁺ across the membrane, from the mitochondrial matrix into the intermembrane space. The H⁺ has a tendency to move back across the membrane, diffusing down its gradient. And the ATP synthases are the only sites on the membrane that are freely permeable to H⁺. The ions pass through a channel in ATP synthase, which uses the exergonic flow of H⁺ to drive the phosphorylation of ADP (see Figure 9.14). Thus, the energy stored in an H⁺ gradient across a membrane couples the redox reactions of the electron transport chain to ATP synthesis, an example of chemiosmosis.

At this point, you may be wondering how the electron transport chain pumps hydrogen ions. Researchers have found that certain members of the electron transport chain

A Figure 9.15 Chemiosmosis couples the electron transport chain to ATP synthesis. NADH and FADH₂ shuttle high-energy electrons extracted from food during glycolysis and the citric acid cycle to an electron transport chain built into the inner mitochondrial membrane. The yellow arrow traces the transport of electrons, which finally pass to oxygen at the “downhill” end of the chain, forming water. As Figure 9.13 showed, most of the electron carriers of the chain are grouped into four complexes. Two mobile

carriers, ubiquinone (Q) and cytochrome c (Cyt c), move rapidly along the membrane, ferrying electrons between the large complexes. As complexes I, III, and IV accept and then donate electrons, they pump hydrogen ions (protons) from the mitochondrial matrix into the intermembrane space. (Note that FADH₂ deposits its electrons via complex II and so results in fewer protons being pumped into the intermembrane space than NADH.) Chemical energy originally harvested from food is transformed into a proton-motive force, a

gradient of H⁺ across the membrane. The hydrogen ions flow back down their gradient through a channel in an ATP synthase, another protein complex built into the membrane. The ATP synthase harnesses the proton-motive force to phosphorylate ADP, forming ATP. The use of an H⁺ gradient (proton-motive force) to transfer energy from redox reactions to cellular work (ATP synthesis, in this case) is called chemiosmosis. Together, electron transport and chemiosmosis compose oxidative phosphorylation.

accept and release protons (H^+) along with electrons. At certain steps along the chain, electron transfers cause H^+ to be taken up and released into the surrounding solution. The electron earners are spatially arranged in the membrane in such a way that H^+ is accepted from the mitochondrial matrix and deposited in the intermembrane space (see Figure 9.15). The H^+ gradient that results is referred to as a **proton-motive force**, emphasizing the capacity of the gradient to perform work. The force drives H^+ back across the membrane through the specific H^+ channels provided by ATP synthases.

In general terms, chemiosmosis is *an energy-coupling mechanism that uses energy stored in the form of an H^+ gradient across a membrane to drive cellular work*. In mitochondria, the energy for gradient formation comes from exergonic redox reactions, and ATP synthesis is the work performed. But chemiosmosis also occurs elsewhere and in other variations. Chloroplasts use chemiosmosis to generate ATP during photosynthesis; in these organelles, light (rather than chemical energy) drives both electron flow down an electron transport chain and the resulting H^+ gradient formation. Prokaryotes, which lack both mitochondria and chloroplasts, generate H^+ gradients across their plasma membranes. They then tap the proton-motive force not only to make ATP but also to pump nutrients and waste products across the membrane and to rotate their flagella. Because of its central importance to energy conversions in prokaryotes and eukaryotes, chemiosmosis has helped unify the study of bioenergetics. Peter Mitchell was

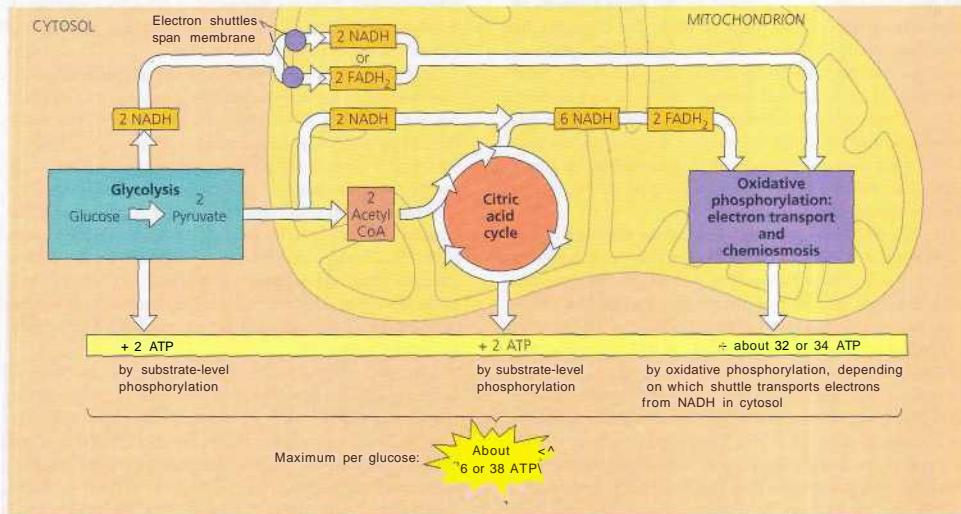

awarded the Nobel Prize in 1978 for originally proposing the chemiosmotic model.

An Accounting of ATP Production by Cellular Respiration

Now that we have looked more closely at the key processes of cellular respiration, let's return to its overall function: harvesting the energy of food for ATP synthesis.

During respiration, most energy flows in this sequence: glucose \rightarrow NADH \rightarrow electron transport chain \rightarrow proton-motive force \rightarrow ATP. We can do some bookkeeping to calculate the ATP profit when cellular respiration oxidizes a molecule of glucose to six molecules of carbon dioxide. The three main departments of this metabolic enterprise are glycolysis, the citric acid cycle, and the electron transport chain, which drives oxidative phosphorylation. Figure 9.16 gives a detailed accounting of the ATP yield per glucose molecule oxidized. The tally adds the 4 ATP produced directly by substrate-level phosphorylation during glycolysis and the citric acid cycle to the many more molecules of ATP generated by oxidative phosphorylation. Each NADH that transfers a pair of electrons from food to the electron transport chain contributes enough to the proton-motive force to generate a maximum of about 3 ATP.

Why are the numbers in Figure 9.16 inexact? There are three reasons we cannot state an exact number of ATP molecules generated by the breakdown of one molecule of glucose. First, phos-

A Figure 9.16 ATP yield per molecule of glucose at each stage of cellular respiration.

phorylation and the redox reactions are not directly coupled to each other, so the ratio of number of NADH molecules to number of ATP molecules is not a whole number. We know that 1 NADH results in 10 H^+ being transported out across the inner mitochondrial membrane, and we also know that somewhere between 3 and 4 H^+ must reenter the mitochondrial matrix via ATP synthase to generate 1 ATP. Therefore, 1 NADH generates enough proton-motive force for synthesis of 2.5 to 3.3 ATP; generally, we round off and say that 1 NADH can generate about 3 ATP. The citric acid cycle also supplies electrons to the electron transport chain via FADH_2 , but since it enters later in the chain, each molecule of this electron carrier is responsible for transport of only enough H^+ for the synthesis of 1–5 to 2 ATP.

Second, the ATP yield varies slightly depending on the type of shuttle used to transport electrons from the cytosol into the mitochondrion. The mitochondrial inner membrane is impermeable to NADH, so NADH in the cytosol is segregated from the machinery of oxidative phosphorylation. The two electrons of NADH captured in glycolysis must be conveyed into the mitochondrion by one of several electron shuttle systems. Depending on the type of shuttle in a particular cell type, the electrons are passed either to NAD^+ or to FAD. If the electrons are passed to FAD, as in brain cells, only about 2 ATP can result from each cytosolic NADH. If the electrons are passed to mitochondrial NAD^+ , as in liver cells and heart cells, the yield is about 3 ATP.

A third variable that reduces the yield of ATP is the use of the proton-motive force generated by the redox reactions of respiration to drive other kinds of work. For example, the proton-motive force powers the mitochondrion's uptake of pyruvate from the cytosol. So, if *all* the proton-motive force generated by the electron transport chain were used to drive ATP synthesis, one glucose molecule could generate a maximum of 34 ATP produced by oxidative phosphorylation plus 4 ATP (net) from substrate-level phosphorylation to give a total yield of about 38 ATP (or only about 36 ATP if the less efficient shuttle were functioning).

We can now make a rough estimate of the efficiency of respiration—that is, the percentage of chemical energy stored in glucose that has been restocked in ATP. Recall that the complete oxidation of a mole of glucose releases 686 kcal of energy ($AG = -686\text{ kcal/mol}$). Phosphorylation of ADP to form ATP stores at least 7.3 kcal per mole of ATP. Therefore, the efficiency of respiration is 7.3 kcal per mole of ATP times 38 moles of ATP per mole of glucose divided by 686 kcal per mole of glucose, which equals 0.4. Thus, about 40% of the energy stored in glucose has been transferred to storage in ATP. The rest of the stored energy is lost as heat. We use some of this heat to maintain our relatively high body temperature (37°C), and we dissipate the rest through sweating and other cooling mechanisms. Cellular respiration is remarkably efficient in its energy conversion. By comparison, the most efficient

automobile converts only about 25% of the energy stored in gasoline to energy that moves the car.

Concept Check 9.4

- What effect would an absence of O_2 have on the process shown in Figure 9.15?
- In the absence of O_2 , as above, what do you think would happen if you decreased the pH of the intermembrane space of the mitochondrion? Explain your answer.

For suggested answers, see Appendix A.

Concept 9.5

Fermentation enables some cells to produce ATP without the use of oxygen

Because most of the ATP generated by cellular respiration is the work of oxidative phosphorylation, our estimate of ATP yield from respiration is contingent upon an adequate supply of oxygen to the cell. Without the electronegative oxygen to pull electrons down the transport chain, oxidative phosphorylation ceases. However, fermentation provides a mechanism by which some cells can oxidize organic fuel and generate ATP without the use of oxygen.

How can food be oxidized without oxygen? Remember, oxidation refers to the loss of electrons to *any* electron acceptor, not just to oxygen. Glycolysis oxidizes glucose to two molecules of pyruvate. The oxidizing agent of glycolysis is NAD^+ , not oxygen. Overall, glycolysis is exergonic, and some of the energy made available is used to produce 2 ATP (net) by substrate-level phosphorylation. If oxygen is present, then additional ATP is made by oxidative phosphorylation when NADH passes electrons removed from glucose to the electron transport chain. But glycolysis generates 2 ATP whether oxygen is present or not—that is, whether conditions are aerobic or anaerobic (from the Greek *aer*, air, and *bios*, life; the prefix *an-* means "without").

Anaerobic catabolism of organic nutrients can occur by fermentation. Fermentation is an extension of glycolysis that can generate ATP solely by substrate-level phosphorylation—as long as there is a sufficient supply of NAD^+ to accept electrons during the oxidation step of glycolysis. Without some mechanism to recycle NAD^+ from NADH, glycolysis would soon deplete the cell's pool of NAD^+ by reducing it all to NADH and shut itself down for lack of an oxidizing agent. Under aerobic conditions, NAD^+ is recycled productively

from NADH by the transfer of electrons to the electron transport chain. The anaerobic alternative is to transfer electrons from NADH to pyruvate, the end product of glycolysis.

Types of Fermentation

Fermentation consists of glycolysis plus reactions that regenerate NAD^+ by transferring electrons from NADH to pyruvate or derivatives of pyruvate. The NAD^+ can then be reused to oxidize sugar by glycolysis, which nets two molecules of ATP by substrate-level phosphorylation. There are many types of fermentation, differing in the end products formed from pyruvate. Two common types are alcohol fermentation and lactic acid fermentation.

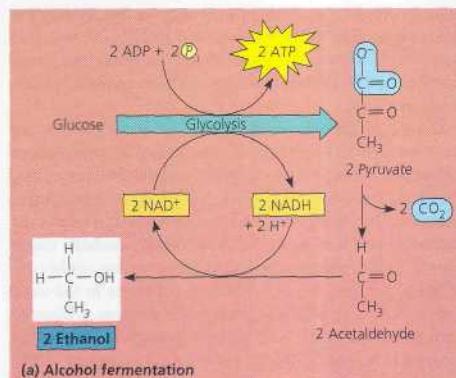

In alcohol fermentation (Figure 9.17a), pyruvate is converted to ethanol (ethyl alcohol) in two steps. The first step releases carbon dioxide from the pyruvate, which is converted to the two-carbon compound acetaldehyde. In the second step, acetaldehyde is reduced by NADH to ethanol. This regenerates the supply of NAD^+ needed for the continuation of glycolysis. Many bacteria carry out alcohol fermentation under anaerobic conditions. Yeast (a fungus) also carries out alcohol fermentation. For thousands of years, humans have used yeast in brewing, winemaking, and baking. The CO_2 bubbles generated by baker's yeast allow bread to rise.

During lactic acid fermentation (Figure 9.17b), pyruvate is reduced directly by NADH to form lactate as an end product, with no release of CO_2 . (Lactate is the ionized form of lactic acid.) Lactic acid fermentation by certain fungi and bacteria is used in the dairy industry to make cheese and yogurt. Other types of microbial fermentation that are commercially important produce acetone and methanol (methyl alcohol).

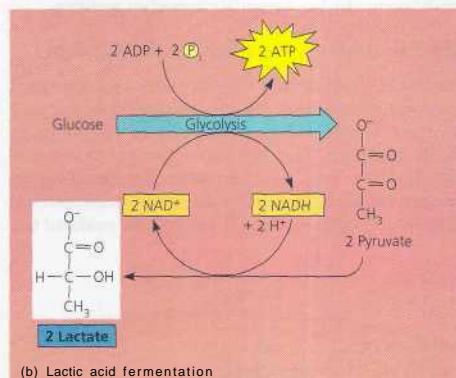

Human muscle cells make ATP by lactic acid fermentation when oxygen is scarce. This occurs during the early stages of strenuous exercise, when sugar catabolism for ATP production outpaces the muscle's supply of oxygen from the blood. Under these conditions, the cells switch from aerobic respiration to fermentation. The lactate that accumulates may cause muscle fatigue and pain, but the lactate is gradually carried away by the blood to the liver. Lactate is converted back to pyruvate by liver cells.

Fermentation and Cellular Respiration Compared

Fermentation and cellular respiration are anaerobic and aerobic alternatives, respectively, for producing ATP by harvesting the chemical energy of food. Both pathways use glycolysis to oxidize glucose and other organic fuels to pyruvate, with a net production of 2 ATP by substrate-level phosphorylation. And in both fermentation and respiration, NAD^+ is the oxidizing agent that accepts electrons from food during glycolysis. A key difference is the contrasting mechanisms for oxidizing NADH back to NAD^+ , which is required to sustain glycolysis. In fer-

(a) Alcohol fermentation

(b) Lactic acid fermentation

A Figure 9.17 Fermentation. In the absence of oxygen, many eels use fermentation to produce ATP by substrate-level phosphorylation. Pyruvate, the end product of glycolysis, serves as an electron acceptor for oxidizing NADH back to NAD^+ , which can then be reused in glycolysis. Two of the common end products formed from fermentation are (a) ethanol and (b) lactate, the ionized form of lactic acid.

mentation., the final electron acceptor is an organic molecule such as pyruvate (lactic acid fermentation) or acetaldehyde (alcohol fermentation). In respiration, by contrast, the final acceptor for electrons from NADH is oxygen. This not only regenerates the NAD^+ required for glycolysis but pays an ATP bonus when the stepwise electron transport from NADH to oxygen drives oxidative phosphorylation. An even bigger ATP payoff comes from the oxidation of pyruvate in the citric acid cycle, which is unique to respiration. Without oxygen, the energy still stored in pyruvate is unavailable to the cell. Thus, cellular respiration harvests much more energy from each

sugar molecule than fermentation can. In fact, respiration yields as much as 19 times more ATP per glucose molecule than does fermentation—up to 38 ATP for respiration, compared to 2 ATP produced by substrate-level phosphorylation in fermentation.

Some organisms, including yeasts and many bacteria, can make enough ATP to survive using either fermentation or respiration. Such species are called facultative anaerobes. On the cellular level, our muscle cells behave as facultative anaerobes. In a facultative anaerobe, pyruvate is a fork in the metabolic road that leads to two alternative catabolic routes (**Figure 9.18**). Under aerobic conditions, pyruvate can be converted to acetyl CoA, and oxidation continues in the citric acid cycle. Under anaerobic conditions, pyruvate is diverted from the citric acid cycle, serving instead as an electron acceptor to recycle NAD⁺. To make the same amount of ATP, a facultative anaerobe would have to consume sugar at a much faster rate when fermenting than when respiring.

The Evolutionary Significance of Glycolysis

The role of glycolysis in both fermentation and respiration has an evolutionary basis. Ancient prokaryotes probably used glycolysis to make ATP long before oxygen was present in Earth's atmosphere. The oldest known fossils of bacteria date back 3.5 billion years, but appreciable quantities of oxygen probably did not begin to accumulate in the atmosphere until about 2.7 billion years ago. Cyanobacteria produced this

O₂ as a by-product of photosynthesis. Therefore, early prokaryotes may have generated ATP exclusively from glycolysis, which does not require oxygen. In addition, glycolysis is the most widespread metabolic pathway, which suggests that it evolved very early in the history of life. The cytosolic location of glycolysis also implies great antiquity; the pathway does not require any of the membrane-bound organelles of the eukaryotic cell, which evolved approximately 1 billion years after the prokaryotic cell. Glycolysis is a metabolic heirloom from early cells that continues to function in fermentation and as the first stage in the breakdown of organic molecules by respiration.

Concept Check 9.5

1. Consider the NADH formed during glycolysis. What is the final acceptor for its electrons during fermentation? What is the final acceptor for its electrons during respiration?
2. A glucose-fed yeast cell is moved from an aerobic environment to an anaerobic one. For the cell to continue generating ATP at the same rate, how would its rate of glucose consumption need to change?

For suggested answers, see Appendix A.

Concept 9.6

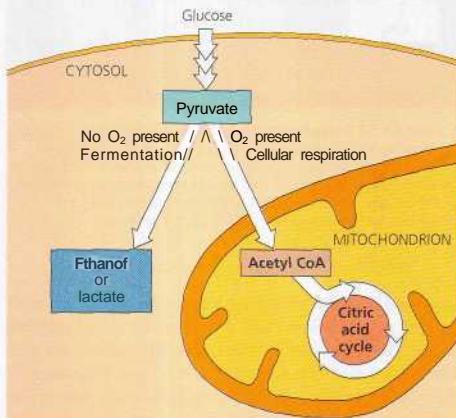

Glycolysis and the citric acid cycle connect to many other metabolic pathways

So far, we have treated the oxidative breakdown of glucose in isolation from the cell's overall metabolic economy. In this section, you will learn that glycolysis and the citric acid cycle are major intersections of various catabolic and anabolic (biosynthetic) pathways.

The Versatility of Catabolism

Throughout this chapter, we have used glucose as the fuel for cellular respiration. But free glucose molecules are not common in the diets of humans and other animals. We obtain most of our calories in the form of fats, proteins, sucrose and other disaccharides, and starch, a polysaccharide. All these organic molecules in food can be used by cellular respiration to make ATP (**Figure 9.19**).

Glycolysis can accept a wide range of carbohydrates for catabolism. In the digestive tract, starch is hydrolyzed to glucose, which can then be broken down in the cells by glycolysis and the citric acid cycle. Similarly, glycogen, the polysaccharide

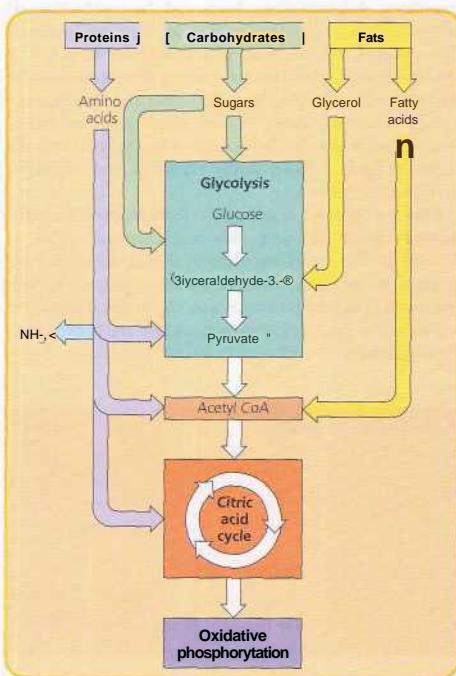

A Figure 9.18 Pyruvate as a key juncture in catabolism.

Glycolysis is common to fermentation and cellular respiration. The end product of glycolysis, pyruvate, represents a fork in the catabolic pathways of glucose oxidation. In a cell capable of both cellular respiration and fermentation, pyruvate is committed to one of those two pathways, usually depending on whether or not oxygen is present.

that humans and many other animals store in their liver and muscle cells, can be hydrolyzed to glucose between meals as fuel for respiration. The digestion of disaccharides, including sucrose, provides glucose and other monosaccharides as fuel for respiration.

Proteins can also be used for fuel, but first they must be digested to their constituent amino acids. Many of the amino acids, of course, are used by the organism to build new proteins. Amino acids present in excess are converted by enzymes to intermediates of glycolysis and the citric acid cycle. Before amino acids can feed into glycolysis or the citric acid cycle, their amino groups must be removed, a process called deamination. The nitrogenous refuse is excreted from the animal in the form of ammonia, urea, or other waste products.

Catabolism can also harvest energy stored in fats obtained either from food or from storage cells in the body. After fats

A Figure 9.19 The catabolism of various molecules from food. Carbohydrates, fats, and proteins can all be used as fuel for cellular respiration. Monomers of these molecules enter glycolysis or the citric acid cycle at various points. Glycolysis and the citric acid cycle are catabolic funnels through which electrons from all kinds of organic molecules flow on their exergonic fall to oxygen.

are digested to glycerol and fatty acids, the glycerol is converted to glyceraldehyde-3-phosphate, an intermediate of glycolysis. Most of the energy of a fat is stored in the fatty-acids. A metabolic sequence called **beta oxidation** breaks the fatty acids down to two-carbon fragments, which enter the citric acid cycle as acetyl CoA. Fats make excellent fuel. A gram of fat oxidized by respiration produces more than twice as much ATP as a gram of carbohydrate. Unfortunately, this also means that a person who is trying to lose weight must work hard to use up fat stored in the body, because so many calories are stockpiled in each gram of fat.

Biosynthesis (Anabolic Pathways)

Cells need substance as well as energy. Not all the organic molecules of food are destined to be oxidized as fuel to make ATP. In addition to calories, food must also provide the carbon skeletons that cells require to make their own molecules. Some organic monomers obtained from digestion can be used directly. For example, as previously mentioned, amino acids from the hydrolysis of proteins in food can be incorporated into the organism's own proteins. Often, however, the body needs specific molecules that are not present as such in food. Compounds formed as intermediates of glycolysis and the citric acid cycle can be diverted into anabolic pathways as precursors from which the cell can synthesize the molecules it requires. For example, humans can make about half of the 20 amino acids in proteins by modifying compounds siphoned away from the citric acid cycle. Also, glucose can be made from pyruvate, and fatty acids can be synthesized from acetyl CoA. Of course, these anabolic, or biosynthetic, pathways do not generate ATP, but instead consume it.

In addition, glycolysis and the citric acid cycle function as metabolic interchanges that enable our cells to convert some kinds of molecules to others as we need them. For example, an intermediate compound generated during glycolysis, dihydroxyacetone phosphate (see Figure 9.9, step 5), can be converted into one of the major precursors of fats. If we eat more food than we need, we store fat even if our diet is fat-free. Metabolism is remarkably versatile and adaptable.

Regulation of Cellular Respiration via Feedback Mechanisms

Basic principles of supply and demand regulate the metabolic economy. The cell does not waste energy making more of a particular substance than it needs. If there is a glut of a certain amino acid, for example, the anabolic pathway that synthesizes that amino acid from an intermediate of the citric acid cycle is switched off. The most common mechanism for this control is feedback inhibition: The end product of the anabolic pathway inhibits the enzyme that catalyzes an early step of the pathway (see Figure 8.20). This prevents the needless

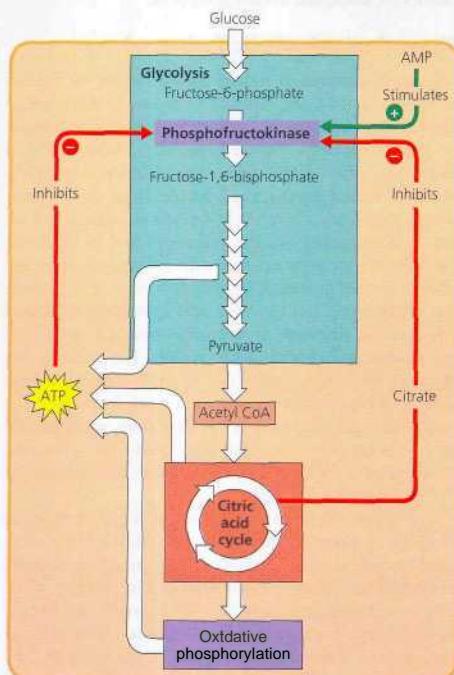

diversion of key metabolic intermediates from uses that are more urgent.

The cell also controls its catabolism. If the cell is working hard and its ATP concentration begins to drop, respiration speeds up. When there is plenty of ATP to meet demand, respiration slows down, sparing valuable organic molecules for other functions. Again, control is based mainly on regulating the activity of enzymes at strategic points in the catabolic pathway. One important switch is phosphofructokinase (Figure 9.20), the enzyme

that catalyzes step 3 of glycolysis (see Figure 9.9). This is the earliest step that commits substrate irreversibly to the glycolytic pathway. By controlling the rate of this step, the cell can speed up or slow down the entire catabolic process; phosphofructokinase can thus be considered the pacemaker of respiration.

Phosphofructokinase is an allosteric enzyme with receptor sites for specific inhibitors and activators. It is inhibited by ATP and stimulated by AMP (adenosine monophosphate), which the cell derives from ADP. As ATP accumulates, inhibition of the enzyme slows down glycolysis. The enzyme becomes active again as cellular work converts ATP to ADP (and AMP) faster than ATP is being regenerated. Phosphofructokinase is also sensitive to citrate, the first product of the citric acid cycle. If citrate accumulates in mitochondria, some of it passes into the cytosol and inhibits phosphofructokinase. This mechanism helps synchronize the rates of glycolysis and the citric acid cycle. As citrate accumulates, glycolysis slows down, and the supply of acetyl groups to the citric acid cycle decreases. If citrate consumption increases, either because of a demand for more ATP or because anabolic pathways are draining off intermediates of the citric acid cycle, glycolysis accelerates and meets the demand. Metabolic balance is augmented by the control of other enzymes at other key locations in glycolysis and the citric acid cycle. Cells are thrifty, expedient, and responsive in their metabolism.

Examine Figure 9.2 again to put cellular respiration into the broader context of energy flow and chemical cycling in ecosystems. The energy that keeps us alive is *released*, but not *produced*, by cellular respiration. We are tapping energy that was stored in food by photosynthesis. In the next chapter, you will learn how photosynthesis captures light and converts it to chemical energy.

A. Figure 9.20 The control of cellular respiration. Allosteric enzymes at certain points in the respiratory pathway respond to inhibitors and activators that help set the pace of glycolysis and the citric acid cycle. Phosphofructokinase, the enzyme that catalyzes step 3 of glycolysis (see Figure 9.9), is one such enzyme. It is stimulated by AMP (derived from ADP) but is inhibited by ATP and by citrate. This feedback regulation adjusts the rate of respiration as the cell's catabolic and anabolic demands change.

Concept Check 9.6

1. Compare the structure of a fat (see Figure 5.11) with that of a carbohydrate (see Figure 5.3). What features of their structures make fat a much better fuel?
2. Under what circumstances might your body synthesize fat molecules?
3. What will happen in a muscle cell that has used up its supply of oxygen and ATP? (See Figure 9.20.)

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

- Life's processes require energy that enters the ecosystem in the form of sunlight. Energy is used for work or dissipated as heat, while the essential chemical elements are recycled by respiration and photosynthesis (p. 160).

Activity Build a Chemical Cycling System

Concept 9.1

Gitabolic pathways yield energy by oxidizing organic fuels

- Catabolic Pathways and Production of ATP** (p. 161) The breakdown of glucose and other organic fuels is exergonic. Starting with glucose or another organic molecule and using O₂, cellular respiration yields H₂O, CO₂, and energy in the form of ATP and heat. To keep working, a cell must regenerate ATP.

- Redox Reactions: Oxidation and Reduction**

(pp. 161–164) The cell taps the energy stored in food molecules through redox reactions, in which one substance partially or totally shifts electrons to another. The substance receiving electrons is reduced; the substance losing electrons is oxidized. During cellular respiration, glucose (C₆H₁₂O₆) is oxidized to CO₂, and O₂ is reduced to H₂O. Electrons lose potential energy during their transfer from organic compounds to oxygen. Electrons from organic compounds are usually passed first to NAD⁺, reducing it to NADH. NADH passes the electrons to an electron transport chain, which conducts them to O₂ in energy-releasing steps. The energy released is used to make ATP.

- The Stages of Cellular Respiration: A Preview**

(pp. 164–165) Glycolysis and the Citric acid cycle supply electrons (via NADH or FADH₂) to the electron transport chain, which drives oxidative phosphorylation. Oxidative phosphorylation generates ATP.

Activity Overview of Cellular Respiration

Concept 9.2

Glycolysis harvests chemical energy by oxidizing glucose to pyruvate

- Glycolysis breaks down glucose into two pyruvate molecules and nets 2 ATP and 2 NADH per glucose molecule (pp. 165–167).

Activity Glycolysis

Concept 9.3

The citric acid cycle completes the energy-yielding oxidation of organic molecules

- The import of pyruvate into the mitochondrion and its conversion to acetyl CoA links glycolysis to the citric acid cycle. The two-carbon acetyl group of acetyl CoA joins the four-carbon oxaloacetate, forming the six-carbon citrate, which is degraded back to oxaloacetate. The cycle releases 2 CO₂, forms 1 ATP, and passes electrons to NAD⁺ and FAD, yielding 3 NADH and 1 FADH₂ per turn (pp. 168–170).

Activity The Citric Acid Cycle

Concept 9.4

During oxidative phosphorylation, chemiosmosis couples electron transport to ATP synthesis

- NADH and FADH₂ donate electrons to the electron transport chain, which powers ATP synthesis via oxidative phosphorylation (p. 170).
- The Pathway of Electron Transport** (pp. 170–171) In the electron transport chain, electrons from NADH and FADH₂ lose energy in several energy-releasing steps. At the end of the chain, electrons are passed to O₂, reducing it to H₂O.

- Chemiosmosis: The Energy-Coupling Mechanism**

(pp. 171–173) At certain steps along the electron transport chain, electron transfer causes protein complexes to move H⁺ from the mitochondrial matrix to the intermembrane space, storing energy as a proton-motive force (H⁺ gradient). As H⁺ diffuses back into the matrix through ATP synthase, its passage drives the phosphorylation of ADP.

Activity Electron Transport

- An Accounting of ATP Production by Cellular Respiration** (pp. 173–174) About 40% of the energy stored in a glucose molecule is transferred to ATP during cellular respiration, producing a maximum of about 38 ATP.

Biology Labs On-line Mitochondrial Lab

Investigation How Is the Rate of Cellular Respiration Measured?

Concept 9.5

Fermentation enables some cells to produce ATP without the use of oxygen

- Types of Fermentation** (p. 175) Glycolysis nets two ATP by substrate-level phosphorylation, whether oxygen is present or not. Under anaerobic conditions, the electrons from NADH are passed to pyruvate or a derivative of pyruvate, regenerating the NAD⁺ required to oxidize more glucose. Two common types of fermentation are alcohol fermentation and lactic acid fermentation.

Activity Fermentation

- Fermentation and Cellular Respiration Compared**

(pp. 175–176) Both use glycolysis to oxidize glucose, but differ in their final electron acceptor. Respiration yields more ATP.

- The Evolutionary Significance of Glycolysis** (p. 176)

Glycolysis occurs in nearly all organisms and probably evolved in ancient prokaryotes before there was O₂ in the atmosphere.

Concept 9.6

Glycolysis and the citric acid cycle connect to many other metabolic pathways

- The Versatility of Catabolism** (pp. 176–177) Catabolic pathways funnel electrons from many kinds of organic molecules into cellular respiration.

- Biosynthesis (Anabolic Pathways)** (p. 177) The body can use small molecules from food directly or use them to build other substances through glycolysis or the citric acid cycle.

- Regulation of Cellular Respiration via Feedback Mechanisms** (pp. 177–178) Cellular respiration is controlled by allosteric enzymes at key points in glycolysis and the citric acid cycle.

Evolution Connection

ATP synthase enzymes are found in the prokaryotic plasma membrane and in mitochondria and chloroplasts. What does this suggest about the evolutionary relationship of these eukaryotic organelles to prokaryotes? How might the amino acid sequences of the ATP synthases from the different sources support or refute your hypothesis?

Scientific Inquiry

In the 1940s, some physicians prescribed low doses of a drug called dinitrophenol (DNP) to help patients lose weight. This unsafe method was abandoned after a few patients died. DNP uncouples the chemiosmotic machinery by making the lipid bilayer of the inner mitochondrial membrane leaky to H⁺. Explain how this causes weight loss.

Biology Labs On-Line *MitochondriaLab*

Investigation *How Is the Rate of Cellular Respiration Measured?*

Nearly all human societies use fermentation to produce alcoholic drinks such as beer and wine. The practice dates back to the earliest days of agriculture. How do you suppose this use of fermentation was first discovered? Why did wine prove to be a more useful beverage, especially to a preindustrial culture, than the grape juice from which it was made?

Biological Inquiry: A Workbook of Investigative Cases Explore fermentation further in the case "Bean Brew."

Photosynthesis

A Figure 10.1 Sunlight consists of a spectrum of colors, visible here in a rainbow.

Key Concepts

- 10.1 Photosynthesis converts light energy to the chemical energy of food
- 10.2 The light reactions convert solar energy to the chemical energy of ATP and NADPH
- 10.3 The Calvin cycle uses ATP and NADPH to convert CO₂ to sugar
- 10.4 Alternative mechanisms of carbon fixation have evolved in hot, arid climates

Overview

The Process That Feeds the Biosphere

Life on Earth is solar powered. The chloroplasts of plants capture light energy that has traveled 150 million kilometers from the sun and convert it to chemical energy stored in sugar and other organic molecules. This conversion process is called photosynthesis. Let's begin by placing photosynthesis in its ecological context.

Photosynthesis nourishes almost the entire living world directly or indirectly. An organism acquires the organic compounds it uses for energy and carbon skeletons by one of two major modes: autotrophic nutrition or heterotrophic nutrition. Autotrophs are "self-feeders" (*auto* means "self," and *trophos* means "feed"); they sustain themselves without eating anything derived from other organisms. Autotrophs produce their organic molecules from CO₂ and other inorganic raw materials obtained from the environment. They are the ultimate sources of organic compounds for all nonautotrophic

organisms, and for this reason, biologists refer to autotrophs as the *producers* of the biosphere.

Almost all plants are autotrophs; the only nutrients they require are water and minerals from the soil and carbon dioxide from the air. Specifically, plants are photoautotrophs, organisms that use light as a source of energy to synthesize organic substances (Figure 10.1). Photosynthesis also occurs in algae, certain other protists, and some prokaryotes (Figure 10.2, on the next page). In this chapter, our emphasis will be on plants; variations in autotrophic nutrition that occur in prokaryotes and algae will be discussed in Chapters 27 and 28.

Heterotrophs obtain their organic material by the second major mode of nutrition. Unable to make their own food, they live on compounds produced by other organisms (*hetero* means "other"). Heterotrophs are the biosphere's *consumers*. The most obvious form of this "other-feeding" occurs when an animal eats plants or other animals. But heterotrophic nutrition may be more subtle. Some heterotrophs consume the remains of dead organisms by decomposing and feeding on organic litter such as carcasses, feces, and fallen leaves; they are known as decomposers. Most fungi and many types of prokaryotes get their nourishment this way. Almost all heterotrophs, including humans, are completely dependent on photoautotrophs for food—and also for oxygen, a by-product of photosynthesis.

In this chapter, you will learn how photosynthesis works. After a discussion of the general principles of photosynthesis, we will consider the two stages of photosynthesis; the light reactions, in which solar energy is captured and transformed into chemical energy; and the Calvin cycle, in which the chemical energy is used to make organic molecules of food. Finally, we will consider photosynthesis from an evolutionary perspective.

- Figure 10.2 Photoautotrophs.** These organisms use light energy to drive the synthesis of organic molecules from carbon dioxide and (in most cases) water. They feed not only themselves, but the entire living world; (a) On land, plants are the predominant producers of food. In aquatic environments, photosynthetic organisms include (b) multicellular algae, such as this kelp; (c) some unicellular protists, such as *Euglena*; (d) the prokaryotes called cyanobacteria; and (e) other photosynthetic prokaryotes, such as these purple sulfur bacteria, which produce sulfur (spherical globules) (c, d, e: LMs).

Concept 10.1

Photosynthesis converts light energy to the chemical energy of food

You were introduced to the chloroplast in Chapter 6. This remarkable organelle is responsible for feeding the vast majority of organisms on our planet. Chloroplasts are present in a variety of photosynthesizing organisms (see Figure 10.2), but here we will focus on plants.

Chloroplasts: The Sites of Photosynthesis in Plants

All green parts of a plant, including green stems and unripened fruit, have chloroplasts, but the leaves are the major sites of photosynthesis in most plants (**Figure 10.3**). There are

about half a million chloroplasts per square millimeter of leaf surface. The color of the leaf is from **chlorophyll**, the green pigment located within chloroplasts. It is the light energy absorbed by chlorophyll that drives the synthesis of organic molecules in the chloroplast. Chloroplasts are found mainly in the cells of the **mesophyll**, the tissue in the interior of the leaf. Carbon dioxide enters the leaf, and oxygen exits, by way of microscopic pores called **stomata** (singular, *stoma*; from the Greek, meaning "mouth"). Water absorbed by the roots is delivered to the leaves in veins. Leaves also use veins to export sugar to roots and other nonphotosynthetic parts of the plant.

A typical mesophyll cell has about 30 to 40 chloroplasts each organelle measuring about 2–4 μm by 4–7 μm . An envelope of two membranes encloses the **stroma**, the dense fluid within the chloroplast. An elaborate system of interconnected membranous sacs called **thylakoids** segregates the stroma from another compartment, the interior of the thylakoids, or **thylakoid space**. In some places, thylakoid sacs are stacked in columns called **grana** (singular, *granum*). Chlorophyll resides

- Figure 10.3 Focusing in on the location of photosynthesis in a plant.** Leaves are the major organs of photosynthesis in plants. These pictures take you into a leaf, then into a cell, and finally into a chloroplast, the organelle where photosynthesis occurs (middle, LM; bottom, TEM).

in the thylakoid membranes. (Photosynthetic prokaryotes lack chloroplasts, but they do have photosynthetic membranes arising from infolded regions of the plasma membrane that function in a manner similar to the thylakoid membranes of chloroplasts; see Figure 27.7b.) Now that we have looked at the sites of photosynthesis in plants, we are ready to look more closely at the process of photosynthesis.

Tracking Atoms Through Photosynthesis: Scientific Inquiry

Scientists have tried for centuries to piece together the process by which plants make food. Although some of the steps are still not completely understood, the overall photosynthetic equation has been known since the 1800s: In the presence of light, the green parts of plants produce organic compounds and oxygen from carbon dioxide and water. Using molecular formulas, we can summarize photosynthesis with this chemical equation:

The carbohydrate $C_6\text{H}_{12}\text{O}_6$ is glucose.* Water appears on both sides of the equation because 12 molecules are consumed and 6 molecules are newly formed during photosynthesis. We can simplify the equation by indicating only the net consumption of water:

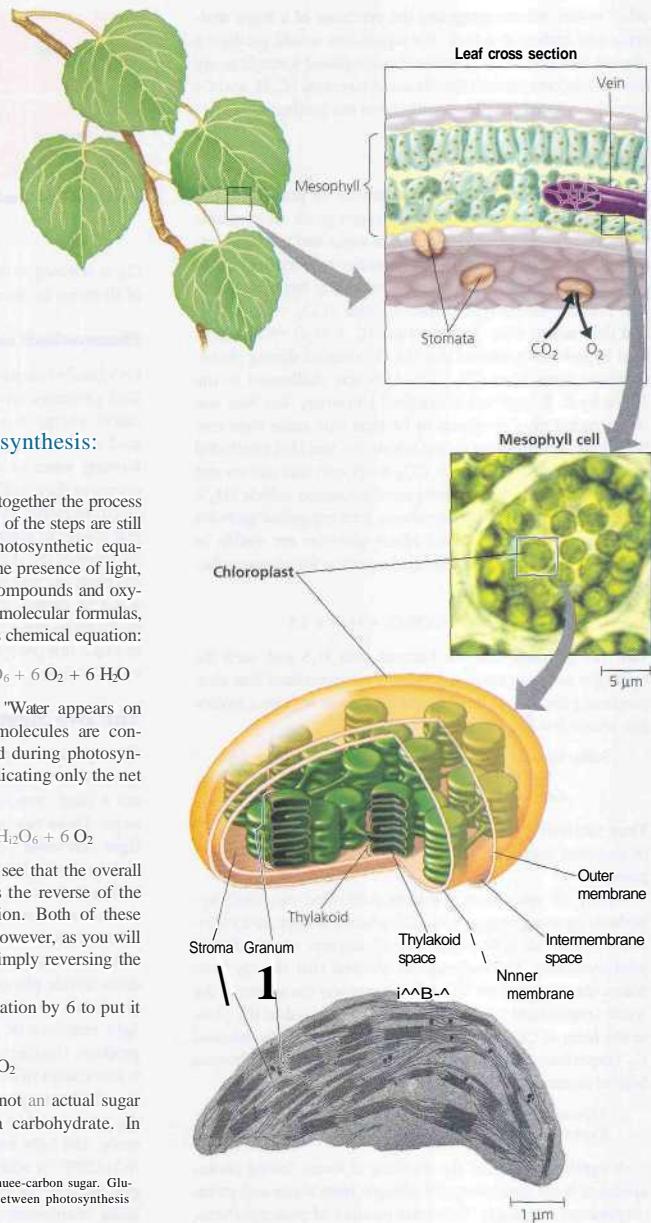

Writing the equation in this form, we can see that the overall chemical change during photosynthesis is the reverse of the one that occurs during cellular respiration. Both of these metabolic processes occur in plant cells. However, as you will soon learn, plants do not make food by simply reversing the steps of respiration.

Now let's divide the photosynthetic equation by 6 to put it in its simplest possible form:

Here, the brackets indicate that CH_2O is not an actual sugar but represents the general formula for a carbohydrate. In

* The direct product of photosynthesis is actually a three-carbon sugar. Glucose is used here only to simplify the relationship between photosynthesis and respiration.

other words, we are imagining the synthesis of a sugar molecule one carbon at a time. Six repetitions would produce a glucose molecule. Let's now use this simplified formula to see how researchers tracked the chemical elements (C, H, and O) from the reactants of photosynthesis to the products.

The Splitting of Water

One of the first clues to the mechanism of photosynthesis came from the discovery that the oxygen given off by plants through their stomata is derived from water and not from carbon dioxide. The chloroplast splits water into hydrogen and oxygen. Before this discovery, the prevailing hypothesis was that photosynthesis split carbon dioxide ($\text{CO}_2 \rightarrow \text{C} + \text{Q}_2$) and then added water to the carbon ($\text{C} + \text{H}_2\text{O} \rightarrow [\text{CH}_2\text{O}]$). This hypothesis predicted that the O_2 released during photosynthesis came from CO_2 . This idea was challenged in the 1930s by C. B. van Niel of Stanford University. Van Niel was investigating photosynthesis in bacteria that make their carbohydrate from CO_2 but do not release O_2 . Van Niel concluded that, at least in these bacteria, CO_2 is not split into carbon and oxygen. One group of bacteria used hydrogen sulfide (H_2S) rather than water for photosynthesis, forming yellow globules of sulfur as a waste product (these globules are visible in Figure 10.2e). Here is the chemical equation for photosynthesis in these sulfur bacteria:

Van Niel reasoned that the bacteria split H_2S and used the hydrogen atoms to make sugar. He then generalized that idea, proposing that all photosynthetic organisms require a hydrogen source but that the source varies:

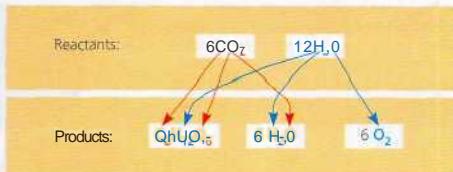

Thus, van Niel hypothesized that plants split water as a source of electrons from hydrogen atoms, releasing oxygen as a by-product.

Nearly 20 years later, scientists confirmed van Niel's hypothesis by using oxygen-18 (^{18}O), a heavy isotope, as a radioactive tracer to follow the fate of oxygen atoms during photosynthesis. The experiments showed that the O_2 from plants was labeled with ^{18}O only if water was the source of the tracer (experiment 1). if the ^{18}O was introduced to the plant in the form of CO_2 , the label did not turn up in the released O_2 (experiment 2). In the following summary red denotes labeled atoms of oxygen (^{18}O):

A significant result of the shuffling of atoms during photosynthesis is the extraction of hydrogen from water and its incorporation into sugar. The waste product of photosynthesis,

A Figure 10.4 Tracking atoms through photosynthesis.

O_2 , is released to the atmosphere. **Figure 10.4** shows the fates of all atoms in photosynthesis.

Photosynthesis as a Redox Process

Lets briefly compare photosynthesis with cellular respiration. Both processes involve redox reactions. During cellular respiration, energy is released from sugar when electrons associated with hydrogen are transported by carriers to oxygen, forming water as a by-product. The electrons lose potential energy as they "fall" down the electron transport chain toward electronegative oxygen, and the mitochondrion harnesses that energy to synthesize ATP (see Figure 9.15). Photosynthesis reverses the direction of electron flow. Water is split, and electrons are transferred along with hydrogen ions from the water to carbon dioxide, reducing it to sugar. Because the electrons increase in potential energy as they move from water to sugar, this process requires energy. This energy boost is provided by light.

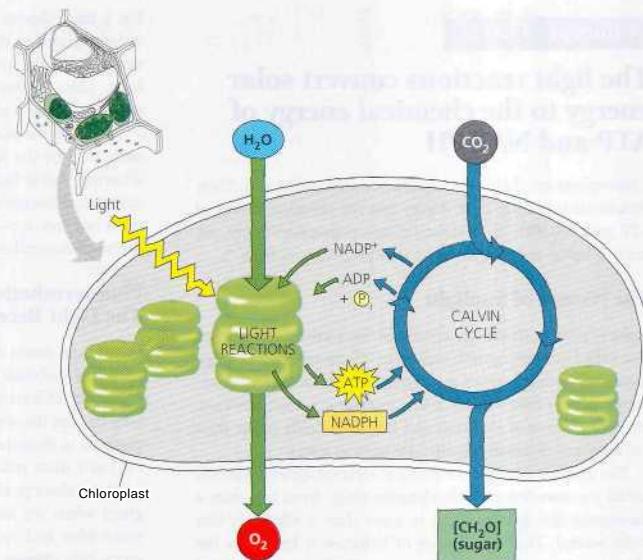

The Two Stages of Photosynthesis: A Preview

The equation for photosynthesis is a deceptively simple summary of a very complex process. Actually, photosynthesis is not a single process, but two processes, each with multiple steps. These two stages of photosynthesis are known as the light reactions (the *photo* part of photosynthesis) and the Calvin cycle (the *synthesis* part) (Figure 10.5).

The light reactions are the steps of photosynthesis that convert solar energy to chemical energy. Light absorbed by chlorophyll drives a transfer of electrons and hydrogen from water to an acceptor called NADP^+ (nicotinamide adenine dinucleotide phosphate), which temporarily stores the **energized** electrons. Water is split in the process, and thus it is the light reactions of photosynthesis that give off O_2 as a by-product. The electron acceptor of the light reactions, NADP^+ , is first cousin to NAD^+ , which functions as an electron carrier in cellular respiration; the two molecules differ only by the presence of an extra phosphate group in the NADP^+ molecule. The light reactions use solar power to reduce NADP^+ to NADPH by adding a pair of electrons along with a hydrogen nucleus, or H^+ . The light reactions also generate ATP, using chemiosmosis to power the addition of a phosphate

- Figure 10.5 An overview of photosynthesis: cooperation of the light reactions and the Calvin cycle.** In the chloroplast, the thylakoid membranes are the sites of the light reactions, whereas the Calvin cycle occurs in the stroma. The light reactions use solar energy to make ATP and NADPH, which function as chemical energy and reducing power, respectively, in the Calvin cycle. The Calvin cycle incorporates CO₂ into organic molecules, which are converted to sugar (Recall from Chapter 5 that most simple sugars have four times that are some multiple of [CH₂O].)

A smaller version of this diagram will reappear in several subsequent figures as a reminder of whether the events being described occur in the light reactions or in the Calvin cycle.

group to ADP, a process called **photophosphorylation**. Thus, light energy is initially converted to chemical energy in the form of two compounds: NADPH, a source of energized electrons ("reducing power"), and ATP, the versatile energy currency of cells. Notice that the light reactions produce no sugar; that happens in the second stage of photosynthesis, the Calvin cycle.

The Calvin cycle is named for Melvin Calvin, who, along with his colleagues, began to elucidate its steps in the late 1940s. The cycle begins by incorporating CO₂ from the air into organic molecules already present in the chloroplast. This initial incorporation of carbon into organic compounds is known as **carbon fixation**. The Calvin cycle then reduces the fixed carbon to carbohydrate by the addition of electrons. The reducing power is provided by NADPH, which acquired energized electrons in the light reactions. To convert CO₂ to carbohydrate, the Calvin cycle also requires chemical energy in the form of ATP, which is also generated by the light reactions. Thus, it is the Calvin cycle that makes sugar, but it can do so only with the help of the NADPH and ATP produced by the light reactions. The metabolic steps of the Calvin cycle are sometimes referred to as the dark reactions, or light-independent reactions, because none of the steps requires light *directly*. Nevertheless, the Calvin cycle in most plants occurs during daylight, for only then can the light reactions provide the NADPH and

ATP that the Calvin cycle requires. In essence, the chloroplast uses light energy to make sugar by coordinating the two stages of photosynthesis.

As Figure 10.5 indicates, the thylakoids of the chloroplast are the sites of the light reactions, while the Calvin cycle occurs in the stroma. In the thylakoids, molecules of NADP⁺ and ADP pick up electrons and phosphate, respectively, and then are released to the stroma, where they transfer their high-energy cargo to the Calvin cycle. The two stages of photosynthesis are treated in this figure as metabolic modules that take in ingredients and crank out products. Our next step toward understanding photosynthesis is to look more closely at how the two stages work, beginning with the light reactions.

Concept Check 10.1

- How do the reactant molecules of photosynthesis reach the chloroplasts in leaves?
- How did the use of an oxygen isotope help elucidate the chemistry of photosynthesis?
- Describe how the two stages of photosynthesis are dependent on each other.

For suggested answers, see Appendix A.

Concept 10.2

The light reactions convert solar energy to the chemical energy of ATP and NADPH

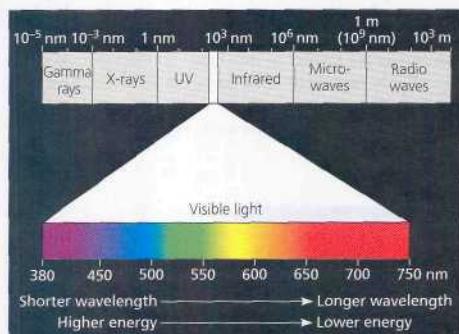

Chloroplasts are chemical factories powered by the sun. Their thylakoids transform light energy into the chemical energy of ATP and NADPH. To understand this conversion better, we need to know about some important properties of light.

The Nature of Sunlight

Light is a form of energy known as electromagnetic energy also called electromagnetic radiation. Electromagnetic energy travels in rhythmic waves analogous to those created by dropping a pebble into a pond. Electromagnetic waves, however, are disturbances of electrical and magnetic fields rather than disturbances of a material medium such as water.

The distance between the crests of electromagnetic waves is called the **wavelength**. Wavelengths range from less than a nanometer (for gamma rays) to more than a kilometer (for radio waves). This entire range of radiation is known as the electromagnetic spectrum (**Figure 10.6**). The segment most important to life is the narrow band from about 380 nm to 750 nm in wavelength. This radiation is known as **visible light** because it is detected as various colors by the human eye.

The model of light as waves explains many of light's properties, but in certain respects light behaves as though it consists of discrete particles, called **photons**. Photons are not tangible objects, but they act like objects in that each of them

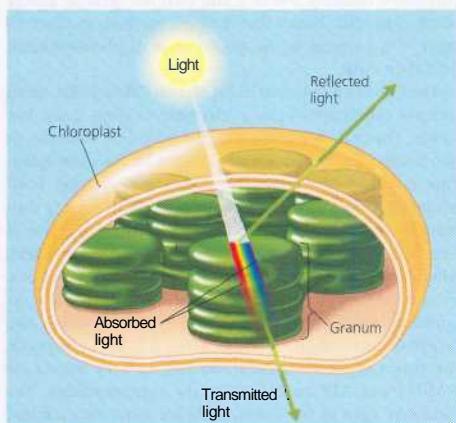

A Figure 10.6 The electromagnetic spectrum. White light is a mixture of all wavelengths of visible light. A prism can sort white light into its component colors by bending light of different wavelengths at different angles. (Droplets of water in the atmosphere can act as prisms, forming a rainbow; see Figure 10.1.) Visible light drives photosynthesis.

has a fixed quantity of energy. The amount of energy is inversely related to the wavelength of the light; the shorter the wavelength, the greater the energy of each photon of **that** light. Thus, a photon of violet light packs nearly twice as much energy as a photon of red light.

Although the sun radiates the full spectrum of electromagnetic energy the atmosphere acts like a selective window, allowing visible light to pass through while screening out a substantial fraction of other radiation. The part of the **spectrum** we can see—visible light—is also the radiation that drives photosynthesis.

Photosynthetic Pigments: The Light Receptors

When light meets matter, it may be reflected, transmitted, or absorbed. Substances that absorb visible light are known as **pigments**. Different pigments absorb light of different wavelengths, and the wavelengths that are absorbed disappear. If a pigment is illuminated with white light, the color we see is the color most reflected or transmitted by the pigment. (If a pigment absorbs all wavelengths, it appears black.) We see green when we look at a leaf because chlorophyll absorbs violet-blue and red light while transmitting and reflecting green light (**Figure 10.7**). The ability of a pigment to absorb various wavelengths of light can be measured with an instrument called a **spectrophotometer**. This machine directs beams of light of different wavelengths through a solution of the pigment and measures the fraction of the light transmitted

A Figure 10.7 Why leaves are green: interaction of light with chloroplasts. The chlorophyll molecules of chloroplasts absorb violet-blue and red light (the colors most effective in driving photosynthesis) and reflect or transmit green light. This is why leaves appear green.

at each wavelength (**Figure 10.8**). A graph plotting a pigment's light absorption versus wavelength is called an absorption spectrum.

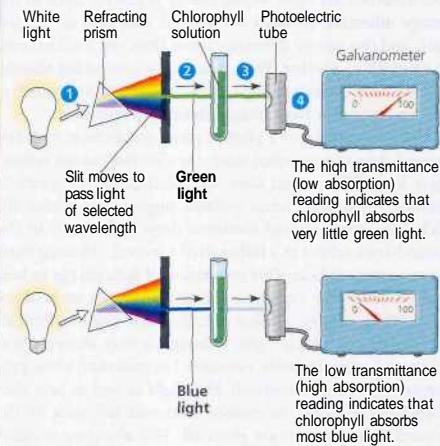

The absorption spectra of chloroplast pigments provide clues to the relative effectiveness of different wavelengths for driving photosynthesis, since light can perform work in chloroplasts only if it is absorbed. **Figure 10.9a** shows the absorption spectra of three types of pigments in chloroplasts. If we look first at the absorption spectrum of chlorophyll *a*, it suggests that violet-blue and red light work best for photosynthesis, since they are

Figure 10.8 Research Method Determining an Absorption Spectrum

APPLICATION An absorption spectrum is a visual representation of how well a particular pigment absorbs different wavelengths of visible light. Absorption spectra of various chloroplast pigments help scientists decipher each pigment's role in a plant.

TECHNIQUE A spectra photo meter measures the relative amounts of light of different wavelengths absorbed and transmitted by a pigment solution.

- White light is separated into colors (wavelengths) by a prism.
- One by one, the different colors of light are passed through the sample (chlorophyll in this example). Green light and blue light are shown here.
- The transmitted light strikes a photoelectric tube, which converts the light energy to electricity.
- The electrical current is measured by a galvanometer. The meter indicates the fraction of light transmitted through the sample, from which we can determine the amount of light absorbed.

RESULTS See Figure 10.9a for absorption spectra of three types of chloroplast pigments.

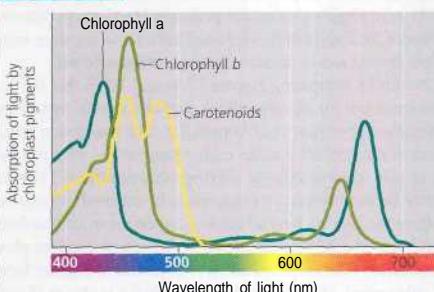

Figure 10.9

Inquiry Which wavelengths of light are most effective in driving photosynthesis?

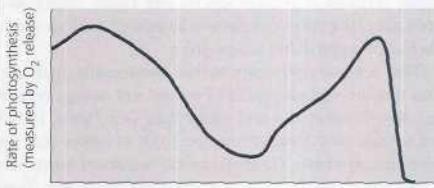

EXPERIMENT

Three different experiments helped reveal which wavelengths of light are photosynthetically important. The results are shown below.

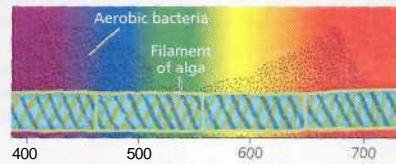

RESULTS

- (a) Absorption spectra.** The three curves show the wavelengths of light best absorbed by three types of chloroplast pigments.

- (b) Action spectrum.** This graph plots the rate of photosynthesis versus wavelength. The resulting action spectrum resembles the absorption spectrum for chlorophyll *a* but does not match exactly (see part a). This is partly due to the absorption of light by accessory pigments such as chlorophyll *b* and carotenoids.

- (c) Engelmann's experiment.** In 1883, Theodor W. Engelmann illuminated a filamentous alga with light that had been passed through a prism, exposing different segments of the alga to different wavelengths. He used aerobic bacteria, which concentrate near an oxygen source, to determine which segments of the alga were releasing the most O_2 and thus photosynthesizing most. Bacteria congregated in greatest numbers around the parts of the alga illuminated with violet-blue or red light. Notice the close match of the bacterial distribution to the action spectrum in part b.

CONCLUSION

Light in the violet-blue and red portions of the spectrum are most effective in driving photosynthesis.

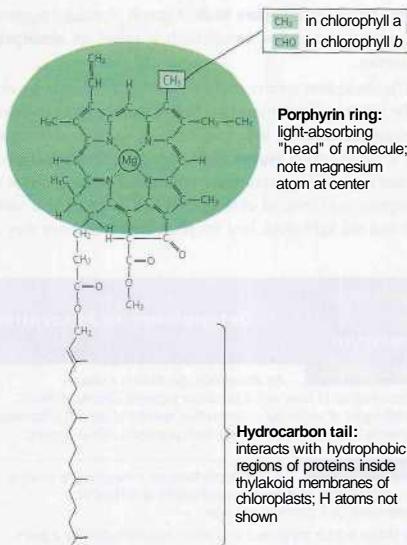

absorbed, while green is the least effective color. This is confirmed by an action spectrum for photosynthesis (**Figure 10.9b**), which profiles the relative effectiveness of different wavelengths of radiation in driving the process. An action spectrum is prepared by illuminating chloroplasts with light of different colors and then plotting wavelength against some measure of photosynthetic rate, such as CO_2 consumption or O_2 release. The action spectrum for photosynthesis was first demonstrated in 1883 in an elegant experiment performed by German botanist Theodor W. Engelmann, who used bacteria to measure rates of photosynthesis in filamentous algae (**Figure 10.9c**).

Notice by comparing Figures 10.9a and 10.9b that the action spectrum for photosynthesis does not exactly match the absorption spectrum of chlorophyll a. The absorption spectrum of chlorophyll a alone underestimates the effectiveness of certain wavelengths in driving photosynthesis. This is partly because accessory pigments with different absorption spectra are also photosynthetically important in chloroplasts and broaden the spectrum of colors that can be used for photosynthesis. One of these accessory pigments is another form of chlorophyll, chlorophyll b. Chlorophyll b is almost identical to chlorophyll a, but a slight structural difference between them (**Figure 10.10**) is enough to give the two pigments slightly different absorption spectra (see Figure 10.9a). As a result, they have different colors—chlorophyll a is blue-green, whereas chlorophyll b is yellow-green.

Other accessory pigments include carotenoids, hydrocarbons that are various shades of yellow and orange because they absorb violet and blue-green light (see Figure 10.9a). Carotenoids may broaden the spectrum of colors that can drive photosynthesis. However, a more important function of at least some carotenoids seems to be *photoprotection*: These compounds absorb and dissipate excessive light energy that would otherwise damage chlorophyll or interact with oxygen, forming reactive oxidative molecules that are dangerous to the cell. Interestingly, carotenoids similar to the photoprotective ones in chloroplasts have a photoprotective role in the human eye. These and other related molecules are highlighted in health food products as "phytochemicals" (from the Greek *phyton*, plant) that have antioxidant powers. Plants can synthesize all the antioxidants they require, whereas humans and other animals must obtain some of them from their diets.

Excitation of Chlorophyll by Light

What exactly happens when chlorophyll and other pigments absorb light? The colors corresponding to the absorbed wavelengths disappear from the spectrum of the transmitted and reflected light, but energy cannot disappear. When a molecule absorbs a photon of light, one of the molecule's electrons is elevated to an orbital where it has more potential energy. When the electron is in its normal orbital, the pigment molecule is said to be in its ground state. Absorption of a photon boosts

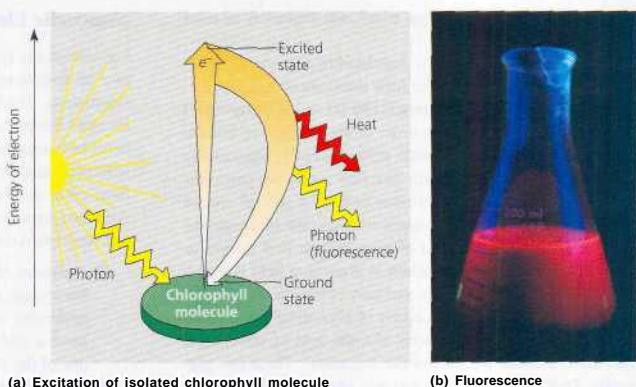

A. Figure 10.10 Structure of chlorophyll molecules in chloroplasts of plants. Chlorophyll a and chlorophyll b differ only in one of the functional groups bonded to the porphyrin ring.

an electron to an orbital of higher energy, and the pigment molecule is then said to be in an excited state. The only photons absorbed are those whose energy is exactly equal to the energy difference between the ground state and an excited state, and this energy difference varies from one kind of atom or molecule to another. Thus, a particular compound absorbs only photons corresponding to specific wavelengths, which is why each pigment has a unique absorption spectrum.

Once absorption of a photon raises an electron from the ground state to an excited state, the electron cannot remain there long. The excited state, like all high-energy states, is unstable. Generally, when isolated pigment molecules absorb light, their excited electrons drop back down to the ground-state orbital in a billionth of a second, releasing their excess energy as heat. This conversion of light energy to heat is what makes the top of an automobile so hot on a sunny day. (White cars are coolest because their paint reflects all wavelengths of visible light, although it may absorb ultraviolet and other invisible radiation.) In isolation, some pigments, including chlorophyll, emit light as well as heat after absorbing photons. As excited electrons fall back to the ground state, photons are given off. This afterglow is called fluorescence. If a solution of chlorophyll isolated from chloroplasts is illuminated, it will fluoresce in the red-orange part of the spectrum and also give off heat (**Figure 10.11**).

- **Figure 10.11 Excitation of isolated chlorophyll by light.** (a) Absorption of a photon causes a transition of the chlorophyll molecule from its ground state to its excited state. The photon boosts an electron to an orbital where it has more potential energy. If the illuminated molecule exists in isolation, its excited electron immediately drops back down to the ground-state orbital, and its excess energy is given off as heat and fluorescence (light). (b) A chlorophyll solution excited with ultraviolet light fluoresces with a red-orange glow.

(b) Fluorescence

A Photosystem: A Reaction Center Associated with Light-Harvesting Complexes

Chlorophyll molecules excited by the absorption of light energy produce very different results in an intact chloroplast than they do in isolation (see Figure 10.11). In their native environment of the thylakoid membrane, chlorophyll molecules are organized along with other small organic molecules and proteins into photosystems.

A photosystem is composed of a reaction center surrounded by a number of light-harvesting complexes (Figure 10.12). Each **light-harvesting complex** consists of pigment molecules (which may include chlorophyll *a*, chlorophyll *b*, and carotenoids) bound to particular proteins. The number and variety of pigment molecules enable a photosystem to harvest light over a larger surface and a larger portion of the spectrum than any single pigment molecule alone could. Together, these light-harvesting complexes act as an antenna for the reaction center. When a pigment molecule absorbs a photon, the energy is transferred from pigment molecule to pigment molecule within a light-harvesting complex until it is funneled into the reaction center. The **reaction center** is a protein complex that includes two special chlorophyll *a* molecules and a molecule called the **primary electron acceptor**. These chlorophyll *a* molecules are special because their molecular environment—their location and the other molecules with which they are associated—enables them to use the energy from light to boost one of their electrons to a higher energy level.

The solar-powered transfer of an electron from a special chlorophyll *a* molecule to the primary electron acceptor is the first step of the light reactions. As soon as the chlorophyll electron is excited to a higher energy level, the primary electron acceptor captures it; this is a redox reaction. Isolated chlorophyll fluoresces because there is no electron acceptor, so electrons of photoexcited chlorophyll drop right back to the ground state.

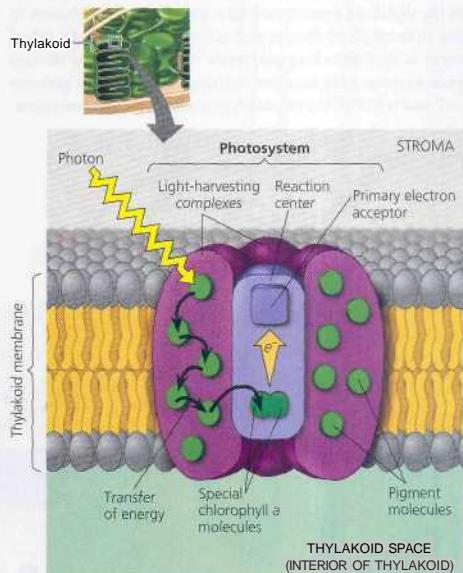

Figure 10.12 How a photosystem harvests light. When a photon strikes a pigment molecule in a light-harvesting complex, the energy is passed from molecule to molecule until it reaches the reaction center. At the reaction center, an excited electron from one of the two special chlorophyll *a* molecules is captured by the primary electron acceptor.

In a chloroplast, this immediate plunge of high-energy electrons back to the ground state is prevented. Thus, each photosystem—a reaction center surrounded by light-harvesting complexes—functions in the chloroplast as a unit. It converts

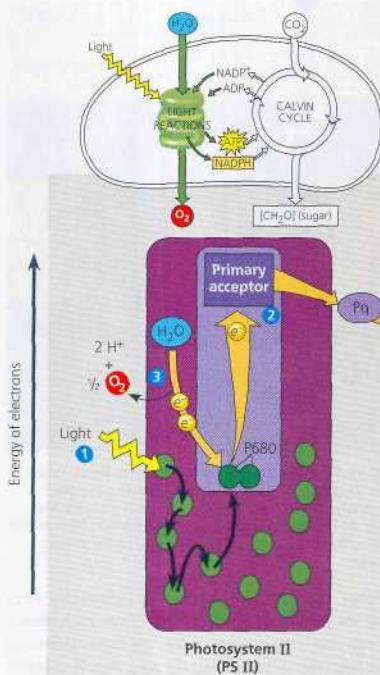

light energy to chemical energy, which will ultimately be used for the synthesis of sugar.

The thylakoid membrane is populated by two types of photosystems that cooperate in the light reactions of photosynthesis. They are called **photosystem II (PS II)** and **photosystem I (PS I)**. (They were named in order of their discovery, but the two function sequentially, with photosystem II functioning first.) Each has a characteristic reaction center—a particular kind of primary electron acceptor next to a pair of special chlorophyll *a* molecules associated with specific proteins. The reaction-center chlorophyll *a* of photosystem II is known as P680 because this pigment is best at absorbing light having a wavelength of 680 nm (in the red part of the spectrum). The chlorophyll *a* at the reaction center of photosystem I is called P700 because it most effectively absorbs light of wavelength 700 nm (in the far red part of the spectrum). These two pigments, P680 and P700, are actually identical chlorophyll *a* molecules. However, their association with different proteins in the thylakoid membrane affects the electron distribution in the chlorophyll molecules and accounts for the slight differences in light-absorbing properties. Now let's see how the two photosystems work together in using light energy to generate ATP and NADPH, the two main products of the light reactions.

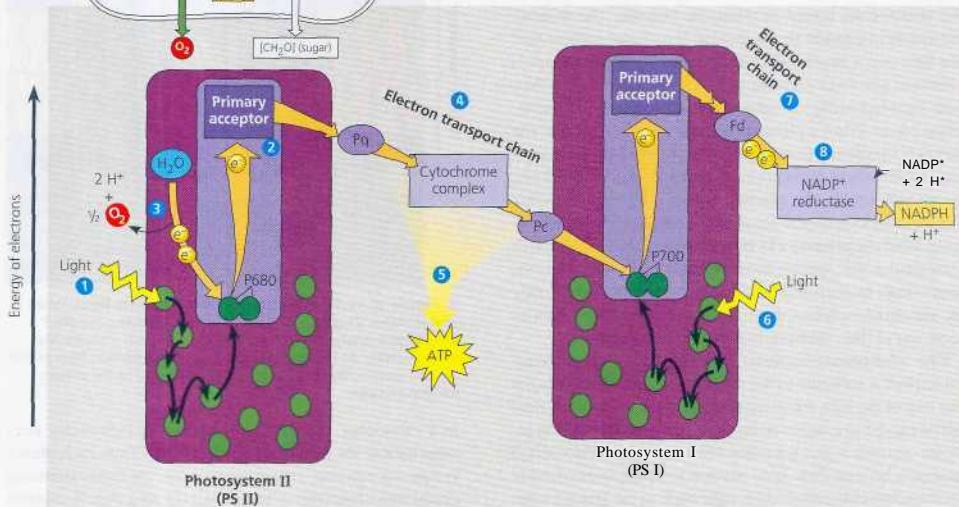

Noncyclic Electron Flow

Light drives the synthesis of NADPH and ATP by energizing the two photosystems embedded in the thylakoid membranes of chloroplasts. The key to this energy transformation is a flow of electrons through the photosystems and other molecular components built into the thylakoid membrane. During the light reactions of photosynthesis, there are two possible routes for electron flow: cyclic and noncyclic. **Noncyclic electron flow**, the predominant route, is shown in **Figure 10.13**. The numbers in the text description correspond to the numbered steps in the figure.

- A photon of light strikes a pigment molecule in a light-harvesting complex and is relayed to other pigment molecules until it reaches one of the two P680 chlorophyll *a* molecules in the PS II reaction center. It excites one of the P680 electrons to a higher energy state.
- This electron is captured by the primary electron acceptor.
- An enzyme splits a water molecule into two electrons, two hydrogen ions, and an oxygen atom. The electrons are supplied one by one to the P680 molecules, each replacing an electron lost to the **primary electron acceptor**. (Missing an electron, P680 is the strongest biological oxidizing agent known; its electron hole must be filled.)

f Figure 10.13 How noncyclic electron flow during the light reactions generates ATP and NADPH. The gold arrows trace the current of light-driven electrons from water to NADPH.

The oxygen atom immediately combines with another oxygen atom, forming O_2 .

- Q Each photoexcited electron passes from the primary electron acceptor of PS II to PS I via an electron transport chain (similar to the electron transport chain that functions in cellular respiration). The electron transport chain between PS II and PS I is made up of the electron carrier plastoquinone (Pq), a cytochrome complex, and a protein called plastocyanin (Pc).

- Q The exergonic "fall" of electrons to a lower energy level provides energy for the synthesis of ATP.

- Q Meanwhile, light energy was transferred via a light-harvesting complex to the PS I reaction center, exciting an electron of one of the two P700 chlorophyll *a* molecules located there. The photoexcited electron was then captured by PS I's primary electron acceptor, creating an electron "hole" in the P700. The hole is filled by an electron that reaches the bottom of the electron transport chain from PS II.

- Q Photoexcited electrons are passed from PS I's primary electron acceptor down a second electron transport chain through the protein ferredoxin (Fd).

- Q The enzyme NADP⁺ reductase transfers electrons from Fd to NADP⁺. Two electrons are required for its reduction to NADPH.

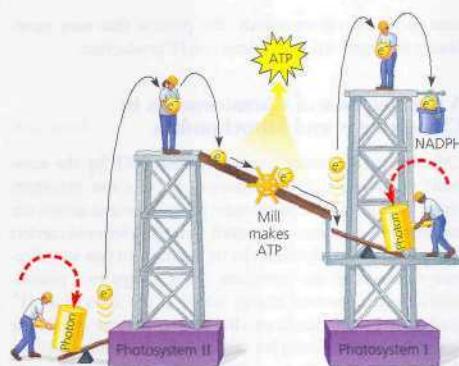

As complicated as the scheme shown in Figure 10.13 is, do not lose track of its functions: The Light reactions use solar power to generate ATP and NADPH, which provide chemical energy and reducing power, respectively, to the sugar-making reactions of the Calvin cycle. The energy changes of electrons as they flow through the light reactions are shown by analogy in **Figure 10.14**.

Cyclic Electron Flow

Under certain conditions, photoexcited electrons take an alternative path called cyclic electron flow, which uses photosystem I but not photosystem II. You can see in **Figure 10.15**

> **Figure 10.15 Cyclic electron flow.**

Photoexcited electrons from PS I are occasionally shunted back from ferredoxin (Fd) to chlorophyll via the cytochrome complex and plastocyanin (Pc). This electron shunt supplements the supply of ATP (via chemiosmosis) but produces no NADPH. The "shadow" of noncyclic electron flow is included in the diagram for comparison with the cyclic route. The two ferredoxin molecules shown in this diagram are actually one and the same—the final electron carrier in the electron transport chain of PS I.

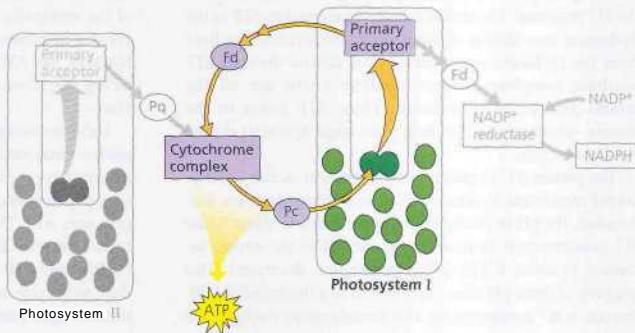

A **Figure 10.14 A mechanical analogy for the light reactions.**

that cyclic flow is a short circuit: The electrons cycle back from ferredoxin (Fd) to the cytochrome complex and from there continue on to a P700 chlorophyll in the PS I reaction center. There is no production of NADPH and no release of oxygen. Cyclic flow does, however, generate ATP.

What is the function of cyclic electron flow? Noncyclic electron flow produces ATP and NADPH in roughly equal quantities, but the Calvin cycle consumes more ATP than NADPH. Cyclic electron flow makes up the difference, since it produces ATP but no NADPH. The concentration of NADPH in the chloroplast may help regulate which pathway, cyclic versus noncyclic, electrons take through the light reactions. If the chloroplast runs low on ATP for the Calvin cycle, NADPH will begin to accumulate as the Calvin cycle slows down. The rise in NADPH may stimulate a temporary shift from noncyclic to cyclic electron flow until ATP supply catches up with demand.

Whether ATP synthesis is driven by noncyclic or cyclic electron flow, the actual mechanism is the same. This is a good

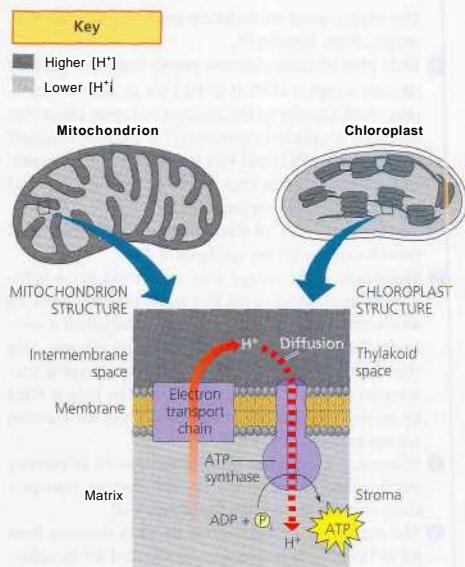

time to review chemiosmosis, the process that uses membranes to couple redox reactions to ATP production.

A Comparison of Chemiosmosis in Chloroplasts and Mitochondria

Chloroplasts and mitochondria generate ATP by the same basic mechanism: chemiosmosis. An electron transport chain assembled in a membrane pumps protons across the membrane as electrons are passed through a series of carriers that are progressively more electronegative. In this way, electron transport chains transform redox energy to a proton-motive force, potential energy stored in the form of an H⁺ gradient across a membrane. Built into the same membrane is an ATP synthase complex that couples the diffusion of hydrogen ions down their gradient to the phosphorylation of ADP. Some of the electron carriers, including the iron-containing proteins called cytochromes, are very similar in chloroplasts and mitochondria. The ATP synthase complexes of the two organelles are also very much alike. But there are noteworthy differences between oxidative phosphorylation in mitochondria and photophosphorylation in chloroplasts. In mitochondria, the high-energy electrons dropped down the transport chain are extracted from organic molecules (which are thus oxidized). Chloroplasts do not need molecules from food to make ATP; their photosystems capture light energy and use it to drive electrons to the top of the transport chain, in other words, mitochondria transfer chemical energy from food molecules to ATP (and NADH), whereas chloroplasts transform light energy into chemical energy in ATP (and NADPH).

The spatial organization of chemiosmosis also differs in chloroplasts and mitochondria (Figure 10.16). The inner membrane of the mitochondrion pumps protons from the mitochondrial matrix out to the intermembrane space, which then serves as a reservoir of hydrogen ions that powers the ATP synthase. The thylakoid membrane of the chloroplast pumps protons from the stroma into the thylakoid space (interior of the thylakoid), which functions as the H⁺ reservoir. The thylakoid membrane makes ATP as the hydrogen ions diffuse down their concentration gradient from the thylakoid space back to the stroma through ATP synthase complexes, whose catalytic knobs are on the stroma side of the membrane. Thus, ATP forms in the stroma, where it is used to help drive sugar synthesis during the Calvin cycle.

The proton (H⁺) gradient, or pH gradient, across the thylakoid membrane is substantial. When chloroplasts are illuminated, the pH in the thylakoid space drops to about 5 (the H⁺ concentration increases), and the pH in the stroma increases to about 8 (the H⁺ concentration decreases). This gradient of three pH units corresponds to a thousandfold difference in H⁺ concentration. If in the laboratory the lights are

A Figure 10.16 Comparison of chemiosmosis in mitochondria and chloroplasts. In both kinds of organelles, electron transport chains pump protons (H⁺) across a membrane from a region of low H⁺ concentration (light gray in this diagram) to one of high H⁺ concentration (dark gray). The protons then diffuse back across the membrane through ATP synthase, driving the synthesis of ATP.

turned off, the pH gradient is abolished, but it can quickly be restored by turning the lights back on. Such experiments provide strong evidence in support of the chemiosmotic model.

Based on studies in several laboratories, Figure 10.17 shows a current model for the organization of the light-reaction "machinery" within the thylakoid membrane. Each of the molecules and molecular complexes in the figure is present in numerous copies in each thylakoid. Notice that NADPH, like ATP, is produced on the side of the membrane facing the stroma, where the Calvin cycle reactions take place.

Let's summarize the light reactions. Noncyclic electron flow pushes electrons from water, where they are at a low state of potential energy, to NADPH, where they are stored at a high state of potential energy. The light-driven electron current also generates ATP. Thus, the equipment of the thylakoid membrane converts light energy to chemical energy stored in NADPH and ATP (Oxygen is a by-product.) Let's now see how the Calvin cycle uses the products of the light reactions to synthesize sugar from CO₂.

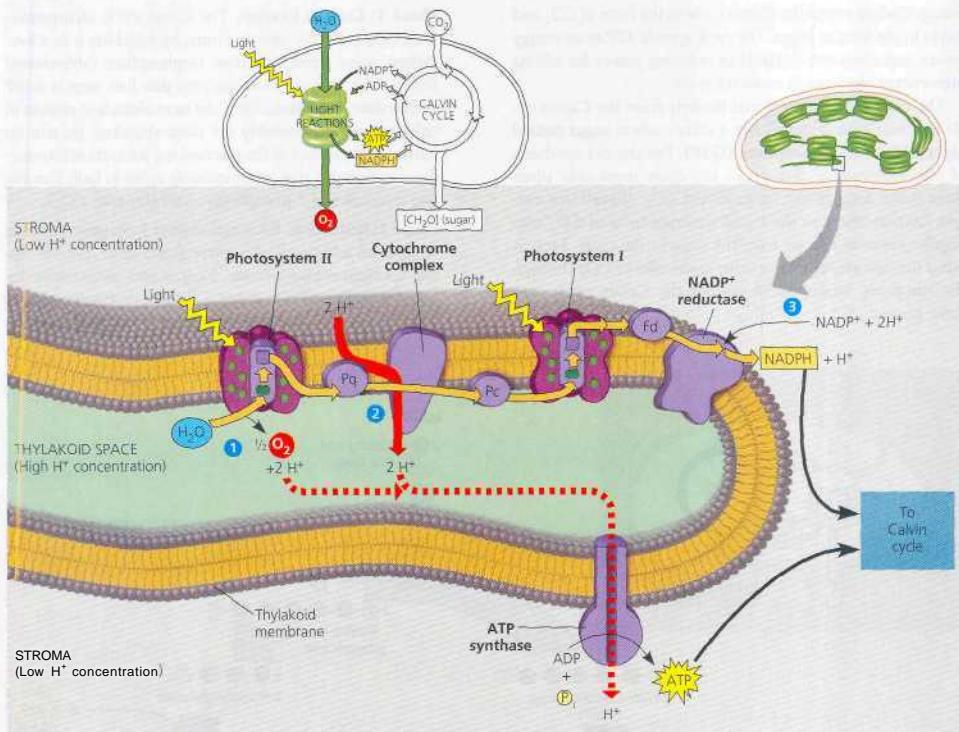

Figure 10.17 The light reactions and ihemiosmosis: the organization of the Thylakoid membrane. This diagram shows a current model for the organization of the thylakoid membrane. The gold arrows track the noncyclic electron flow outlined in Figure 10.13. As electrons pass from carrier to carrier in redox reactions, hydrogen ions removed from the stroma are deposited in the thylakoid space,

storing energy as a proton-motive force (H^+ gradient). At least three steps in the light reactions contribute to the proton gradient: ① Water is split by photosystem II on the side of the membrane facing the thylakoid space; ② as plastochlorophyll (P_Q), a mobile carrier, transfers electrons to the cytochrome complex, protons are translocated across the membrane into the thylakoid space; and ③ a hydrogen ion is

removed from the stroma when it is taken up by NADP⁺. Notice how, as in Figure 10.16, hydrogen ions are being pumped from the stroma into the thylakoid space. The diffusion of H^+ from the thylakoid space back to the stroma (along the H^+ concentration gradient) powers the ATP synthase. These light-driven reactions store chemical energy in NADPH and ATP, which shuttle the energy to the sugar-producing Calvin cycle.

Concept Check 10.2

- What color of light is *least* effective in driving photosynthesis? Explain.
- Compared to a solution of isolated chlorophyll, why do intact chloroplasts release less heat and fluorescence when illuminated?
- In the light reactions, what is the electron donor? Where do the electrons end up?

for suggested answers, see Appendix A.

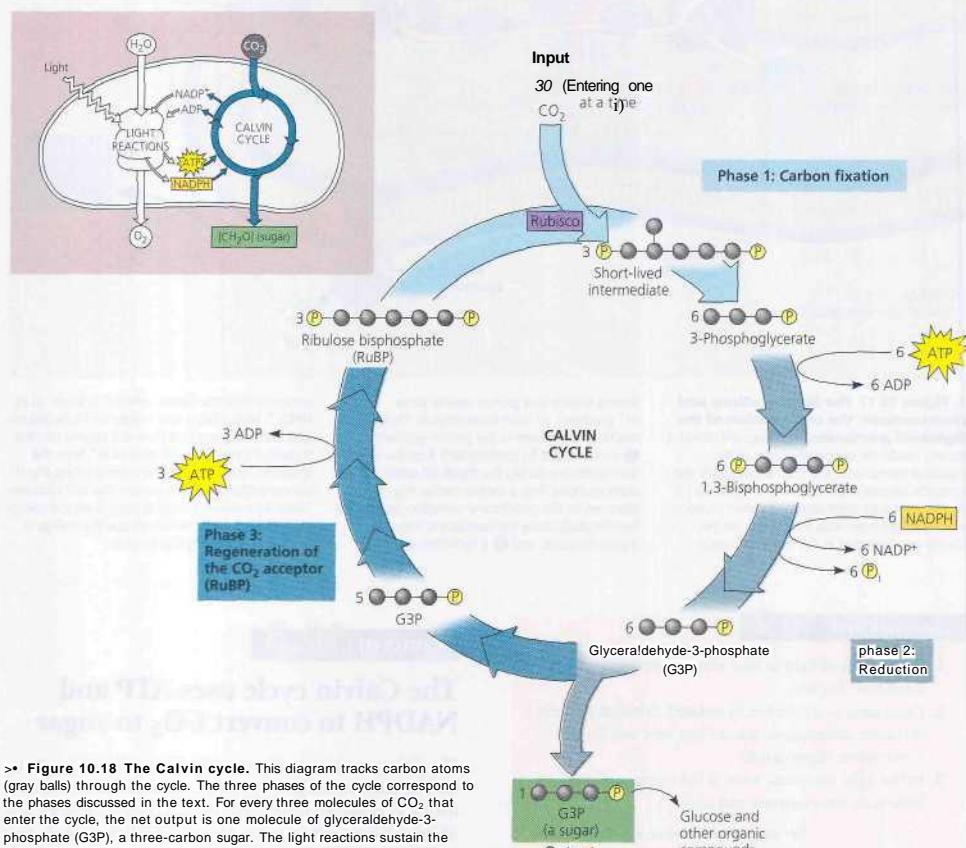

Concept 10.3

The Calvin cycle uses ATP and NADPH to convert CO_2 to sugar

The Calvin cycle is similar to the citric acid cycle in that, a starting material is regenerated after molecules enter and leave the cycle. However, while the citric acid cycle is catabolic, oxidising glucose and releasing energy, the Calvin cycle is anabolic, building sugar from smaller molecules and consuming

energy. Carbon enters the Calvin cycle in the form of CO_2 and leaves in the form of sugar. The cycle spends ATP as an energy source and consumes NADPH as reducing power for adding high-energy electrons to make the sugar.

The carbohydrate produced directly from the Calvin cycle is actually not glucose, but a three-carbon sugar named **glyceraldehyde-3-phosphate (G3P)**. For the net synthesis of one molecule of this sugar, the cycle must take place three times, fixing three molecules of CO_2 . (Recall that carbon fixation refers to the initial incorporation of CO_2 into organic material.) As we trace the steps of the cycle, keep in mind that we are following three molecules of CO_2 through the reactions. **Figure 10.18** divides the Calvin cycle into three phases:

► **Figure 10.18 The Calvin cycle.** This diagram tracks carbon atoms (gray balls) through the cycle. The three phases of the cycle correspond to the phases discussed in the text. For every three molecules of CO_2 that enter the cycle, the net output is one molecule of glyceraldehyde-3-phosphate (G3P), a three-carbon sugar. The light reactions sustain the Calvin cycle by regenerating ATP and NADPH.

Phase 1: Carbon fixation. The Calvin cycle incorporates each CO_2 molecule, one at a time, by attaching it to a five-carbon sugar named ribulose bisphosphate (abbreviated RuBP). The enzyme that catalyzes this first step is RuBP carboxylase, or **rubisco**. (It is the most abundant protein in chloroplasts and probably the most abundant protein on Earth.) The product of the reaction is a six-carbon intermediate so unstable that it immediately splits in half, forming two molecules of 3-phosphoglycerate (for each CCA).

Phase 2: Reduction. Each molecule of 3-phosphoglycerate receives an additional phosphate group from ATP, becoming 1,3-bisphosphoglycerate. Next, a pair of electrons donated from NADPH reduces 1,3-bisphosphoglycerate to G3P. Specifically, the electrons from NADPH reduce the

carboxyl group of 3-phosphoglycerate to the aldehyde group of G3P, which stores more potential energy. G3P is a sugar—the same three-carbon sugar formed in glycolysis by the splitting of glucose. Notice in Figure 10.18 that for every *three* molecules of CO₂, there are six molecules of 33P. But only one molecule of this three-carbon sugar can be counted as a net gain of carbohydrate. The cycle began with 15 carbons' worth of carbohydrate in the form of three molecules of the E4-carbon sugar RuBP. Now there are 18 carbons' worth of carbohydrate in the form of six molecules of G3P. One molecule exits the cycle to be used by the plant cell, but the other five molecules must be recycled to regenerate the three molecules of RuBP.

Phase 3: Regeneration of the CO₂ acceptor (RuBP). In a complex series of reactions, the carbon skeletons of five molecules of G3P are rearranged by the last steps of the Calvin cycle into three molecules of RuBP. To accomplish this, the cycle spends three more molecules of ATP. The RuBP is now prepared to receive CO₂ again, and the cycle continues.

For the net synthesis of one G3P molecule, the Calvin cycle consumes a total of nine molecules of ATP and six molecules of NADPH. The light reactions regenerate the ATP and NADPH. The G3P spun off from the Calvin cycle becomes the starting material for metabolic pathways that synthesize other organic compounds, including glucose and other carbohydrates. Neither the light reactions nor the Calvin cycle alone can make sugar from CO₂. Photosynthesis is an emergent property of the intact chloroplast, which integrates the two stages of photosynthesis.

I Concept Check 10.3

- To synthesize one glucose molecule, the Calvin cycle uses _____ molecules of C₃B, _____ molecules of ATP, and _____ molecules of NADPH.
- Explain why the high number of ATP and NADPH molecules used during the Calvin cycle is consistent with the high value of glucose as an energy source.
- Explain why a poison that inhibits an enzyme of the Calvin cycle will also inhibit the light reactions.

For suggested answers, see Appendix A.

Concept 10.4

Alternative mechanisms of carbon fixation have evolved in hot, arid climates

Ever since plants first moved onto land about 475 million years ago, they have been adapting to the problems of terrestrial life, particularly the problem of dehydration. In Chapters

29 and 36, we will consider anatomical adaptations that help plants conserve water. Here we are concerned with metabolic adaptations. The solutions often involve trade-offs. An important example is the compromise between photosynthesis and the prevention of excessive water loss from the plant. The CO₂ required for photosynthesis enters a leaf via stomata, the pores through the leaf surface (see Figure 10.3). However, stomata are also the main avenues of transpiration, the evaporative loss of water from leaves. On a hot, dry day, most plants close their stomata, a response that conserves water. This response also reduces photosynthetic yield by limiting access to CO₂. With stomata even partially closed, CO₂ concentrations begin to decrease in the air spaces within the leaf, and the concentration of O₂ released from the light reactions begins to increase. These conditions within the leaf favor a seemingly wasteful process called photorespiration,

Photorespiration: An Evolutionary Relic?

In most plants, initial fixation of carbon occurs via rubisco, the Calvin cycle enzyme that adds CO₂ to ribulose bisphosphate. Such plants are called C₃ plants because the first organic product of carbon fixation is a three-carbon compound, 3-phosphoglycerate (see Figure 10.18). Rice, wheat, and soybeans are C₄ plants that are important in agriculture. When their stomata partially close on hot, dry days, C₃ plants produce less sugar because the declining level of CO₂ in the leaf starves the Calvin cycle. In addition, rubisco can bind O₂ in place of CO₂. As CO₂ becomes scarce within the air spaces of the leaf, rubisco adds O₂ to the Calvin cycle instead of CO₂. The product splits, and a two-carbon compound leaves the chloroplast. Peroxisomes and mitochondria rearrange and split this compound, releasing CO₂. The process is called photorespiration because it occurs in the light (*photo*) and consumes O₂ while producing CO₂ (*respiration*). However, unlike normal cellular respiration, photorespiration generates no ATP; in fact, photorespiration consumes ATP. And unlike photosynthesis, photorespiration produces no sugar. In fact, photorespiration *decreases* photosynthetic output by siphoning organic material from the Calvin cycle.

How can we explain the existence of a metabolic process that seems to be counterproductive for the plant? According to one hypothesis, photorespiration is evolutionary baggage—a metabolic relic from a much earlier time, when the atmosphere had less O₂ and more CO₂ than it does today. In the ancient atmosphere that prevailed when rubisco first evolved, the inability of the enzyme's active site to exclude O₂ would have made little difference. The hypothesis speculates that modern rubisco retains some of its chance affinity for O₂, which is now so concentrated in the atmosphere that a certain amount of photorespiration is inevitable.

It is not known whether photorespiration is beneficial to plants in any way. It is known that in many types of plants—

including crop plants—photorespiration drains away as much as 50% of the carbon fixed by the Calvin cycle. As heterotrophs that depend on carbon fixation in chloroplasts for our food, we naturally view photorespiration as wasteful. Indeed, if photorespiration could be reduced in certain plant species without otherwise affecting photosynthetic productivity, crop yields and food supplies might increase.

In certain plant species, alternate modes of carbon fixation have evolved that minimize photorespiration and optimize the Calvin cycle—even in hot, arid climates. The two most important of these photosynthetic adaptations are C₄ photosynthesis and CAM.

C₄ Plants

The C₄ plants are so named because they preface the Calvin cycle with an alternate mode of carbon fixation that forms a four-carbon compound as its first product. Several thousand species in at least 19 plant families use the C₄ pathway. Among the C₄ plants important to agriculture are sugarcane and corn, members of the grass family.

A unique leaf anatomy is correlated with the mechanism of C₄ photosynthesis (**Figure 10.19**; compare with Figure 10.3). In C₄ plants, there are two distinct types of photosynthetic cells: bundle-sheath cells and mesophyll cells. **Bundle-sheath cells** are arranged into tightly packed sheaths around the veins of the leaf. Between the bundle sheath and the leaf surface are the more loosely arranged mesophyll cells. The Calvin cycle is confined to the chloroplasts of the bundle sheath. However, the cycle is preceded by incorporation of CO₂ into organic compounds in the mesophyll. The first step,

carried out by the enzyme PEP carboxylase, is the addition of CO₂ to phosphoenolpyruvate (PEP), forming the four-carbon product oxaloacetate. PEP carboxylase has a much higher affinity for CO₂ than rubisco and no affinity for O₂. Therefore, PEP carboxylase can fix carbon efficiently when rubisco cannot—that is, when it is hot and dry and stomata are partially closed, causing CO₂ concentration in the leaf to fall and O₂ concentration to rise. After the C₄ plant fixes carbon from CO₂, the mesophyll cells export their four-carbon products (malate in the example shown in Figure 10.19) to bundle-sheath cells through plasmodesmata (see Figure 6.30). Within the bundle-sheath cells, the four-carbon compounds release CO₂, which is reassimilated into organic material by rubisco and the Calvin cycle. Pyruvate is also regenerated for conversion to PEP in mesophyll cells.

In effect, the mesophyll cells of a C₄ plant pump CO₂ into the bundle sheath, keeping the CO₂ concentration in the bundle-sheath cells high enough for rubisco to bind carbon dioxide rather than oxygen. The cyclic series of reactions involving PEP carboxylase and the regeneration of PEP can be thought of as a CO₂-concentrating pump that is powered by ATP. In this way, C₄ photosynthesis minimizes photorespiration and enhances sugar production. This adaptation is especially advantageous in hot regions with intense sunlight, where stomata partially close during the day, and it is in such environments that C₄ plants evolved and thrive today.

CAM Plants

A second photosynthetic adaptation to arid conditions has evolved in succulent (water-storing) plants (including jade

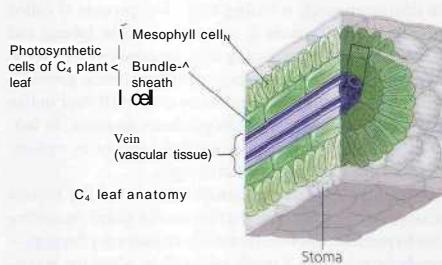

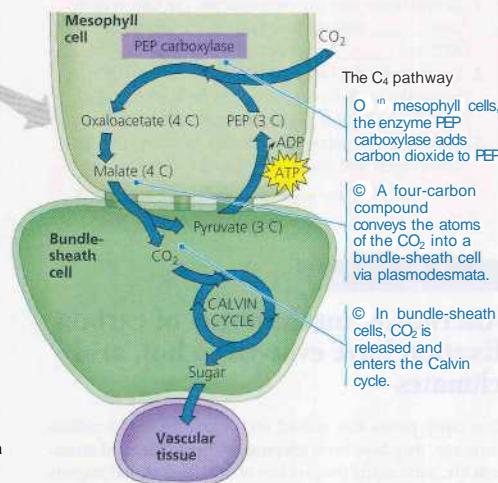

Figure 10.19 C₄ (leaf anatomy and the C₄ pathway. The structure and biochemical functions of the leaves of C₄ plants are an evolutionary adaptation to hot, dry climates. This adaptation maintains a CO₂ concentration in the bundle sheath that favors photosynthesis over photorespiration.

plants), many cacti, pineapples, and representatives of several other plant families. These plants open their stomata during the night and close them during the day, just the reverse of how other plants behave. Closing stomata during the day¹ helps desert plants conserve water, but it also prevents CO₂ from entering the leaves. During the night, when their stomata are open, these plants take up CO₂ and incorporate it into a variety of organic acids. This mode of carbon fixation is called crassulacean acid metabolism, or CAM, after the plant family Crassulaceae, the succulents in which the process was first discovered. The mesophyll cells of CAM plants store the organic acids they make during the night in their vacuoles until morning, when the stomata close. During the day, when the light reactions can supply ATP and NADPH for the Calvin cycle, CO₂ is released from the organic acids made the night before to become incorporated into sugar in the chloroplasts.

Notice in **Figure 10.20** that the CAM pathway is similar to the C₄ pathway in that carbon dioxide is first incorporated into organic intermediates before it enters the Calvin cycle. The difference is that in C₄ plants, the initial steps of carbon

fixation are separated structurally from the Calvin cycle, whereas in CAM plants, the two steps occur at separate times but within the same cell. (Keep in mind that CAM, C₄, and C₃ plants all eventually use the Calvin cycle to make sugar from carbon dioxide.)

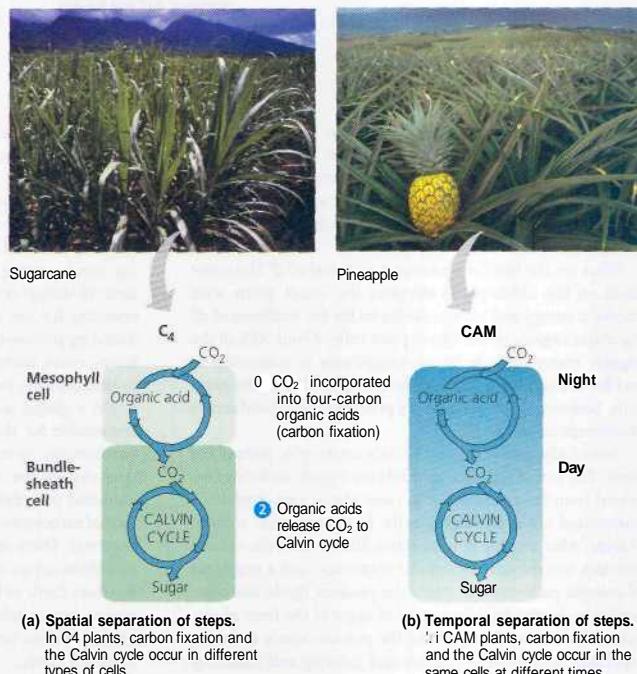

Concept Check 10.4

- Explain why photorespiration lowers photosynthetic output for plants.
- How would you expect the relative abundance of C₃ versus C₄ and CAM species to change in a geographic region whose climate becomes much hotter and drier?

For suggested answers, see Appendix A.

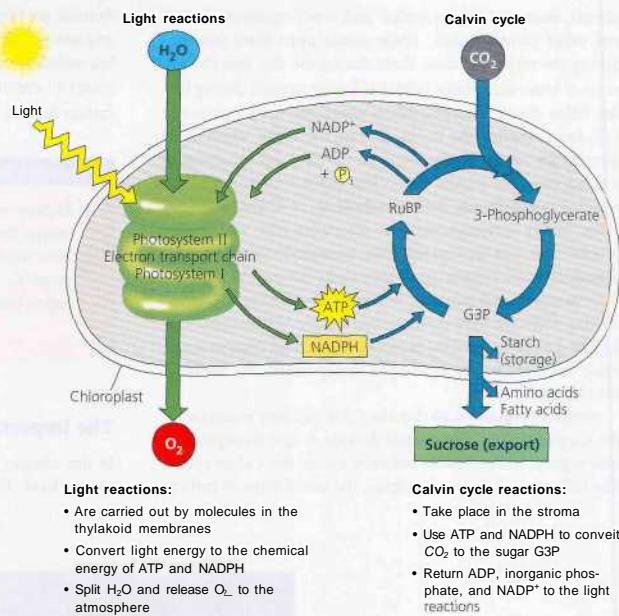

The Importance of Photosynthesis: A Review

In this chapter, we have followed photosynthesis from photons to food. The light reactions capture solar energy and use

- Figure 10.20 C₄ and CAM photosynthesis compared.** Both adaptations are characterized by preliminary incorporation of CO₂ into organic acids, followed by transfer of CO₂ to the Calvin cycle. The C₄ and CAM pathways are two evolutionary solutions to the problem of maintaining photosynthesis with stomata partially or completely closed on hot, dry days.

Figure 10.21 A review of photosynthesis. This diagram outlines the main reactants and products of the light reactions and the Calvin cycle as they occur in the chloroplasts of plant cells. The entire ordered operation depends on the structural integrity of the chloroplast and its membranes. Enzymes in the chloroplast and cytosol convert glyceraldehyde-3-phosphate (G3P), the direct product of the Calvin cycle, into many other organic compounds.

it to make ATP and transfer electrons from water to NADP^{+} . The Calvin cycle uses the ATP and NADPH to produce sugar from carbon dioxide. The energy that enters the chloroplasts as sunlight becomes stored as chemical energy in organic compounds. See **Figure 10.21** for a review of the entire process.

What are the fates of photosynthetic products? The sugar made in the chloroplasts supplies the entire plant with chemical energy and carbon skeletons for the synthesis of all the major organic molecules of plant cells. About 50% of the organic material made by photosynthesis is consumed as fuel for cellular respiration in the mitochondria of the plant cells. Sometimes there is a loss of photosynthetic products to photorespiration.

Technically green cells are the only autotrophic parts of the plant. The rest of the plant depends on organic molecules exported from leaves via veins. In most plants, carbohydrate is transported out of the leaves in the form of sucrose, a disaccharide. After arriving at nonphotosynthetic cells, the sucrose provides raw material for cellular respiration and a multitude of anabolic pathways that synthesize proteins, lipids, and other products. A considerable amount of sugar in the form of glucose is linked together to make the polysaccharide cellulose, especially in plant cells that are still growing and maturing.

Cellulose, the main ingredient of cell walls, is the most abundant organic molecule in the plant—and probably on the surface of the planet.

Most plants manage to make more organic material each day than they need to use as respiratory fuel and precursors for biosynthesis. They stockpile the extra sugar by synthesizing starch, storing some in the chloroplasts themselves and some in storage cells of roots, tubers, seeds, and fruits. In accounting for the consumption of the food molecules produced by photosynthesis, let's not forget that most plants lose leaves, roots, stems, fruits, and sometimes their entire bodies to heterotrophs, including humans.

On a global scale, photosynthesis is the process that is responsible for the presence of oxygen in our atmosphere. Furthermore, in terms of food production, the collective productivity of the minute chloroplasts is prodigious; it is estimated that photosynthesis makes about 160 billion metric tons of carbohydrate per year (a metric ton is 1,000 kg, about 1.1 tons). That's organic matter equivalent to a stack of about 60 trillion copies of this textbook—17 stacks of books reaching from Earth to the sun! No other chemical process on the planet can match the output of photosynthesis. And no process is more important than photosynthesis to the welfare of life on Earth.

SUMMARY OF KEY CONCEPTS

- Plants and other autotrophs are the producers of the biosphere. Photoautotrophs use the energy of sunlight to make organic molecules from CO_2 and H_2O . Heterotrophs consume organic molecules from other organisms for energy and carbon (p. 181).

Concept 10.1

Photosynthesis converts light energy to the chemical energy of food

- **Chloroplasts: The Sites of Photosynthesis in Plants** (pp. 182–183) In autotrophic eukaryotes, photosynthesis occurs in chloroplasts, organelles containing thylakoids. Stacks of thylakoids form grana.

Activity *The Sites of Photosynthesis*

- **Tracking Atoms Through Photosynthesis: Scientific Inquiry** (pp. 183–184) Photosynthesis is summarized as

Chloroplasts split water into hydrogen and oxygen, incorporating the electrons of hydrogen into sugar molecules. Photosynthesis is a redox process: H_2O is oxidized, CO_2 is reduced.

I* The Two Stages of Photosynthesis: A Preview

(pp. 184–185) The light reactions in the grana split water, releasing O_2 , producing ATP, and forming NADPH. The Calvin cycle in the stroma forms sugar from CO_2 , "using ATP for energy and NADPH for reducing power."

Activity *Overview of Photosynthesis*

Concept 10.2

The light reactions convert solar energy to the chemical energy of ATP and NADPH

- **The Nature of Sunlight** (p. 186) Light is a form of electromagnetic energy. The colors we see as visible light include those wavelengths that drive photosynthesis.

Photosynthetic Pigments: The Light Receptors

(pp. 186–188) A pigment absorbs visible light of specific wavelengths. Chlorophyll *a* is the main photosynthetic pigment in plants. Other accessory pigments absorb different wavelengths of light and pass the energy on to chlorophyll *a*.

Activity *Light Energy and Pigments*

Investigation *How Does Paper Chromatography Separate Plant Pigments?*

- **Excitation of Chlorophyll by Light** (p. 188) A pigment goes from a ground state to an excited state when a photon boosts one of its electrons to a higher-energy orbital. This excited state is unstable. Electrons from isolated pigments tend to fall back to the ground state, giving off heat and/or light.

- **A Photosystem: A Reaction Center Associated with Light-Harvesting Complexes** (pp. 189–190) A photosystem is composed of a reaction center surrounded by light-harvesting complexes that funnel the energy of photons to the reaction center. When a reaction-center chlorophyll *a* molecule absorbs energy, one of its electrons gets bumped up to the primary electron acceptor. Photosystem I contains P700

chlorophyll *a* molecules at the reaction center; photosystem II contains P680 molecules.

- **Noncyclic Electron Flow** (pp. 190–191) Noncyclic electron flow produces NADPH, ATP, and oxygen.

- **Cyclic Electron Flow** (pp. 191–192) Cyclic electron flow employs only photosystem I, producing ATP but no NADPH or O_2 .

- **A Comparison of Chemiosmosis in Chloroplasts and Mitochondria** (pp. 192–193) [in both organelles, the redox reactions of electron transport chains generate an H^+ gradient across a membrane. ATP synthase uses this proton-motive force to make ATP.

Activity *The Light Reactions*

Concept 10.3

The Calvin cycle uses ATP and NADPH to convert CO_2 to sugar

- The Calvin cycle occurs in the stroma and consists of carbon fixation, reduction, and regeneration of the CO_2 acceptor. Using electrons from NADPH and energy from ATP, the cycle synthesizes a three-carbon sugar (G3P). Most of the G3P is reused in the cycle, but some exits the cycle and is converted to glucose and other organic molecules (pp. 193–195).

Activity *The Calvin Cycle*

Investigation *How Is the Rate of Photosynthesis Measured? Biology Lab On-Line LeafLab*

Concept 10.4

Alternative mechanisms of carbon fixation have evolved in hot, arid climates

- **Photorespiration: An Evolutionary Relic?** (pp. 195–196) On dry, hot days, plants close their stomata, conserving water. Oxygen from the light reactions builds up. In photorespiration, O_2 substitutes for CO_2 in the active site of rubisco. This process consumes organic fuel and releases CO_2 without producing ATP or sugar.

- **C₄ Plants** (p. 196) C₄ plants minimize the cost of photorespiration by incorporating CO_2 into four-carbon compounds in mesophyll cells. These compounds are exported to bundle-sheath cells, where they release carbon dioxide for use in the Calvin cycle.

- **CAM Plants** (pp. 196–197) CAM plants open their stomata at night, incorporating CO_2 into organic acids, which are stored in mesophyll cells. During the day the stomata close, and the CO_2 is released from the organic acids for use in the Calvin cycle.

Activity *Photosynthesis in Dry Climates*

The Importance of Photosynthesis: A Review

(pp. 197–198) Organic compounds produced by photosynthesis provide the energy and building material for ecosystems.

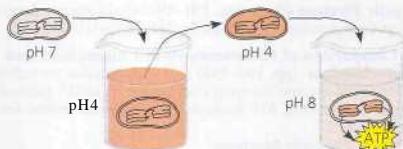

TESTING YOUR KNOWLEDGE

Evolution Connection

Photorespiration can substantially decrease soybeans¹ photosynthetic output by about 50%. Would you expect this figure to be higher or lower in wild relatives of soybeans? Why?

Scientific Inquiry

The diagram below represents an experiment with isolated chloroplasts. The chloroplasts were first made acidic by soaking them in a solution at pH 4. After the thylakoid space reached pH 4, the chloroplasts were transferred to a basic solution at pH 8. The chloroplasts then made ATP in the dark. Explain this result.

Science, Technology, and Society

CO₂ in the atmosphere traps heat and warms the air, just as clear glass does in a greenhouse. Scientific evidence indicates that the CO₂ added to the air by the burning of wood and fossil fuels is contributing to a rise in global temperature. Tropical rain forests are estimated to be responsible for more [ban 20% of global photosynthesis. It seems reasonable to expect that the rain forests would reduce global warming by consuming large amounts of CO₂, but many experts now think that rain forests make little or no net contribution to reduction of global warming. Why might this be? (Hint: What happens to the food produced by a rain forest tree when it's eaten by animals or the tree dies?)

Cell Communication

Key Concepts

- 11.1 **External** signals are converted into responses within the cell
- 11.2 **Reception:** A signal molecule binds to a receptor protein, causing it to change shape
- 11.3 **Transduction:** Cascades of molecular interactions relay signals from receptors to target molecules in the cell
- 11.4 **Response:** Cell signaling leads to regulation of cytoplasmic activities or transcription

Overview

The Cellular Internet

A hiker slips and falls down a steep ravine, injuring her leg in the fall. Tragedy is averted when she is able to pull out a cell phone and call for help. Cell phones, the Internet, e-mail, instant messaging—no one would deny the importance of communication in our lives. The role of communication in life at the cellular level is equally critical. Cell-to-cell communication is absolutely essential for multicellular organisms such as humans and oak trees. The trillions of cells in a multicellular organism must communicate with each other to coordinate their activities in a way that enables the organism to develop from a fertilized egg, then survive and reproduce in turn. Communication between cells is also important for many unicellular organisms. Networks of communication between cells can be even more complicated than the World Wide Web.

In studying how cells signal to each other and how they interpret the signals they receive, biologists have discovered some universal mechanisms of cellular regulation, additional evidence for the evolutionary relatedness of all life. The same small set of cell-signaling mechanisms shows up again and

A Figure 11.1 Viagra (multicolored) bound to an enzyme (purple) involved in a signaling pathway.

again in many lines of biological research—from embryonic development to hormone action to cancer. In one example, a common cell-Lo-cell signaling pathway leads to dilation of blood vessels. Once the signal subsides, the response is shut down by the enzyme shown in purple in **Figure 11.1**. Also shown is a multicolored molecule that blocks the action of this enzyme and keeps blood vessels dilated. Enzyme-inhibiting compounds like this one are often prescribed for treatment of medical conditions. The action of the multicolored compound, known as Viagra, will be discussed later in the chapter. The signals received by cells, whether originating from other cells or from changes in the physical environment, take various forms, including light and touch. However, cells most often communicate with each other by chemical signals. In this chapter, we focus on the main mechanisms by which cells receive, process, and respond to chemical signals sent from other cells.

Concept 11.1

External signals are converted into responses within the cell

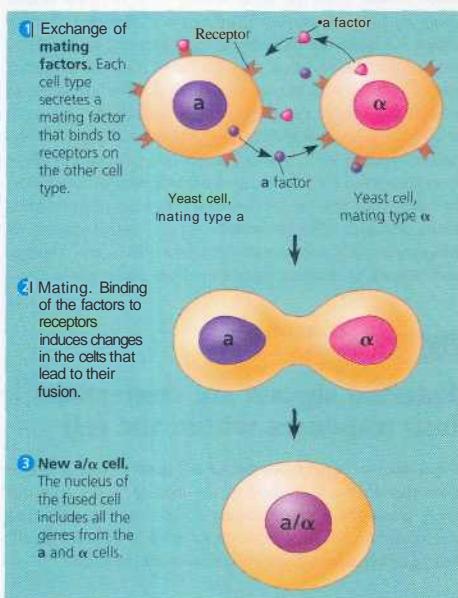

What does a "talking" cell say to a "listening" cell, and how does the latter cell respond to the message? Let's approach these questions by first looking at communication among microorganisms, for modern microbes are a window on the role of cell signaling in the evolution of life on Earth.

Evolution of Cell Signaling

One topic of cell "conversation" is sex—at least for the yeast *Saccharomyces cerevisiae*, which people have used for millennia to make bread, wine, and beer. Researchers have learned that

cells of this yeast identify their mates by chemical signaling. There are two sexes, or mating types, called *a* and *α* (Figure 11.2). Cells of mating type *a* secrete a chemical signal called a factor, which can bind to specific receptor proteins on nearby *α* cells. At the same time, *α* cells secrete a factor, which binds to receptors on *a* cells. Without actually entering the cells, the two mating factors cause the cells to grow toward each other and bring about other cellular changes. The result is the fusion, or mating, of two cells of opposite type. The new *a/α* cell contains all the genes of both original cells, a combination of genetic resources that provides advantages to the cell's descendants, which arise by subsequent cell divisions.

How is the mating signal at the yeast cell surface changed, or *transduced*, into a form that brings about the cellular response of mating? The process by which a signal on a cell's surface is converted into a specific cellular response is a series of steps called a signal transduction pathway. Many such pathways have been extensively studied in both yeast and animal cells. Amazingly, the molecular details of signal transduction in yeast and mammals are strikingly similar, even though

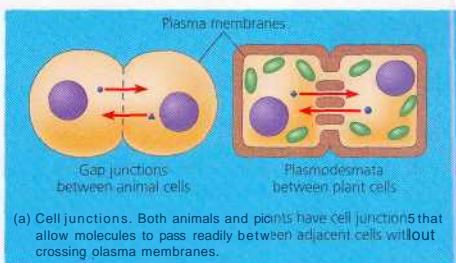

A Figure 11.2 Communication between mating yeast cells. *Saccharomyces cerevisiae* cells use chemical signaling to identify cells of opposite mating type and initiate the mating process. The two mating types and their corresponding chemical signals, or mating factors, are called *a* and *α*.

the last common ancestor of these two groups of organisms lived over a billion years ago. These similarities—and others more recently uncovered between signaling systems in bacteria and plants—suggest that early versions of the cell-signaling mechanisms used today evolved well before the first multicellular creatures appeared on Earth. Scientists think that signaling mechanisms evolved first in ancient prokaryotes and single-celled eukaryotes and were then adopted for new uses by their multicellular descendants.

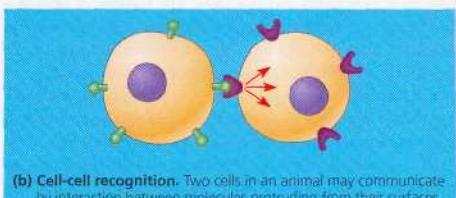

Local and Long-Distance Signaling

Like yeast cells, cells in a multicellular organism usually communicate via chemical messengers targeted for cells that may or may not be immediately adjacent. Cells may communicate by direct contact, as we saw in Chapters 6 and 7. Both animals and plants have cell junctions that, where present, directly connect the cytoplasms of adjacent cells (Figure 11.3a). In these cases, signaling substances dissolved in the cytosol can pass freely between adjacent cells. Moreover, animal cells may communicate via direct contact between membrane-bound cell surface molecules (Figure 11.3b). This sort of signaling, called cell-cell recognition, is important in such processes as embryonic development and the immune response.

In many other cases, messenger molecules are secreted by the signaling cell. Some of these travel only short distances; such local regulators influence cells in the vicinity. One class of local regulators in animals, *growth factors*, are compounds

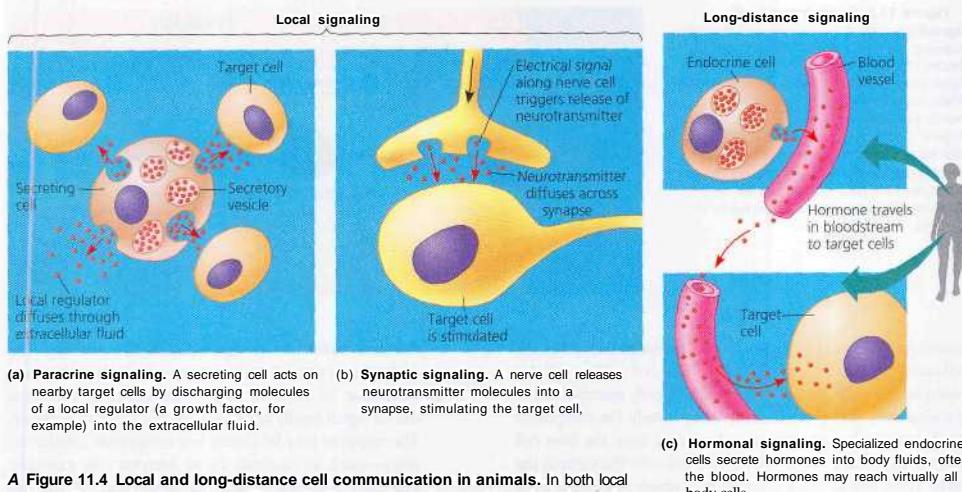

(a) Cell junctions. Both animals and plants have cell junctions that allow molecules to pass readily between adjacent cells without crossing plasma membranes.

(b) Cell-cell recognition. Two cells in an animal may communicate by interaction between molecules protruding from their surfaces.

A Figure 11.3 Communication by direct contact between cells.

A Figure 11.4 Local and long-distance cell communication in animals. In both local and long-distance signaling, only specific target cells recognize and respond to a given chemical signal.

that stimulate nearby target cells to grow and multiply. Numerous cells can simultaneously receive and respond to the molecules of growth factor produced by a single cell in their vicinity. This type of local signaling in animals is called *paracrine signaling* (Figure 11.4a).

Another, more specialized type of local signaling called *synaptic signaling* occurs in the animal nervous system. An electrical signal along a nerve cell triggers the secretion of a chemical signal in the form of neurotransmitter molecules. These diffuse across the synapse, the narrow space between the nerve cell and its target cell (often another nerve cell). The neurotransmitter stimulates the target cell (Figure 11.4b).

Local signaling in plants is not as well understood. Because of their cell walls, plants must use mechanisms somewhat different from those operating locally in animals.

Both animals and plants use chemicals called hormones for long-distance signaling. In hormonal signaling in animals, also known as *endocrine signaling*, specialized cells release hormone molecules into vessels of the circulatory system, by which they travel to target cells in other parts of the body (Figure 11.4c). Plant hormones (often called *growth regulators*) sometimes travel in vessels but more often reach their targets by moving through cells (see Chapter 39) or by diffusion through the air as a gas. Hormones vary widely in molecular size and type, as do local regulators. For instance, the plant hormone ethylene, a gas that promotes fruit ripening and helps regulate growth, is a hydrocarbon of only six atoms (C_2H_4) that can pass through cell walls. In contrast, the mam-

malian hormone insulin, which regulates sugar levels in the blood, is a protein with thousands of atoms.

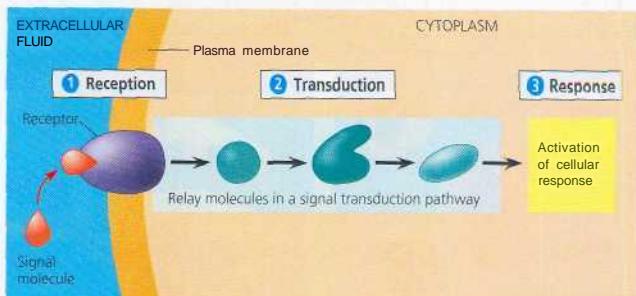

The transmission of a signal through the nervous system can also be considered an example of long-distance signaling. An electrical signal travels the length of a nerve cell and is then converted back to a chemical signal that crosses the synapse to another nerve cell. Here it is converted back into an electrical signal. In this way, a nerve signal can travel along a series of nerve cells. Since some nerve cells are quite long, the nerve signal can quickly travel great distances—from your brain to your big toe, for example. This type of long-distance signaling will be covered in detail in Chapter 48.

What happens when a cell encounters a signal? The signal must be recognized by a specific receptor molecule, and the information it carries must be changed into another form—transduced—inside the cell before the cell can respond. The remainder of the chapter discusses this process, primarily as it occurs in animal cells.

The Three Stages of Cell Signaling: A Preview

Our current understanding of how chemical messengers act via signal transduction pathways had its origins in the pioneering work of Earl W. Sutherland, whose research led to a Nobel Prize in 1971. Sutherland and his colleagues at Vanderbilt University were investigating how the animal hormone epinephrine stimulates the breakdown of the storage polysaccharide glycogen within liver cells and skeletal muscle cells. Glycogen

Figure 11.5 Overview of cell signaling. From the perspective of the cell receiving the message, cell signaling can be divided into three stages: signal reception, signal transduction, and cellular response. When reception occurs at the plasma membrane, as shown here, the transduction stage is usually a pathway of several steps, with each molecule in the pathway bringing about a change in the next molecule. The last molecule in the pathway triggers the cell's response. The three stages are explained in the text.

breakdown releases the sugar glucose-1-phosphate, which the cell converts to glucose-6-phosphate. The cell (a liver cell, for example) can then use this compound, an early intermediate in glycolysis, for energy production. Alternatively, the compound can be stripped of phosphate and released from the liver cell into the blood as glucose, which can fuel cells throughout the body. Thus, one effect of epinephrine, which is secreted from the adrenal gland during times of physical or mental stress, is the mobilization of fuel reserves.

Sutherland's research team discovered that epinephrine stimulates glycogen breakdown by somehow activating a cytosolic enzyme, glycogen phosphorylase. However, when epinephrine was added to a test-tube mixture containing the enzyme and its substrate, glycogen, no breakdown occurred. Epinephrine could activate glycogen phosphorylase only when the hormone was added to a solution containing *intact* cells. This result told Sutherland two things. First, epinephrine does not interact directly with the enzyme responsible for glycogen breakdown; an intermediate step or series of steps must be occurring inside the cell. Second, the plasma membrane is somehow involved in transmitting the epinephrine signal.

Sutherland's early work suggested that the process going on at the receiving end of a cellular conversation can be dissected into three stages: reception, transduction, and response (Figure 11.5):

O Reception. Reception is the target cell's detection of a signal molecule coming from outside the cell. A chemical signal is "detected" when it binds to a receptor protein located at the cell's surface or inside the cell.

© Transduction. The binding of the signal molecule changes the receptor protein in some way, initiating the process of transduction. The transduction stage converts the signal to a form that can bring about a specific cellular response. In Sutherland's system, the binding of epinephrine to a receptor protein in a liver cell's plasma membrane leads to activation of glycogen phosphorylase. Transduction sometimes occurs in a single step but more often requires a sequence of changes in a series of

different molecules—a *signal transduction pathway*. The molecules in the pathway are often called relay molecules.

③ Response. In the third stage of cell signaling, the transduced signal finally triggers a specific cellular response. The response may be almost any imaginable cellular activity—such as catalysis by an enzyme (for example, glycogen phosphorylase), rearrangement of the cytoskeleton, or activation of specific genes in the **nucleus**. The cell-signaling process helps ensure that crucial activities like these occur in the right cells, at the right time, and in proper coordination with the other cells of the organism. We'll now explore the mechanisms of cell signaling in more detail.

Concept Check 11.1

- Explain how nerve cells provide examples of both local and long-distance signaling.
- When epinephrine is mixed with glycogen phosphorylase and glycogen in a test tube, is glucose-1-phosphate generated? Why or why not?

For suggested answers, see Appendix A.

Concept 11.2

Reception: A signal molecule binds to a receptor protein, causing it to change shape

When we speak to someone, others nearby may hear our message, sometimes with unfortunate consequences. However, errors of this kind rarely occur among cells. The signals emitted by a yeast cell are "heard" only by its prospective mates, a cells. Similarly, although epinephrine encounters many types of cells as it circulates in the blood, only certain target

cells detect and react to the hormone. A receptor protein on or in the target cell allows the cell to "hear" the signal and respond to it. The signal molecule is complementary in shape to a specific site on the receptor and attaches there, like a key in a lock or a substrate in the catalytic site of an enzyme. The signal molecule behaves as a **ligand**, the term for a molecule that specifically binds to another molecule, often a larger one. Ligand binding generally causes a receptor protein to undergo a change in conformation—that is, to change shape. For many receptors, this shape change directly activates the receptor, enabling it to interact with other cellular molecules. For other kinds of receptors, the immediate effect of ligand binding is to cause the aggregation of two or more receptor molecules, which leads to further molecular events inside the cell.

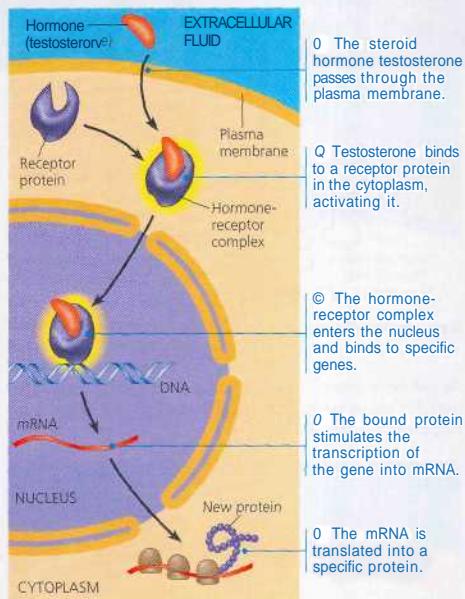

Most signal receptors are plasma membrane proteins. Their ligands are water-soluble and generally too large to pass freely through the plasma membrane. Other signal receptors, however, are located inside the cell. We discuss these next, before returning to membrane receptors.

Intracellular Receptors

Intracellular receptor proteins are found in either the cytoplasm or nucleus of target cells. To reach such a receptor, a chemical messenger passes through the target cell's plasma membrane. A number of important signaling molecules can do this because they are either hydrophobic enough or small enough to cross the phospholipid interior of the membrane. Such hydrophobic chemical messengers include the steroid hormones and thyroid hormones of animals. Another chemical signal with an intracellular receptor is nitric oxide (NO), a gas; its very small molecules readily pass between the membrane phospholipids.

The behavior of testosterone is representative of steroid hormones. Secreted by cells of the testis, the hormone travels through the blood and enters cells all over the body. In the cytoplasm of target cells, the only cells that contain receptor molecules for testosterone, the hormone binds to the receptor protein, activating it (Figure 11.6). With the hormone attached, the active form of the receptor protein then enters the nucleus and turns on specific genes that control male sex characteristics.

How does the activated hormone-receptor complex turn on genes? Recall that the genes in a cell's DNA function by being transcribed and processed into messenger RNA (mRNA), which leaves the nucleus and is translated into a specific protein by ribosomes in the cytoplasm (see Figure 5.25). Special proteins called *transcription factors* control which genes are turned on—that is, which genes are transcribed into mRNA—in a particular cell at a particular time. The testosterone receptor, when activated, acts as a transcription factor that turns on specific genes.

A Figure 11.6 Steroid hormone interacting with an intracellular receptor.

By acting as a transcription factor, the testosterone receptor itself carries out the complete transduction of the signal. Most other intracellular receptors function in the same way, although many of them are already in the nucleus before the signal molecule reaches them, (an example is the thyroid hormone receptor). Interestingly, many of these intracellular receptor proteins are structurally similar, suggesting an evolutionary kinship. We will look more closely at hormones with intracellular receptors in Chapter 45.

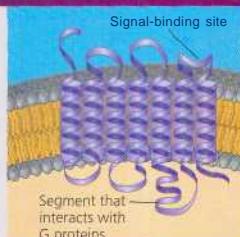

Receptors in the Plasma Membrane

Most water-soluble signal molecules bind to specific sites on receptor proteins embedded in the cell's plasma membrane. Such a receptor transmits information from the extracellular environment to the inside of the cell by changing shape or aggregating when a specific ligand binds to it. We can see how membrane receptors work by looking at three major types: G-protein-linked receptors, receptor tyrosine kinases, and ion channel receptors. These receptors are discussed and illustrated in Figure 11.7 on the next three pages; please study this figure before going on.

Figure 11.7

Exploring Membrane Receptors

G-PROTEIN-LINKED RECEPTORS

**G-protein-linked receptor**

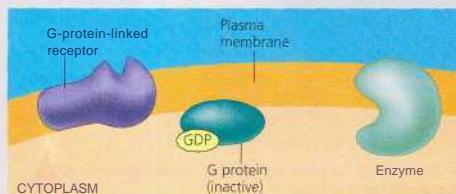

the cell. Nevertheless, G-protein-linked receptor proteins are all remarkably similar in structure. They each have seven α helices spanning the membrane, as shown above.

A G-protein-linked receptor is a plasma membrane receptor that works with the help of a protein called a G protein. Many different signal molecules use G-protein-linked receptors, including yeast mating factors, epinephrine and many other hormones, and neurotransmitters. These receptors vary in their binding sites for recognizing signal molecules and for recognizing different G proteins inside the cell.

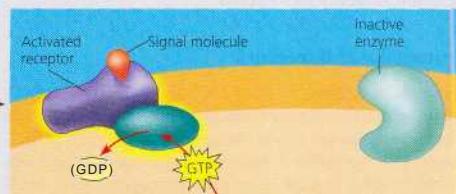

A large family of eukaryotic receptor proteins has this secondary structure, where the single polypeptide, represented here as a ribbon, has seven transmembrane α helices, represented as cylinders and depicted in a row for clarity. Specific loops between the helices form binding sites for signal and G-protein molecules.

G-protein-linked receptor systems are extremely widespread and diverse in their functions, including roles in embryonic development and sensory reception. In humans, for example, both vision and smell depend on such proteins. Similarities in structure among G proteins and G-protein-linked receptors of modern organisms suggest that G proteins and associated receptors evolved very early.

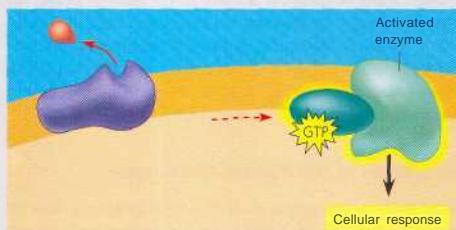

G-protein systems are involved in many human diseases, including bacterial infections. The bacteria that cause cholera, pertussis (whooping cough), and botulism, among others, make their victims ill by producing toxins that interfere with G-protein function. Pharmacologists now realize that up to 60% of all medicines used today exert their effects by influencing G-protein pathways.

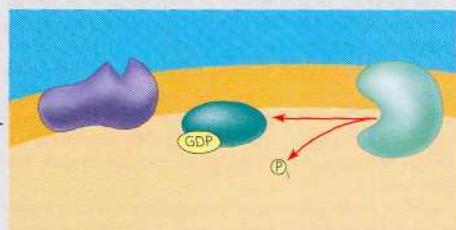

- Loosely attached to the cytoplasmic side of the membrane, the G protein functions as a molecular switch that is either on or off, depending on which of two guanine nucleotides is attached, GDP or GTP—hence the term G protein. (GTP, or guanosine triphosphate, is similar to ATP.) When GDP is bound to the G protein, as shown above, the G protein is inactive. The receptor and G protein work together with another protein, usually an enzyme.

- When the appropriate signal molecule binds to the extracellular side of the receptor, the receptor is activated and changes shape. Its cytoplasmic side then binds an inactive G protein, causing a GTP to displace the GDP. This activates the G protein.

- The activated G protein dissociates from the receptor and diffuses along the membrane, then binds to an enzyme and alters its activity. When the enzyme is activated, it can trigger the next step in a pathway leading to a cellular response.

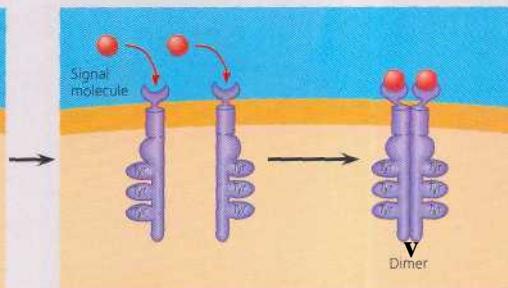

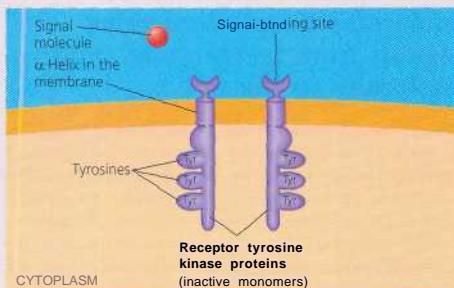

- The changes in the enzyme and G protein are only temporary, because the G protein also functions as a GTPase enzyme and soon hydrolyzes its bound GTP to GDP. Now inactive again, the G protein leaves the enzyme, which returns to its original state. The G protein is now available for reuse. The GTPase function of the G protein allows the pathway to shut down rapidly when the signal molecule is no longer present.

Continued on next page.

RECEPTOR TYROSINE KINASES

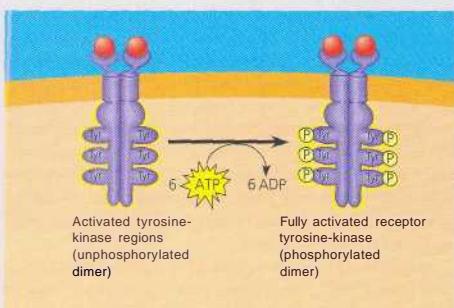

A receptor tyrosine kinase can trigger more than one signal transduction pathway at once, helping the cell regulate and coordinate many aspects of cell growth and cell reproduction. This receptor is one of 3 major class of plasma membrane receptors characterized by having enzymatic activity. A *kinase* is an enzyme that catalyzes the transfer of phosphate groups. The part of the receptor protein extending into the cytoplasm functions as an enzyme, called tyrosine kinase, that catalyzes the transfer of a phosphate group from ATP to the amino acid tyrosine on a substrate protein. Thus, receptor tyrosine kinases are membrane receptors that attach phosphates to tyrosines.

One receptor tyrosine kinase complex may activate ten or more different transduction pathways and cellular responses. The ability of a single ligand-binding event to trigger so many pathways is a key difference between receptor tyrosine kinases and G-protein-Like receptors. Abnormal receptor tyrosine kinases that dimerize even in the absence of signal molecules may contribute to some kinds of cancer.

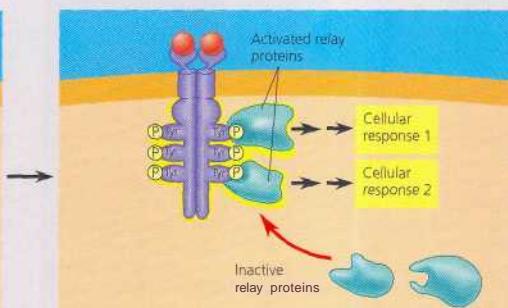

- 1** Many receptor tyrosine kinases have the structure depicted schematically here. Before the signal molecule binds, the receptors exist as individual polypeptides. Notice that each has an extracellular signal-binding site, an α helix spanning the membrane, and an intracellular tail containing multiple tyrosines.

- 2** The binding of a signal molecule (such as a growth factor) causes two receptor polypeptides to associate closely with each other, forming a dimer (dimerization).

- 3** Dimerization activates the tyrosine-kinase region of each polypeptide; each tyrosine kinase adds a phosphate from an ATP molecule to a tyrosine on the tail of the other polypeptide.

- 4** Now that the receptor protein is fully activated, it is recognized by specific relay proteins inside the cell. Each such protein binds to a specific phosphorylated tyrosine, undergoing a resulting structural change that activates the bound protein. Each activated protein triggers a transduction pathway, leading to a cellular response.

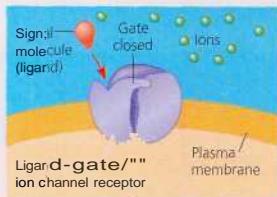

Figure 11.7 (continued)

Exploring Membrane Receptors

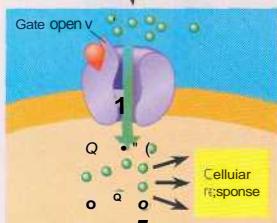

ION CHANNEL RECEPTORS

A **ligand-gated ion channel** is a type of membrane receptor, a region of which can act as a "gate" when the receptor changes shape. When a signal molecule binds as a ligand to the receptor protein, the gate opens or closes, allowing or blocking the flow of specific ions, such as Na^+ or Ca^{2+} , through a channel in the receptor. Like the other receptors we have discussed, these proteins bind the ligand at a specific site on their extracellular side.

- 1 Here we show a ligand-gated ion channel receptor that remains closed until a ligand binds to it.

- 2 When the ligand binds to the receptor and the gate opens, specific ions can flow through the channel and rapidly change the concentration of that particular ion inside the cell. This change may directly affect the activity of the cell in some way.

- 3 When the ligand dissociates from this receptor, the gate closes and ions no longer enter the cell.

Ligand-gated ion channels are very important in the nervous system. For example, the neurotransmitter molecules released at a synapse between two nerve cells (see Figure 11.4b) bind as ligands to ion channels on the receiving cell, causing the channels to open. Ions flow in and trigger an electrical signal that propagates down the length of the receiving cell. Some gated ion channels are controlled by electrical signals instead of ligands; these voltage-gated ion channels are also crucial to the functioning of the nervous system, as we will discuss in Chapter 48.

Concept Check 11.2

1. Nerve growth factor (NGF) is a water-soluble signal molecule. Would you expect the receptor for NGF to be intracellular or in the plasma membrane?

For suggested answers, see Appendix A.

Concept 11.3

Transduction: Cascades of molecular interactions relay signals from receptors to target molecules in the cell

When signal receptors are plasma membrane proteins, like most of those we have discussed, the transduction stage of cell signaling is usually a multistep pathway. One benefit of such pathways is the possibility of greatly amplifying a signal, if some of the molecules in a pathway transmit the signal to multiple molecules of the next component in the series, the result can be a large number of activated molecules at the end of the pathway. In other words, a small number of extracellular signal molecules can produce a large cellular response. Moreover, multistep pathways provide more opportunities for coordination and regulation than simpler systems do, as we'll discuss later.

Signal Transduction Pathways

The binding of a specific signal molecule to a receptor in the plasma membrane triggers the first step in the chain of molecular interactions—the signal transduction pathway—that leads to a particular response within the cell. Like falling dominoes, the signal-activated receptor activates another protein, which activates another molecule, and so on, until the protein that produces the final cellular response is activated. The molecules that relay a signal from receptor to response, which we call relay molecules in this book, are mostly proteins. The interaction of proteins is a major theme of cell signaling. Indeed, protein interaction is a unifying theme of all regulation at the cellular level.

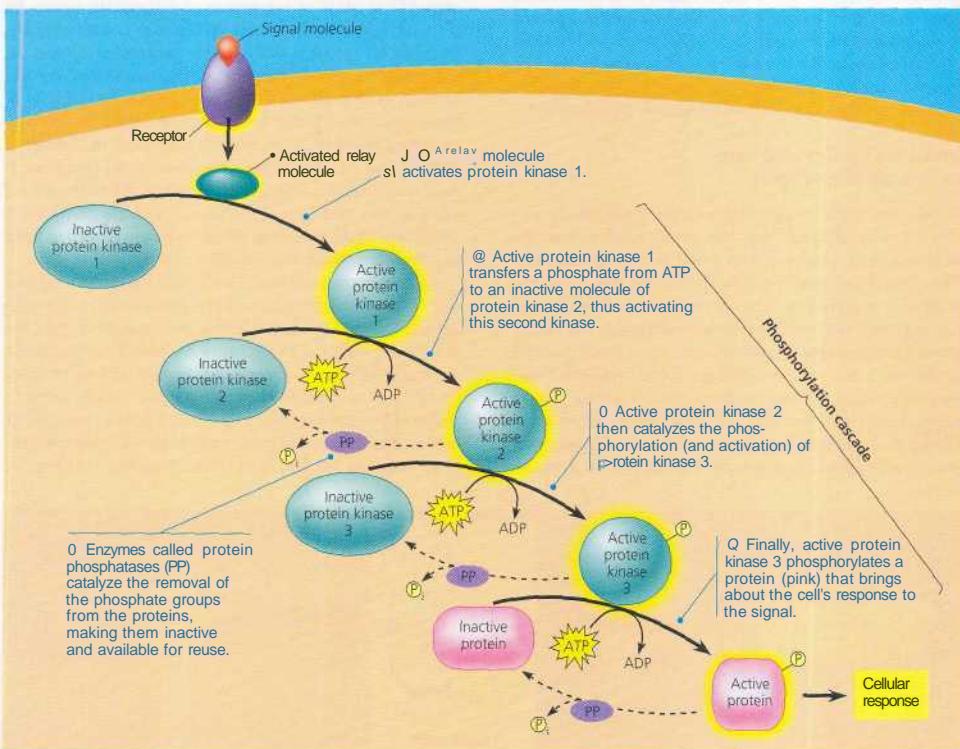

Keep in mind that the original signal molecule is not physically passed along a signaling pathway; in most cases, it never even enters the cell. When we say that the signal is relayed along a pathway, we mean that certain information is passed on. At each step, the signal is transduced into a different form, commonly a conformational change in a protein. Very often, the conformational change is brought about by phosphorylation.

Protein Phosphorylation and Dephosphorylation

Previous chapters introduced the concept of activating a protein by adding one or more phosphate groups to it (see Figure 8.11). In Figure 11.7, we have already seen how phosphorylation is involved in the activation of receptor tyrosine kinases; in fact, the phosphorylation and dephosphorylation of proteins is a widespread cellular mechanism for regulating protein activity. The general name for an enzyme that transfers phosphate groups from ATP to a protein is **protein kinase**. Recall that receptor tyrosine kinases phosphorylate other receptor tyrosine kinase monomers. Most cytoplasmic protein kinases, however, act on proteins different from themselves. Another distinction is that most cytoplasmic protein kinases phosphorylate either the amino acid serine or threonine,

rather than tyrosine. Such serine/threonine kinases are widely involved in signaling pathways in animals, plants, and fungi.

Many of the relay molecules in signal transduction pathways are protein kinases, and they often act on other protein kinases in the pathway. Figure 11.8 depicts a hypothetical pathway containing three different protein kinases, which create a "phosphorylation cascade." The sequence shown is similar to many known pathways, including those triggered in yeast by mating factors and in animal cells by many growth factors. The signal is transmitted by a cascade of protein phosphorylations, each bringing with it a conformational change. Each shape change results from the interaction of the newly added phosphate groups with charged or polar amino acids (see Figure 5.17). The addition of phosphate groups often changes a protein from an inactive form to an active form (although in other cases phosphorylation *decreases* the activity of the protein).

A. Figure 11.8 A phosphorylation cascade. In a phosphorylation cascade, a series of different molecules in a pathway are phosphorylated in turn, each molecule adding a phosphate group to the next one in line. The active and inactive forms of each protein are represented by different shapes to remind you that activation is usually associated with a change in molecular conformation.

The importance of protein kinases can hardly be overstated. About 2% of our own genes are thought to code for protein kinases. A single cell may have hundreds of different kinds, each specific for a different substrate protein. Together, they probably regulate a large proportion of the thousands of proteins in a cell. Among these are most of the proteins that, in turn, regulate cell reproduction. Abnormal activity of such a kinase can cause abnormal cell growth and contribute to the development of cancer.

Equally important in the phosphorylation cascade are the protein phosphatases, enzymes that can rapidly remove phosphate groups from proteins, a process called dephosphorylation. By dephosphorylating and thus inactivating protein kinases, phosphatases provide the mechanism for turning off the signal transduction pathway when the initial signal is no longer present. Phosphatases also make the protein kinases available for reuse, enabling the cell to respond again to an extracellular signal. At any given moment, the activity of a protein regulated by phosphorylation depends on the balance in the cell between active kinase molecules and active phosphatase molecules. The phosphorylation/dephosphorylation system acts as a molecular switch in the cell, turning activities on or off as required.

Small Molecules and Ions as Second Messengers

Not all components of signal transduction pathways are proteins. Many signaling pathways also involve small, nonprotein, water-soluble molecules or ions called second messengers. (The extracellular signal molecule that binds to the membrane receptor is a pathway's "first messenger.") Because second messengers are both small and water-soluble, they can readily spread throughout the cell by diffusion. For example, as we'll see shortly, it is a second messenger called cyclic AMP that carries the signal initiated by epinephrine from the plasma membrane of a liver or muscle cell into the cell's interior, where it brings about glycogen breakdown. Second messengers participate in pathways initiated by both G-protein-linked receptors

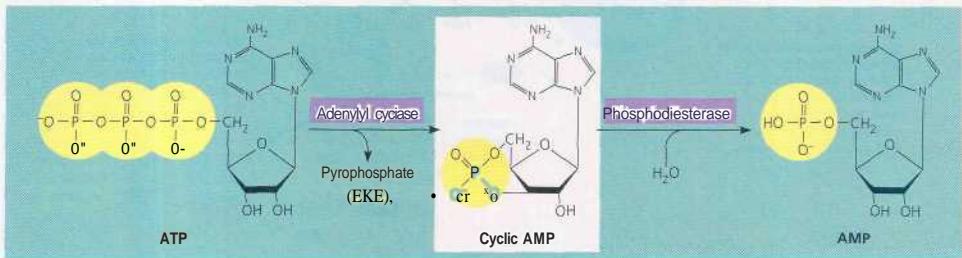

and receptor tyrosine kinases. The two most widely used second messengers are cyclic AMP and calcium ions, Ca^{2+} . A large variety of relay proteins are sensitive to the cytosolic concentration of one or the other of these second messengers.

Cyclic AMP

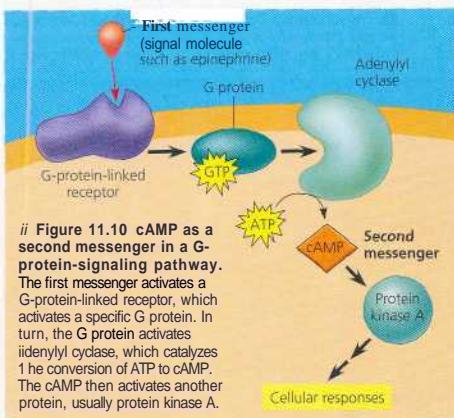

Once Earl Sutherland had established that epinephrine somehow causes glycogen breakdown without passing through the plasma membrane, the search began for the second messenger (he coined the term) that transmits the signal from the plasma membrane to the metabolic machinery in the cytoplasm.

Sutherland found that the binding of epinephrine to the plasma membrane of a liver cell elevates the cytosolic concentration of a compound called cyclic adenosine mono phosphate, abbreviated cyclic AMP or cAMP (Figure 11.9). An enzyme embedded in the plasma membrane, adenylyl cyclase, converts ATP to cAMP in response to an extracellular signal—in this case, epinephrine. But the epinephrine doesn't stimulate the adenylyl cyclase directly. When epinephrine outside the cell binds to a specific receptor protein, the protein activates adenylyl cyclase, which in turn can catalyze the synthesis of many molecules of cAMP. In this way, the normal cellular concentration of cAMP can be boosted twentyfold in a matter of seconds. The cAMP broadcasts the signal to the cytoplasm. It does not persist for long in the absence of the hormone, because another enzyme, called phosphodiesterase, converts the cAMP to AMP. Another surge of epinephrine is needed to boost the cytosolic concentration of cAMP again.

Subsequent research has revealed that epinephrine is only one of many hormones and other signal molecules that trigger the formation of cAMP. It has also brought to light that other components of cAMP pathways, including G proteins, G-protein-linked receptors, and protein kinases (Figure 11.10). The immediate effect of cAMP is usually the activation of a serine/threonine kinase called *protein kinase A*. The activated kinase then phosphorylates various other proteins, depending on the cell type. (The complete pathway for

A Figure 11.9 Cyclic AMP. The second messenger cyclic AMP (cAMP) is made from ATP by adenylyl cyclase, an enzyme embedded in the plasma membrane. Cyclic AMP is inactivated by phosphodiesterase, an enzyme that converts it to AMP.

epinephrine's stimulation of glycogen breakdown is shown later, in Figure 11.13.)

Further regulation of cell metabolism is provided by other G-protein systems that inhibit adenylyl cyclase. In these systems, a different signal molecule activates a different receptor, which activates an inhibitory G protein.

Now that we know about the role of cAMP in G-protein-signaling pathways, we can explain in molecular detail how certain microbes cause disease. Consider cholera, a disease that is frequently epidemic in places where the water supply is contaminated with human feces. People acquire the cholera bacterium, *Vibrio cholerae*, by drinking contaminated water. The bacteria colonize the lining of the small intestine and produce a toxin. The cholera toxin is an enzyme that chemically modifies a G protein involved in regulating salt and water secretion. Because the modified G protein is unable to hydrolyze GTP to GDP, it remains stuck in its active form, continuously stimulating adenylyl cyclase to make cAMP. The resulting high concentration of cAMP causes the intestinal cells to secrete large amounts of water and salts into the intestines. An infected person quickly develops profuse diarrhea and if left untreated can soon die from the loss of water and salts.

Our understanding of signaling pathways involving cyclic AMP or related messengers has allowed us to develop treatments for certain conditions in humans. One such pathway uses *cyclic GMP*, or cGMP, as a signaling molecule; its effects include relaxation of smooth muscle cells in artery walls. A compound that inhibits the hydrolysis of cGMP to GMP, thus prolonging the signal, was originally prescribed for chest pains because it increased blood flow to the heart muscle. Under the trade name Viagra (see Figure 11.1), this compound is now widely used as a treatment for erectile dysfunction. Viagra causes dilation of blood vessels, which allows increased

blood flow to the penis, optimizing physiological conditions for penile erections.

Calcium Ions and Inositol Trisphosphate (IP₃)

Many signal molecules in animals, including neurotransmitters, growth factors, and some hormones, induce responses in their target cells via signal transduction pathways that increase the cytosolic concentration of calcium ions (Ca^{2+}). Calcium is even more widely used than cAMP as a second messenger. Increasing the cytosolic concentration of Ca^{2+} causes many responses in animal cells, including muscle cell contraction, secretion of certain substances, and cell division. In plant cells, a wide range of hormonal and environmental stimuli can cause brief increases in cytosolic Ca^{2+} concentration, triggering various signaling pathways, such as the pathway for greening in response to light (see Figure 39.4). Cells use Ca^{2+} as a second messenger in both G-protein and receptor tyrosine kinase pathways.

Although cells always contain some Ca^{2+} , this ion can function as a second messenger because its concentration in the cytosol is normally much lower than the concentration outside the cell (Figure 11.11). In fact, the level of Ca^{2+} in

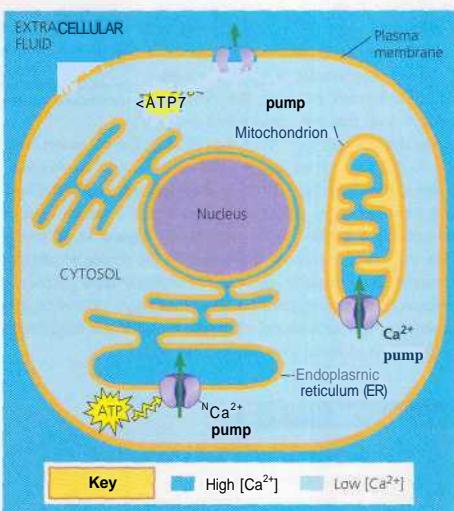

Figure 11.11 The maintenance of calcium ion concentrations in an animal cell. The Ca^{2+} concentration in the cytosol is usually much lower (light blue) than in the extracellular fluid and ER (darker blue). Protein pumps in the plasma membrane and the ER membrane, driven by ATP, move Ca^{2+} from the cytosol into the extracellular fluid and into the lumen of the ER. Mitochondrial pumps, driven by chemiosmosis (see Chapter 9), move Ca^{2+} into mitochondria when the calcium level in the cytosol rises significantly.

- Figure 11.12 Calcium and IP₃ in signaling pathways.** Calcium ions (Ca^{2+}) and inositol trisphosphate (IP₃) function as second messengers in many signal transduction pathways. In this figure, the process is initiated by the binding of a signal molecule to a G-protein-linked receptor. A receptor tyrosine kinase could also initiate this pathway by activating phospholipase C.

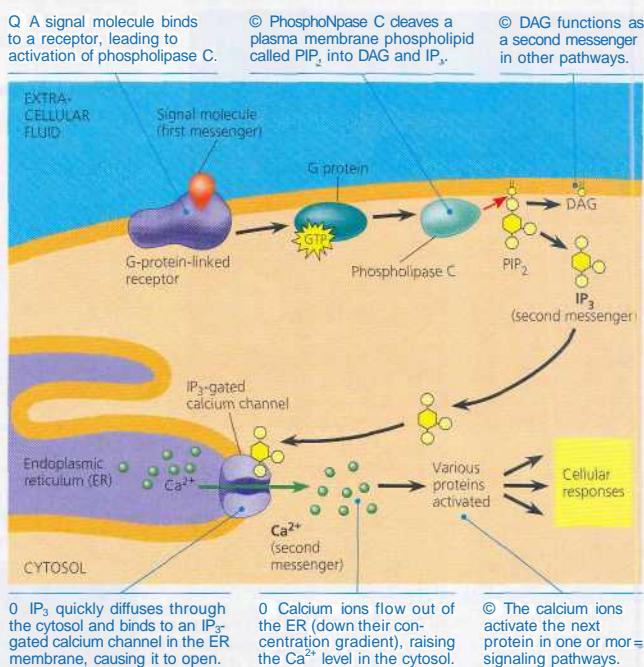

the blood and extracellular fluid of an animal often exceeds that in the cytosol by more than 10,000 times. Calcium ions are actively transported out of the cell and are actively imported from the extracellular fluid into the endoplasmic reticulum (and, under some conditions, into mitochondria and chloroplasts) by various protein pumps (see Figure 11.11). As a result, the calcium concentration in the ER is usually much higher than that in the cytosol. Because the cytosolic calcium level is low, a small change in absolute numbers of ions represents a relatively large percentage change in calcium concentration.

In response to a signal relayed by a signal transduction pathway, the cytosolic calcium level may rise, usually by a mechanism that releases Ca^{2+} from the cell's ER. The pathways leading to calcium release involve still other second messengers, inositol trisphosphate (IP₃) and diacylglycerol (DAG). These two messengers are produced by cleavage of a certain kind of phospholipid in the plasma membrane. Figure 11.12 shows how this occurs and how IP₃ stimulates the release of calcium from the ER. Because IP₃ acts before calcium in these pathways, calcium could be considered a "third messenger." However, scientists use the term *second messenger* for all small, nonprotein components of signal transduction pathways.

Concept Check 11.3

- What is a protein kinase, and what is its role in a signal transduction pathway?
- When a signal transduction pathway involves a phosphorylation cascade, how does the cell's response get turned off?
- Upon activation of phospholipase C by Gq/G11 binding to a receptor, what effect does the IP₃-gated calcium channel have on Ca^{2+} concentration in the cytosol?

For suggested answers, see Appendix A.

- A signal molecule binds to a receptor, leading to activation of phospholipase C.
- Phospholipase C cleaves a plasma membrane phospholipid called PIP₂ into DAG and IP₃.

- DAG functions as a second messenger in other pathways.

- IP₃ quickly diffuses through the cytosol and binds to an IP₃-gated calcium channel in the ER membrane, causing it to open.
- Calcium ions flow out of the ER (down their concentration gradient), raising the Ca^{2+} level in the cytosol.
- The calcium ions activate the next protein in one or more signaling pathways.

Concept 11.4

Response: Cell signaling leads to regulation of cytoplasmic activities or transcription

We now take a closer look at the cell's subsequent response to an extracellular signal—what some researchers call the "output response." What is the nature of the final step in a signaling pathway?

Cytoplasmic and Nuclear Responses

Ultimately, a signal transduction pathway leads to the regulation of one or more cellular activities. The response may occur in the cytoplasm or may involve action in the nucleus.

In the cytoplasm, a signal may cause, for example, the opening or closing of an ion channel in the plasma membrane or a change in cell metabolism. As we have discussed already, the response of liver cells to signaling by the hormone epinephrine helps regulate cellular energy metabolism. The final step in the signaling pathway activates the enzyme that catalyzes the

breakdown of glycogen. **Figure 11.13** shows the complete pathway leading to the release of glucose-1-phosphate from glycogen. Note that at each step the response is amplified, as we will discuss later.

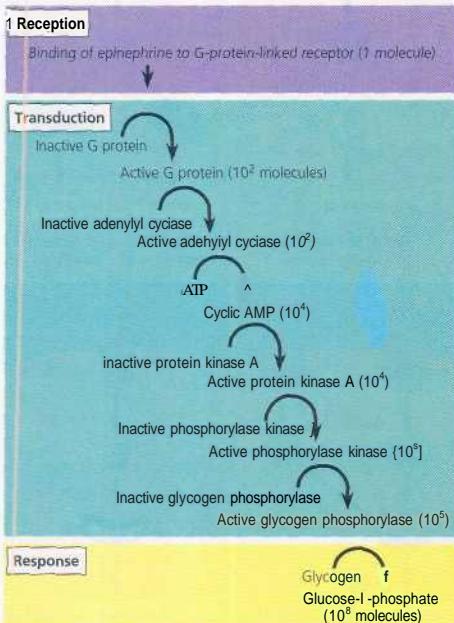

Many other signaling pathways ultimately regulate not the *activity* of enzymes but the *synthesis* of enzymes or other proteins, usually by turning specific genes on or off in the nucleus. Like an activated steroid receptor (see Figure 11.6), the final activated molecule in a signaling pathway may function as a transcription factor. **Figure 11.14** shows an example in which a signaling pathway activates a transcription factor that turns a gene on: The response to the growth factor signal is the synthesis of mRNA, which will be translated in the cytoplasm into a specific protein. In other cases, the transcription factor

might regulate a gene by turning it off. Often a transcription factor regulates several different genes.

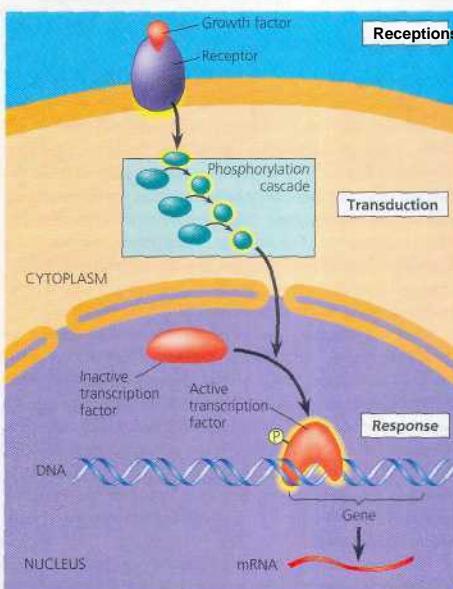

All the different kinds of signal receptors and relay molecules introduced in this chapter participate in various gene-regulating pathways, as well as in pathways leading to other kinds of responses. The molecular messengers that produce gene regulation responses include growth factors and certain plant and animal hormones. Malfunctioning of growth factor pathways like the one in Figure 11.14 can contribute to the development of cancer, as we will see in Chapter 19.

Fine-Tuning of the Response

Why are there often so many steps between a signaling event at the cell surface and the cell's response? As mentioned earlier, signaling pathways with a multiplicity of steps have

A Figure 11.13 Cytoplasmic response to a signal: the stimulation of glycogen breakdown by epinephrine. In this signaling system, the hormone epinephrine acts through a G-protein-linked receptor to activate a succession of relay molecules, including cAMP and two protein kinases (see also Figure 11.10). The final protein to be activated is the enzyme glycogen phosphorylase, which releases glucose-1-phosphate units from glycogen. This pathway amplifies the hormonal signal, because one receptor protein can activate about 100 molecules of G protein, and each enzyme in the pathway can act on many molecules of its substrate, the next molecule in the cascade. The number of activated molecules given for each step is approximate.

B Figure 11.14 Nuclear responses to a signal: the activation of a specific gene by a growth factor. This diagram is a simplified representation of a typical signaling pathway that leads to the regulation of gene activity in the cell nucleus. The initial signal molecule, a local regulator called a growth factor, triggers a phosphorylation cascade. (The ATP molecules that serve as sources of phosphate are not shown.) Once phosphorylated, the last kinase in the sequence enters the nucleus and there activates a gene-regulating protein, a transcription factor. This protein stimulates a specific gene so that an mRNA is synthesized, which then directs the synthesis of a particular protein in the cytoplasm.

two important benefits: They amplify the signal (and thus the response), and they contribute to the specificity of response.

Signal Amplification

Elaborate enzyme cascades amplify the cell's response to a signal. At each catalytic step in the cascade, the number of activated products is much greater than in the preceding step. For example, in the epinephrine-triggered pathway in Figure 11.13, each adenylyl cyclase molecule catalyzes the formation of many cAMP molecules, each molecule of protein kinase A phosphorylates many molecules of the next kinase in the pathway and so on. The amplification effect stems from the fact that these proteins persist in the active form long enough to process numerous molecules of substrate before they become inactive again. As a result of the signal's amplification, a small number of epinephrine molecules binding to receptors on the surface of a liver cell or muscle cell can lead to the release of hundreds of millions of glucose molecules from glycogen.

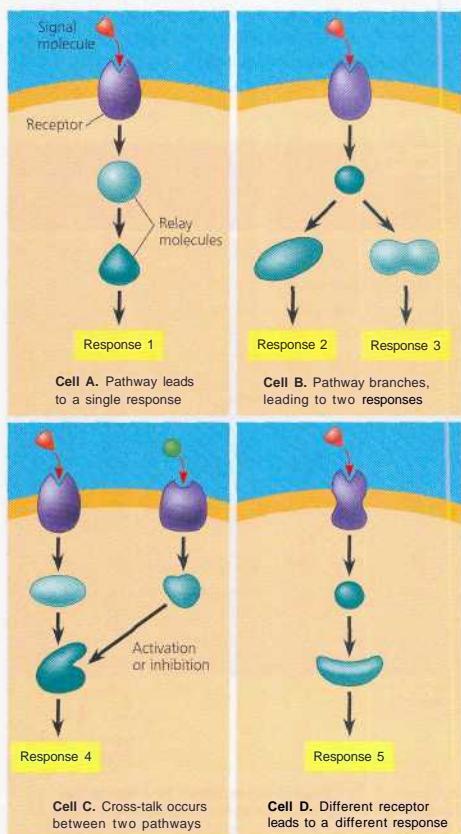

The Specificity of Cell Signaling

Consider two different cells in your body—a liver cell and a heart muscle cell, for example. Both are in contact with your bloodstream and are therefore constantly exposed to many different hormone molecules, as well as to local regulators secreted by nearby cells. Yet the liver cell responds to some signals but ignores others, and the same is true for the heart cell. And some kinds of signals trigger responses in both cells—but different responses. For instance, epinephrine stimulates the liver cell to break down glycogen, but the main response of the heart cell to epinephrine is contraction, leading to a more rapid heartbeat. How do we account for this difference?

The explanation for the specificity exhibited in cellular responses to signals is the same as the basic explanation for virtually all differences between cells: *Different kinds of cells have different collections of proteins* (Figure 11.15). The response of a particular cell to a signal depends on its particular collection of signal receptor proteins, relay proteins, and proteins needed to carry out the response. A liver cell, for example, is poised to respond appropriately to epinephrine by having the proteins listed in Figure 11.13 as well as those needed to manufacture glycogen.

Thus, two cells that respond differently to the same signal differ in one or more of the proteins that handle and respond to the signal. Notice in Figure 11.15 that different pathways may have some molecules in common. For example, cells A, B, and C all use the same receptor protein for the orange signal molecule; differences in other proteins account for their differing responses. In cell D, a different receptor protein is used for the same signal molecule, leading to yet another response. In cell B, a pathway that is triggered by a single kind of signal diverges to produce two responses; such branched pathways often involve receptor tyrosine kinases (which can

activate multiple relay proteins) or second messengers (which can regulate numerous proteins). In cell C, two pathways triggered by separate signals converge to modulate a single response. Branching of pathways and "cross-talk" (interaction) between pathways are important in regulating and coordinating a cell's responses to information coming in from different sources in the body. Moreover, the use of some of the same proteins in more than one pathway allows the cell to economize on the number of different proteins it must make.

A Figure 11.15 The specificity of cell signaling. The particular proteins a cell possesses determine what signal molecules it responds to and the nature of the response. The four cells in these diagrams respond to the same signal molecule (orange) in different ways because each has a different set of proteins (purple and teal shapes). Note, however, that the same kinds of molecules can participate in more than one pathway.

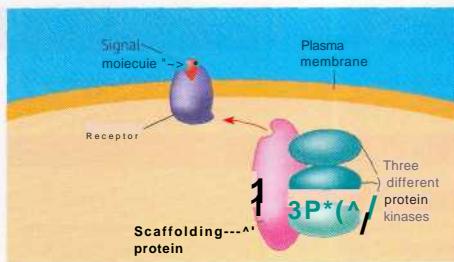

Signaling Efficiency: Scaffolding Proteins and Signaling Complexes

The signaling pathways in Figure 11.15 (as well as some of the other pathway depictions in this chapter) are greatly simplified. The diagrams show only a few relay molecules and, for clarity's sake, display these molecules spread out in the cytosol. If this were true in the cell, signaling pathways would operate very inefficiently because most relay molecules are proteins, and proteins are too large to diffuse quickly through the viscous cytosol. How does a particular protein kinase, for instance, find its substrate?

Recent research suggests that the efficiency of signal transduction may in many cases be increased by the presence of **scaffolding proteins**, large relay proteins to which several other relay proteins are simultaneously attached. For example, one scaffolding protein isolated from mouse brain cells holds three protein kinases and carries these kinases with it when it binds to an appropriately activated membrane receptor; it thus facilitates a specific phosphorylation cascade (Figure 11.16). In fact, researchers are finding scaffolding proteins in brain cells that *permanently* hold together networks of signaling-pathway proteins at synapses. This hardwiring enhances the speed and accuracy of signal transfer between cells.

When signaling pathways were first discovered, they were thought to be linear, independent pathways. Our understanding of the processes of cellular communication has benefited from the realization that things are not that simple. In fact, as seen in Figure 11.15, some proteins may participate in more than one pathway, either in different cell types or in the same cell at different times or under different conditions. This view underscores the importance of permanent or transient protein complexes in the functioning of a cell.

The importance of the relay proteins that serve as points of branching or intersection in signaling pathways is **highlighted** by the problems arising when these proteins are defective or missing. For instance, in an inherited disorder called Wiskott-Aldrich syndrome (WAS), the absence of a single relay protein leads to such diverse effects as abnormal bleeding, eczema, and a predisposition to infections and leukemia. These symptoms are thought to arise primarily from the absence of the protein in cells of the immune system. By studying normal cells, scientists found that the WAS protein is located just beneath the cell surface. The protein interacts both with micro filaments of the cytoskeleton and with several different components of signaling pathways that relay information from the cell surface, including pathways regulating immune cell proliferation. This multifunctional relay protein is thus both a branch point and an important intersection point in a complex signal transduction network that controls immune cell behavior. When the WAS protein is absent, the cytoskeleton is not properly organized and signaling pathways are disrupted, leading to the WAS symptoms.

A Figure 11.16 A scaffolding protein. The scaffolding protein shown here (pink) simultaneously binds to a specific activated membrane receptor and three different protein kinases. This physical arrangement facilitates signal transduction by these molecules.

Termination of the Signal

To keep Figure 11.15 simple, we have not indicated the *inactivation* mechanisms that are an essential aspect of cell signaling. For a cell of a multicellular organism to remain alert and capable of responding to incoming signals, each molecular change in its signaling pathways must last only a short time. As we saw in the cholera example, if a signaling pathway component becomes locked into one state, whether active or inactive, dire consequences for the organism can result.

Thus, a key to a cell's continuing receptiveness to regulation is the reversibility of the changes that signals produce. The binding of signal molecules to receptors is reversible, with the result that the lower the concentration of signal molecules, the fewer will be bound at any given moment. When signal molecules leave the receptor, the receptor reverts to its inactive form. Then, by a variety of means, the relay molecules return to their inactive forms: The GTPase activity intrinsic to a G protein hydrolyzes its bound GTP; the enzyme phosphodiesterase converts cAMP to AMP; protein phosphatases inactivate phosphorylated kinases and other proteins; and so forth. As a result, the cell is soon ready to respond to a fresh signal.

This chapter has introduced you to many of the general mechanisms of cell communication, such as ligand binding, conformational changes, cascades of interactions, and protein phosphorylation. As you continue through the text, you will encounter numerous examples of cell signaling.

Concept Check 11.4

- How can a target cell's response to a hormone be amplified more than a millionfold?
- Explain how two cells with different scaffolding proteins could behave differently in response to the same signaling molecule.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 11.1

External signals are converted into responses within the cell

- **Evolution of Cell Signaling** (pp. 201–202) Signaling in microbes has much in common with processes in multicellular organisms, suggesting an early origin.
- **Local and Long-Distance Signaling** (pp. 202–203) In local signaling, animal cells may communicate by direct contact or by secreting local regulators*, such as growth factors or neurotransmitters. For signaling over long distances, both animals and plants use hormones; animals also signal along nerve cells.

Investigation How Do Cells Communicate, with Each Other?

- **The Three Stages of Cell Signaling: A Preview** (pp. 203–204) Earl Sutherland discovered how the hormone epinephrine acts on cells. The signal molecule epinephrine binds to receptors on a cell's surface (reception), leading to a series of changes in the receptor and other molecules inside the cell (transduction) and finally to the activation of an enzyme that breaks down glycogen * response).

Activity Overview of Cell Signaling

Concept 11.2

Reception: A signal molecule binds to a receptor protein, causing it to change shape

- The binding between signal molecule (ligand) and receptor is highly specific. A conformational change in a receptor is often the initial transduction of the signal (pp. 204–205).
- **Intracellular Receptors** (p. 205) Intracellular receptors are cytoplasmic or nuclear proteins. Signal molecules that are small or hydrophobic and can readily cross the plasma membrane use these receptors.
- **Receptors in the Plasma Membrane** (pp. 205–208) A G-protein-linked receptor is a membrane receptor that works with the help of a cytoplasmic G protein. Ligand binding activates the receptor, which then activates a specific G protein, which activates yet another protein, thus propagating the signal along a signal transduction pathway.

Receptor tyrosine kinases react to the binding of signal molecules by forming dimers and then adding phosphate groups to tyrosines on the cytoplasmic side of the other subunit of the receptor. Relay proteins in the cell can then be activated by binding to different phosphorylated tyrosines, allowing this receptor to trigger several pathways at once.

Specific signal molecules cause ligand-gated ion channels in a membrane to open or close, regulating the flow of specific ions.

Activity Reception

Concept 11.3

Transduction: Cascades of molecular interactions relay signals from receptors to target molecules in the cell

- **Signal Transduction Pathways** (p. 208) At each step in a pathway, the signal is transduced into a different form, commonly a conformational change in a protein.

- **Protein Phosphorylation and Dephosphorylation** (pp. 209–210) Many signal transduction pathways include phosphorylation cascades, in which a series of protein kinases each add a phosphate group to the next one in line, activating it. Phosphatase enzymes soon remove the phosphates.

- **Small Molecules and Ions as Second Messengers** (pp. 210–212) Second messengers, such as cyclic AMP (cAMP) and Ca^{2+} , diffuse readily through the cytosol and thus help broadcast signals quickly. Many G proteins activate adenylyl cyclase, which makes cAMP from ATP. Cells use Ca^{2+} as a second messenger in both G-protein and tyrosine kinase pathways. The tyrosine kinase pathways can also involve two other second messengers, DAG and IP_3 . IP_3 can trigger a subsequent increase in Ca^{2+} levels.

Activity Signal Transduction Pathways

Concept 11.4

Response: Cell signaling leads to regulation of cytoplasmic activities or transcription

- **Cytoplasmic and Nuclear Responses** (pp. 212–213) In the cytoplasm, signaling pathways regulate, for example, enzyme activity and cytoskeleton rearrangement. Other pathways regulate genes by activating transcription factors, proteins that turn specific genes on or off.

Activity Cellular Responses

Activity Build a Signaling Pathway

- **Fine-Tuning of the Response** (pp. 213–215) Each catalytic protein in a signaling pathway amplifies the signal by activating multiple copies of the next component of the pathway; for long pathways, the total amplification may be a millionfold or more. The particular combination of proteins in a cell gives the cell great specificity in both the signals it detects and the responses it carries out. Scaffolding proteins can increase signal transduction efficiency. Pathway branching and cross-talk further help the cell coordinate incoming signals. Signal response is terminated quickly by the reversal of ligand binding.

TESTING YOUR KNOWLEDGE

Evolution Connection

You learned in this chapter that cell-to-cell signaling is thought to have arisen early in the history of life, because the same mechanisms of signaling are found in distantly related organisms. But why hasn't some "better" mechanism arisen? Is it too difficult to evolve wholly new signaling mechanisms, or are existing mechanisms simply adequate and therefore maintained? Put another way, do superior signaling mechanisms need to evolve if existing mechanisms are adequate and effective? Why or why not?

Scientific Inquiry

Epiinephrine initiates a signal transduction pathway that involves production of cyclic AMP (cAMP) and leads to the breakdown of glycogen to glucose, a major energy source for cells. But glycogen breakdown is actually only part of a "fight-or-flight response" that epinephrine brings about; the overall effect on the body includes increased heart rate and alertness, as well as a burst of energy. Given that caffeine blocks the activity of cAMP phosphodiesterase, propose a mechanism by which caffeine ingestion leads to heightened alertness and sleeplessness.

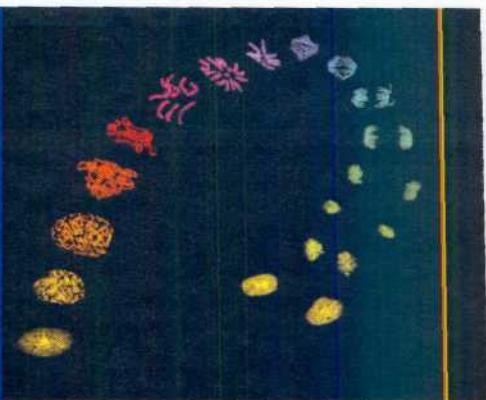

investigation How Do Cells Communicate with Each Other?

Science, Technology, and Society

The aging process is thought to be initiated at the cellular level. Among the changes that can occur after a certain number of cell divisions is the loss of a cell's ability to respond to growth factors and other chemical signals. Much research into aging is aimed at understanding such losses, with the ultimate goal of significantly extending the human life span. Not everyone, however, agrees that this is a desirable goal. If life expectancy were greatly increased, what might be the social and ecological consequences? How might we cope with them?

The Cell Cycle

A Figure 12.1 Chromosomes in a dividing cell.

Key Concepts

- 12.1 Cell division results in genetically identical daughter cells
- 12.2 The mitotic phase alternates with interphase in the cell cycle
- 12.3 The cell cycle is regulated by a molecular control system

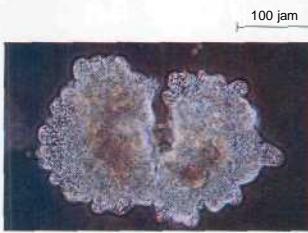

Overview

The Key Roles of Cell Division

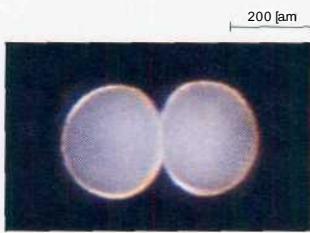

The ability of organisms to reproduce their own kind is the one characteristic that best distinguishes living things from nonliving matter. This unique capacity to procreate, like all biological functions, has a cellular basis. Rudolf Virchow, a German physician, put it this way in 1855: "Where a cell exists, there must have been a preexisting cell, just as the animal arises only from an animal and the plant

only from a plant." He summarized this concept with the Latin axiom "*Omnis cellula e cellula*," meaning "Every cell from a cell." The continuity of life is based on the reproduction of cells, or cell division. The series of fluorescence micrographs in Figure 12.1 follows an animal cell's chromosomes, from lower left to lower right, as one cell divides into two.

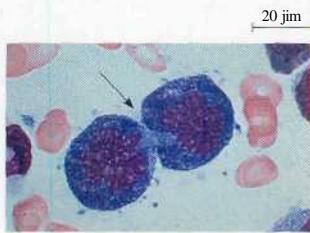

Cell division plays several important roles in the life of an organism. When a unicellular organism, such as an amoeba, divides and forms duplicate offspring, the division of one cell reproduces an entire organism (Figure 12.2a). Cell division on a larger scale can produce progeny from some multicellular organisms (such as plants that grow from cuttings). Cell division also enables sexually reproducing organisms to develop from a single cell—the fertilized egg, or zygote (Figure 12.2b). And after an organism is fully grown, cell division continues to function in renewal and repair, replacing cells that die from normal wear and tear or accidents. For example, dividing cells in your bone marrow continuously make new blood cells (Figure 12.2c).

(a) **Reproduction.** An amoeba, a single-celled eukaryote, is dividing into two cells. Each new cell will be an individual organism (LM).

(b) **Growth and development.** This micrograph shows a sand dollar embryo shortly after the fertilized egg divided, forming two cells (LM).

(c) **Tissue renewal.** These dividing bone marrow cells (arrow) will give rise to new blood cells (LM).

A Figure 12.2 The functions of cell division.

The cell division process is an integral part of the **cell cycle**, the life of a cell from the time it is first formed from a dividing parent cell until its own division into two cells. Passing identical genetic material to cellular offspring is a crucial function of cell division. In this chapter, you will learn how cell division distributes identical genetic material, to daughter cells.* After studying the cellular mechanics of cell division, you will learn about the molecular control system that regulates progress through the cell cycle and what happens when the control system malfunctions. Because cell cycle regulation, or a lack thereof, plays a major role in cancer development, this aspect of cell biology is an active area of research.

Concept 12.1

Cell division results in genetically identical daughter cells

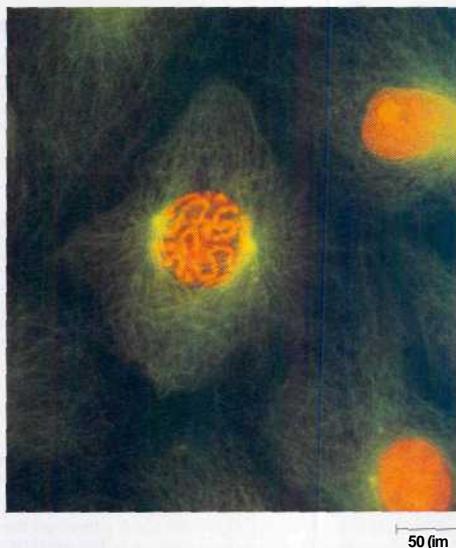

The reproduction of an ensemble as complex as a cell cannot occur by a mere pinching in half; a cell is not like a soap bubble that simply enlarges and splits in two. Cell division involves the distribution of identical genetic material—DNA—to two **daughter** cells. What is most remarkable about cell division is the fidelity with which the DNA is passed along from one generation of cells to the next. A dividing cell duplicates its DNA, allocates the two copies to opposite ends of the cell, and only then splits into daughter cells.

Cellular Organization of the Genetic Material

A cell's endowment of DNA, its genetic information, is called its **genome**. Although a prokaryotic genome is often a single long DNA molecule, eukaryotic genomes usually consist of a number of DNA molecules. The overall length of DNA in a eukaryotic cell is enormous. A typical human cell, for example, has about 2 m of DNA—a length about 250,000 times greater than the cell's diameter. Yet before the cell can divide, all of this DNA must be copied and then the two copies separated so that each daughter cell ends up with a complete genome.

The replication and distribution of so much DNA is manageable because the DNA molecules are packaged into **chromosomes**, so named because they take up certain dyes used in microscopy (from the Greek *chroma*, color, and *soma*, body) (Figure 12.3). Every eukaryotic species has a characteristic number of chromosomes in each cell nucleus. For example, the nuclei of human **somatic cells** (all body cells except the reproductive cells) each contain 46 chromosomes made up of two sets of 23, one set inherited from each parent.

* Although the terms *daughter cells* and *sister chromatids* (a term you will encounter later in the chapter) are traditional and will be used throughout this book, the structures they refer to have no gender.

A Figure 12.3 Eukaryotic chromosomes. Chromosomes (stained orange) are visible within the nucleus of the kangaroo rat epithelial cell in the center of this micrograph. The cell is preparing to divide (LM).

Reproductive cells, or **gametes**—sperm cells and egg cells—have half as many chromosomes as somatic cells, or one set of 23 chromosomes in humans.

Eukaryotic chromosomes are made of **chromatin**, a complex of DNA and associated protein molecules. Each single chromosome contains one very long, linear DNA molecule that carries several hundred to a few thousand genes. The associated proteins maintain the structure of the chromosome and help control the activity of the genes.

Distribution of Chromosomes During Cell Division

When a cell is not dividing, and even as it duplicates its DNA in preparation for cell division, each chromosome is in the form of a long, thin chromatin fiber. After DNA duplication, however, the chromosomes condense: Each chromatin fiber becomes densely coiled and folded, making the chromosomes much shorter and so thick that we can see them with a light microscope.

Each duplicated chromosome has two **sister chromatids**. The two chromatids, each containing an identical DNA molecule, are initially attached by adhesive proteins all along their lengths. In its condensed form, the duplicated chromosome

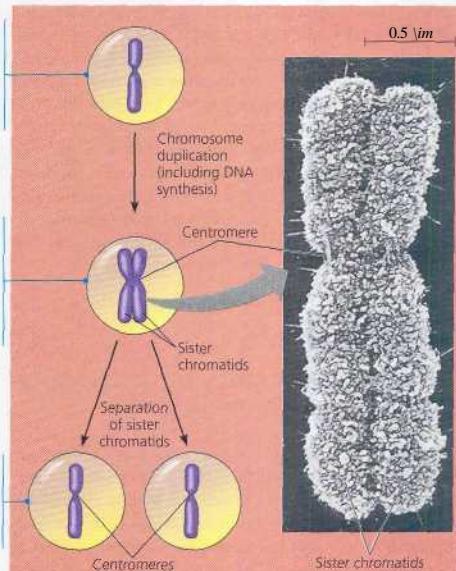

Figure 12.4 Chromosome duplication and distribution during cell division. A eukaryotic cell preparing to divide duplicates each of its chromosomes. The micrograph shows a duplicated human chromosome (SEM). The copies of each chromosome are then distributed to two daughter cells during cell division.

(Chromosomes normally exist in the highly condensed state shown here only during the process of cell division; the chromosomes in the top and bottom cells are shown in condensed form for illustration purposes only.)

A eukaryotic cell has multiple chromosomes, one of which is represented here. Before duplication, each chromosome has a single DNA molecule.

Once duplicated, a chromosome consists of two sister chromatids connected at the centromere. Each chromatid contains a copy of the DNA molecule.

Mechanical processes separate the sister chromatids into two chromosomes and distribute them to two daughter cells.

has a narrow "waist" at a specialized region called the centromere where the two chromatids are most closely attached (**Figure 12.4**). Later in the cell division process, the two sister chromatids of each duplicated chromosome separate and move into two new nuclei, one at each end of the cell. Once the sister chromatids separate, they are considered individual chromosomes. Thus, each new nucleus receives a group of chromosomes identical to the original group in the parent cell. **Mitosis**, the division of the nucleus, is usually followed immediately by cytokinesis, the division of the cytoplasm. Where there was one cell, there are now two, each the genetic equivalent of the parent cell.

What happens to chromosome number as we follow the human life cycle through the generations? You inherited 46 chromosomes, one set of 23 from each parent. They were combined in the nucleus of a single cell when a sperm cell from your father united with an egg cell from your mother, forming a fertilized egg, or zygote. Mitosis and cytokinesis produced the 200 trillion somatic cells that now make up your body and the same processes continue to generate new cells to replace dead and damaged ones. In contrast, you produce gametes—eggs or sperm cells—by a variation of cell division called **meiosis**, which yields nonidentical daughter cells that have only one set of chromosomes, thus half as many chromosomes as the parent cell. Meiosis occurs only in your gonads (ovaries or testes). In each generation of

humans, meiosis reduces the chromosome number from 46 (two sets of chromosomes) to 23 (one set). Fertilization fuses two gametes together and returns the chromosome number to 46, and mitosis conserves that number in every somatic cell nucleus of the new individual. In Chapter 13, we will examine the role of meiosis in reproduction and inheritance in more detail. In the remainder of this chapter, we focus on mitosis and the rest of the cell cycle.

Concept Check 12.1

- Starting with a fertilized egg (zygote), a series of five cell divisions would produce an early embryo with how many cells?
- How many chromatids are in a duplicated chromosome?
- A chicken has 78 chromosomes in its somatic cells; how many chromosomes did the chicken inherit from each parent? How many chromosomes are in each of the chicken's gametes? How many chromosomes will be in each somatic cell of the chicken's offspring? How many chromosomes are in a "set"?

For suggested answers, see Appendix A.

Concept 12.2

The mitotic phase alternates with interphase in the cell cycle

In 1882, a German anatomist named Walther Flemming developed dyes that allowed him to observe, for the first time, the behavior of chromosomes during mitosis and cytokinesis. (In fact, Flemming coined the terms *mitosis* and *chromatin*.) During the period between one cell division and the next, it appeared to Flemming that the cell was simply growing larger. But we now know that many critical events occur during this stage in the life of a cell.

Phases of the Cell Cycle

Mitosis is just one part of the cell cycle (Figure 12.5). In fact, the mitotic (M) phase, which includes both mitosis and cytokinesis, is usually the shortest part of the cell cycle. Mitotic cell division alternates with a much longer stage called interphase, which often accounts for about 90% of the cycle. During interphase the cell grows and copies its chromosomes in preparation for cell division. Interphase can be divided into subphases: the G₁ phase ("first gap"), the S phase ("synthesis"), and the G₂ phase ("second gap"). During all three subphases, the cell grows by producing proteins and cytoplasmic organelles such as mitochondria and endoplasmic reticulum. However, chromosomes are duplicated only during the S phase (we discuss synthesis of DNA in Chapter 16). Thus, a cell grows (G₁), continues to grow as it copies its chromosomes (S), grows more as it completes preparations for cell division (G₂), and divides (M). The daughter cells may then repeat the cycle.

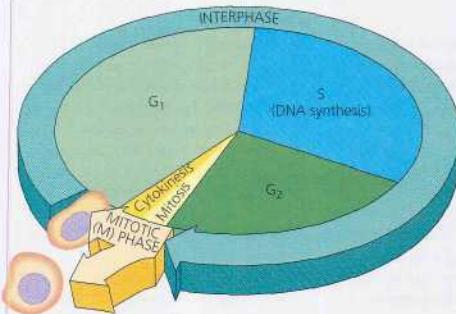

Figure 12.5 The cell cycle. In a dividing cell, the mitotic (M) phase alternates with interphase, a growth period. The first part of interphase, called G₁, is followed by the S phase, when the chromosomes replicate; the last part of interphase is called G₂. In the M phase, mitosis divides the nucleus and distributes its chromosomes to the daughter nuclei, and cytokinesis divides the cytoplasm, producing two daughter cells.

A typical human cell might undergo one division in 24 hours. Of this time, the M phase would occupy less than 1 hour, while the S phase might occupy about 10–12 hours, or about half the cycle. The rest of the time would be apportioned between the G₁ and G₂ phases. The G₂ phase usually takes 4–6 hours; in our example, G₁ would occupy about 5–6 hours. G₁ is the most variable in length in different types of cells.

Time-lapse films of living, dividing cells reveal the dynamics of mitosis as a continuum of changes. For purposes of description, however, mitosis is conventionally broken down into five stages: prophase, prometaphase, metaphase, anaphase, and telophase. Overlapping with the latter stages of mitosis, cytokinesis completes the mitotic phase. **Figure 12.6**, on the next two pages, describes these stages in an animal cell. Be sure to study this figure thoroughly before progressing to the next two sections, which examine mitosis and cytokinesis more closely.

The Mitotic Spindle: A Closer Look

Many of the events of mitosis depend on the mitotic spindle, which begins to form in the cytoplasm during prophase. This structure consists of fibers made of microtubules and associated proteins. While the mitotic spindle assembles, the other microtubules of the cytoskeleton partially disassemble, probably providing the material used to construct the spindle. The spindle microtubules elongate by incorporating more subunits of the protein tubulin (see Table 6.1).

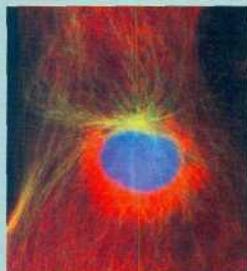

The assembly of spindle microtubules starts at the centrosome, a nonmembranous organelle that functions throughout the cell cycle to organize the cell's microtubules (it is also called the *microtubule-organizing center*). In animal cells, a pair of centrioles is located at the center of the centrosome, but the centrioles are not essential for cell division; in fact, the centrosomes of most plants lack centrioles, and if the centrioles of an animal cell are destroyed with a laser microbeam, a spindle nevertheless forms during mitosis.

During interphase, the single centrosome replicates, forming two centrosomes, which remain together near the nucleus (see Figure 12.6). The two centrosomes move apart from each other during prophase and prometaphase of mitosis, as spindle microtubules grow out from them. By the end of prometaphase, the two centrosomes, one at each pole of the spindle, are at opposite ends of the cell. An aster, a radial array of short microtubules, extends from each centrosome. The spindle includes the centrosomes, the spindle microtubules, and the asters.

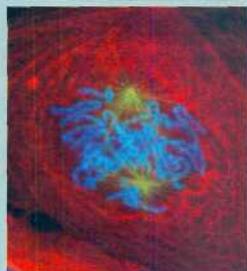

Each of the two sister chromatids of a chromosome has a kinetochore, a structure of proteins associated with specific sections of chromosomal DNA at the centromere. The chromosome's two kinetochores face in opposite directions. During prometaphase, some of the spindle microtubules attach to the kinetochores; these are called kinetochore microtubules. (The number of microtubules attached to a kinetochore varies

Figure 12.6

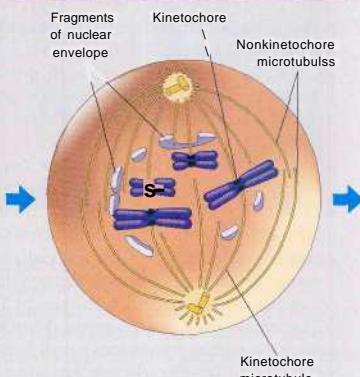

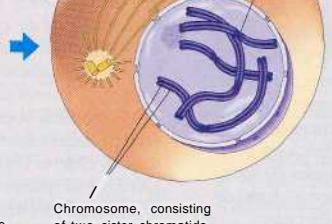

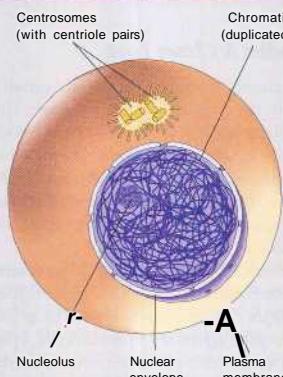

Exploring The Mitotic Division of an Animal Cell

G₂ OF INTERPHASE

PROPHASE

PROMETAPHASE

**G₂ of interphase**

- A nuclear envelope bounds the nucleus.
- The nucleus contains one or more nucleoli (singular, *nucleolus*).
- Two centrosomes have formed by replication of a single centrosome.
- In animal cells, each centrosome features two centrioles,
- Chromosomes, duplicated during S phase, cannot be seen individually because they have not yet condensed.

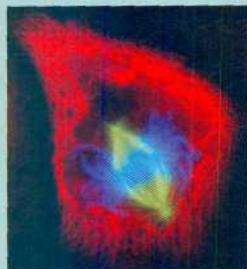

The light micrographs show dividing lung cells from a newt, which has 22 chromosomes in its somatic cells (chromosomes appear blue, microtubules green, intermediate filaments red). For simplicity, the drawings show only four chromosomes.

Prophase

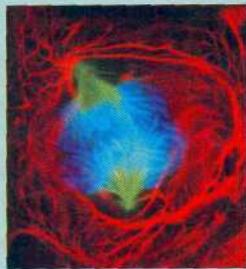

- The chromatin fibers become more tightly coiled, condensing into discrete chromosomes observable with a light microscope.
- The nucleoli disappear.
- Each duplicated chromosome appears as two identical sister chromatids joined together.
- The mitotic spindle begins to form. It is composed of the centrosomes and the microtubules that extend from them. The radial arrays of shorter microtubules that extend from the centrosomes are called asters ("stars").
- The centrosomes move away from each other, apparently propelled by the lengthening microtubules between them.

Prometaphase

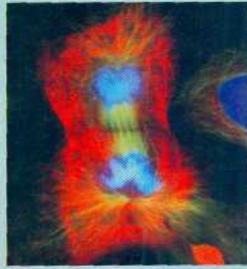

- The nuclear envelope fragments.
- The microtubules of the spindle can now invade the nuclear area and interact with the chromosomes, which then become even more condensed.
- Microtubules extend from each centrosome toward the middle of the cell.
- Each of the two chromatids of a chromosome now has a kinetochore, a specialized protein structure located at the centromere.
- Some of the microtubules attach to the kinetochores, becoming "kinetochore microtubules." These kinetochore microtubules jerk the chromosomes back and forth.
- Nonkinetochore microtubules interact with those from the opposite pole of the spindle.

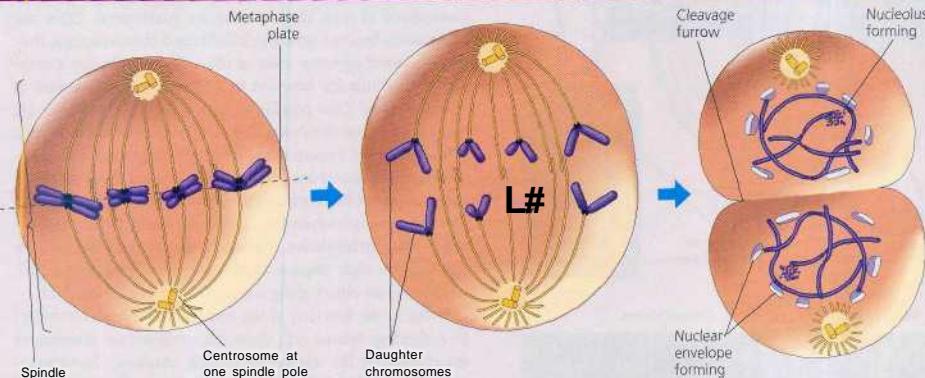

METAPHASE

ANAPHASE

TELOPHASE AND CYTOKINESIS

Metaphase

- Metaphase is the longest stage of mitosis, lasting about 20 minutes.
- The centrosomes are now at opposite ends of the cell.
- The chromosomes convene on the metaphase plate, an imaginary plane that is equidistant between the spindle's two poles. The chromosomes' centromeres lie on the metaphase plate.
- For each chromosome, the kinetochores of the sister chromatids are attached to kinetochore microtubules coming from opposite poles.
- The entire apparatus of microtubules is called the spindle because of its shape.

Anaphase

- Anaphase is the shortest stage of mitosis, lasting only a few minutes.
- Anaphase begins when the two sister chromatids of each pair suddenly part. Each chromatic! thus becomes a full-fledged chromosome.
- The two liberated chromosomes begin moving toward opposite ends of the cell, as their kinetochore microtubules shorten. Because these microtubules are attached at the centromere region, t.e. chromosomes move centromere first (at about 1 $\mu\text{m}/\text{min}$).
- !* T'v ceii elongates as the nonkinetochore microtubules lengthen.
- By the end of anaphase, the two ends of the cell have equivalent—and compete—collection; of chromosomes.

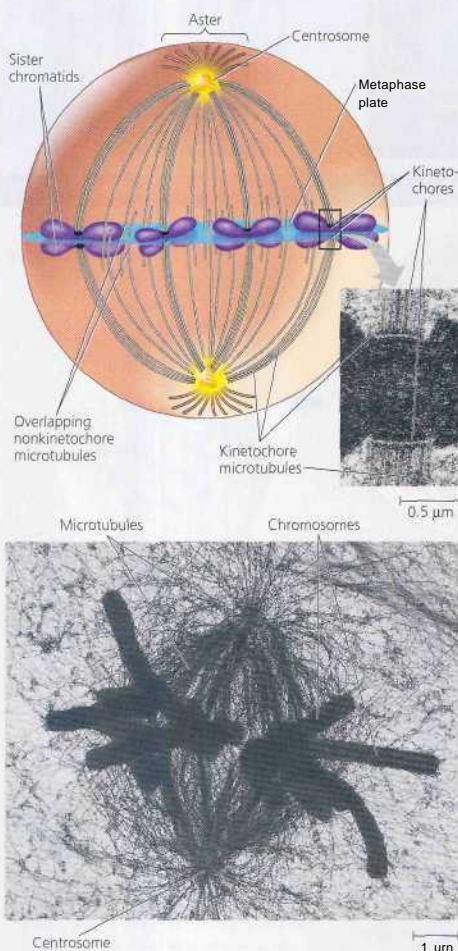

Telophase

- Two daughter nuclei begin to form in the cell.
- Nuclear envelopes arise from the fragments of the parent cell's nuclear envelope and other portions of the endomembrane system.
- The chromosomes become less condensed.
- Mitosis, the division of one nucleus into two genetically identical nuclei, is now complete.

Cytokinesis

- The division of the cytoplasm is usually well underway by late telophase, so the two daughter cells appear shortly after the end of mitosis.
- In animal cells, cytokinesis involves the formation of a cleavage furrow, which pinches the cell in two.

among species, from one microtubule in yeast cells to 40 or so in some mammalian cells.) When one of a chromosome's kinetochores is "captured" by microtubules, the chromosome begins to move toward the pole from which those microtubules extend. However, this movement is checked as soon as microtubules from the opposite pole attach to the other kinetochore.

A. Figure 12.7 The mitotic spindle at metaphase. The kinetochores of a chromosome's two sister chromatids face in opposite directions. Here, each kinetochore is actually attached to a *cluster* of kinetochore microtubules extending from the nearest centrosome. Nonkinetochore microtubules overlap at the metaphase plate (TEMs).

What happens next is like a tug-of-war that ends in a draw. The chromosome moves first in one direction, then the other, back and forth, finally settling midway between the two ends of the cell. At metaphase, the centromeres of all the duplicated chromosomes are on a plane midway between the spindle's two poles. This imaginary plane is called the metaphase plate of the cell (**Figure 12.7**). Meanwhile, microtubules that do not attach to kinetochores have been growing, and by metaphase they overlap and interact with other nonkinetochore microtubules from the opposite pole *of* the spindle. (These are sometimes called "polar" microtubules.) By metaphase, the microtubules of the asters have also grown and are in contact with the plasma membrane. The spindle is now complete.

Let's now see how the structure of the completed spindle correlates with its function during anaphase. Anaphase commences suddenly when proteins holding together the sister chromatids of each chromosome are inactivated. Once the chromatids become separate, full-fledged chromosomes, they move toward opposite ends of the cell. How do the kinetochore microtubules function in this poleward movement of chromosomes? One possibility is that the chromosomes are "reeled in" by microtubules that are shortening at the spindle poles. However, experimental evidence supports the hypothesis that the primary mechanism of movement involves motor proteins on the kinetochores that "walk" a chromosome along the attached microtubules toward the nearest pole. Meanwhile, the microtubules shorten by depolymerizing at their kinetochore ends (**Figure 12.8**). (To review how motor proteins move an object along a microtubule, see Figure 6.21.)

What is the function of the nonkinetochore microtubules?⁷ In a dividing animal cell, these microtubules are responsible for elongating the whole cell during anaphase. Nonkinetochore microtubules from opposite poles overlap each other extensively during metaphase (see Figure 12.7). During anaphase, the region of overlap is reduced as motor proteins attached to the microtubules walk them away from one another, using energy from ATP. As the microtubules push apart from each other, their spindle poles are pushed apart, elongating the cell. At the same time, the microtubules lengthen somewhat by the addition of tubulin subunits to their overlapping ends. As a result, the microtubules continue to overlap.

At the end of anaphase, duplicate groups of chromosomes have arrived at opposite ends of the elongated parent cell. Nuclei re-form during telophase. Cytokinesis generally begins during these later stages of mitosis, and the spindle eventually disassembles.

Cytokinesis: A Closer Look

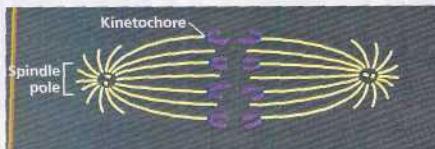

In animal cells, cytokinesis occurs by a process known as cleavage. The first sign of cleavage is the appearance of a cleavage furrow, a shallow groove in the cell surface near the old metaphase plate (**Figure 12.9a**). On the cytoplasmic side of

Figure 12.8

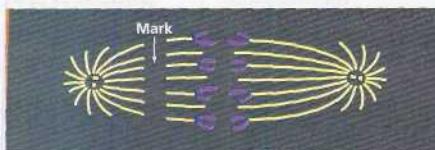

Inquiry During anaphase, do kinetochore microtubules shorten at their spindle pole ends or their kinetochore ends?

EXPERIMENT

O The microtubules of a cell in early anaphase were labeled with a fluorescent dye that glows in the microscope (yellow).

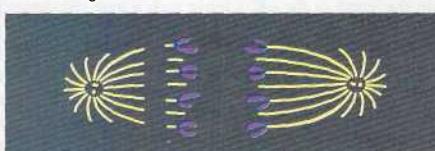

Q A laser was used to mark the kinetochore microtubules by eliminating the fluorescence in a region between one spindle pole and the chromosomes. As anaphase proceeded, researchers monitored the changes in the lengths of the microtubules on either side of the mark.

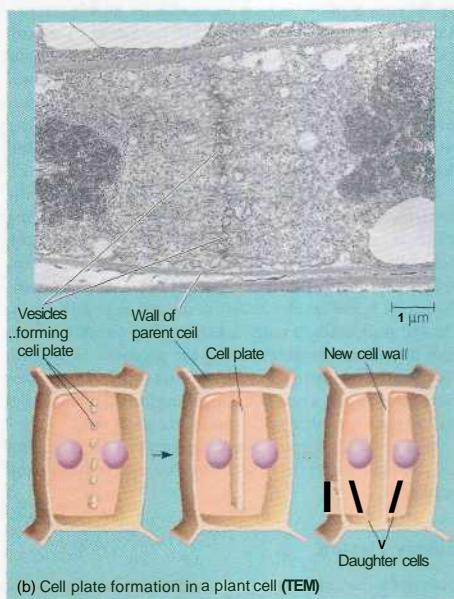

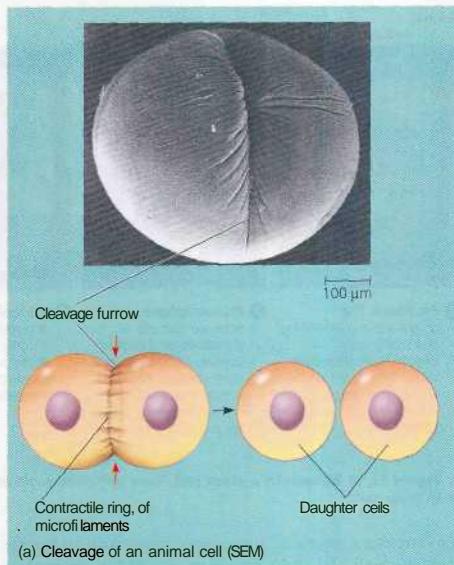

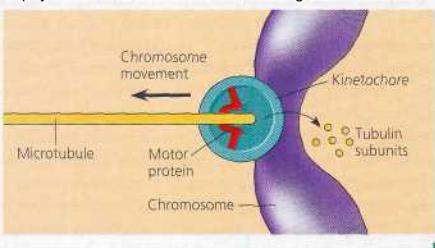

RESULTS

As the chromosomes moved toward the poles, the microtubule segments on the kinetochore side of the laser mark shortened, while those on the spindle pole side stayed the same length.

CONCLUSION

This experiment demonstrated that during anaphase, kinetochore microtubules shorten at their kinetochore ends, not at their spindle pole ends. This is just one of the experiments supporting the hypothesis that during anaphase, a chromosome tracks along a microtubule as the microtubule depolymerizes at its kinetochore end, releasing tubulin subunits.

▲ Figure 12.9 Cytokinesis in animal and plant cells.

1 Prophase. The chromatin is condensing. The nucleolus is beginning to disappear. Although not yet visible in the micrograph, the mitotic spindle is starting to form.

2 Prometaphase. We now see discrete chromosomes; each consists of two identical sister chromatids. Later in prometaphase, the nuclear envelope will fragment.

3 Metaphase. The spindle is complete, and the chromosomes, attached to microtubules at their kinetochores, are all at the metaphase plate.

4 Anaphase. The chromatids of each chromosome have separated, and the daughter chromosomes are moving to the ends of the cell as their kinetochore microtubules shorten.

5 Telophase. Daughter nuclei are forming. Meanwhile, cytokinesis has started; The cell plate, which will divide the cytoplasm in two, is growing toward the perimeter of the parent cell.

A Figure 12.10 Mitosis in a plant cell. These light micrographs show mitosis in cells of an onion root.

the furrow is a contractile ring of actin microfilaments associated with molecules of the protein myosin. (Actin and myosin are the same proteins that are responsible for muscle contraction as well as many other kinds of cell movement.) The actin microfilaments interact with the myosin molecules, causing the ring to contract. The contraction of the dividing cell's ring of microfilaments is like the pulling of drawstrings. The cleavage furrow deepens until the parent cell is pinched in two, producing two completely separated cells, each with its own nucleus and share of cytosol and organelles.

Cytokinesis in plant cells, which have cell walls, is markedly different. There is no cleavage furrow. Instead, during telophase, vesicles derived from the Golgi apparatus move along microtubules to the middle of the cell, where they coalesce, producing a cell plate (Figure 12.9b). Cell wall materials carried in the vesicles collect in the cell plate as it grows. The cell plate enlarges until its surrounding membrane fuses with the plasma membrane along the perimeter of the cell. Two daughter cells result, each with its own plasma membrane. Meanwhile, a new cell wall arising from the contents of the cell plate has formed between the daughter cells.

Figure 12.10 is a series of micrographs of a dividing plant cell. Examining this figure will help you review mitosis and cytokinesis.

Binary Fission

Prokaryotes (bacteria) reproduce by a type of cell division called binary fission, meaning literally "division in half." Most bacterial genes are carried on a single *bacterial chromosome* that consists

of a circular DNA molecule and associated proteins. Although bacteria are smaller and simpler than eukaryotic cells, the problem of replicating their genomes in an orderly fashion and distributing the copies equally to two daughter cells is still formidable. The chromosome of the bacterium *Escherichia coli*, for example, when it is fully stretched out, is about 500 times longer than the length of the cell. Clearly, such a long chromosome must be highly coiled and folded within the cell—and it is.

In *E. coli*, the process of cell division begins when the DNA of the bacterial chromosome begins to replicate at a specific place on the chromosome called the origin of replication, producing two origins. As the chromosome continues to replicate, one origin moves rapidly toward the opposite end of the cell (Figure 12.11). While the chromosome is replicating, the cell elongates. When replication is complete and the bacterium has reached about twice its initial size, its plasma membrane grows inward, dividing the parent *E. coli* cell into two daughter cells. Each cell inherits a complete genome.

Using the techniques of modern DNA technology to tag the origins of replication with molecules that glow green in fluorescence microscopy (see Figure 6.3), researchers have directly observed the movement of bacterial chromosomes. This movement is reminiscent of the poleward movements of the centromere regions of eukaryotic chromosomes during anaphase of mitosis, but bacteria don't have visible mitotic spindles or even microtubules. In most bacterial species studied, the two origins of replication end up at opposite ends of the cell or in some other very specific location, possibly anchored there by one or more proteins. How bacterial chromosomes move and how their specific location is established and maintained are

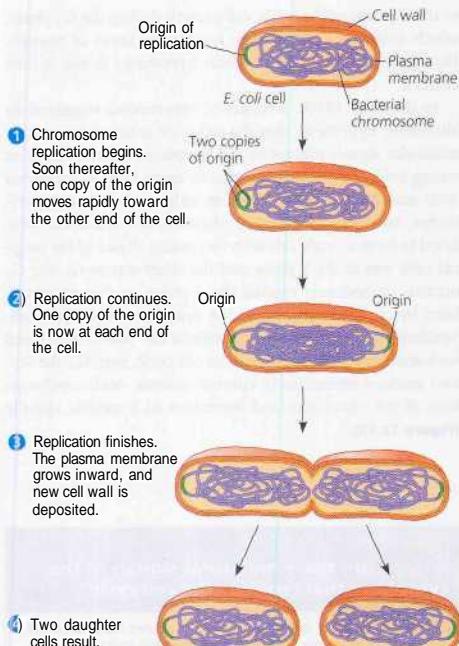

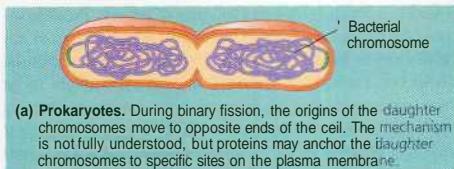

Figure 12.11 **Bacterial cell division (binary fission).** The example shown here is the bacterium *E. coli*. The single, circular chromosome replicates, and the two copies move apart by an unknown mechanism, so that the two origins of replication (green) end up at opposite ends of the cell. Meanwhile, the cell elongates. When chromosomal replication is complete, the plasma membrane grows inward, dividing the cell in two as a new cell wall is deposited between the daughter cells.

becoming clearer but are still not fully understood. Several proteins have been identified that play important roles.

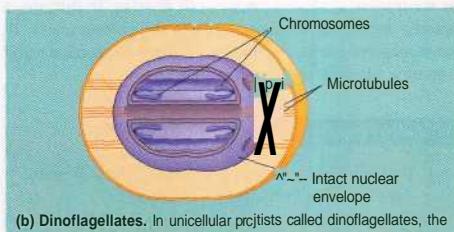

The Evolution of Mitosis

How did mitosis evolve? Given that prokaryotes preceded eukaryotes on Earth by billions of years, we might hypothesize that mitosis had its origins in simpler bacterial mechanisms of cell reproduction. In fact, some of the proteins involved in bacterial binary fission are related to eukaryotic proteins, strengthening the case for the evolution of mitosis from bacterial cell division. Intriguingly, recent work has shown that two of the proteins involved in binary fission are related to eukaryotic tubulin and actin proteins.

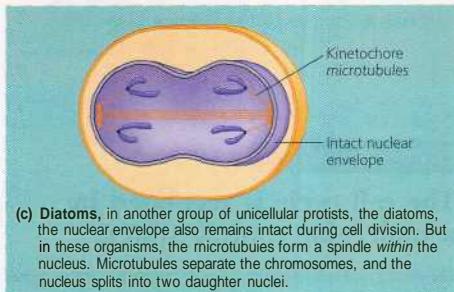

As eukaryotes evolved, along with their larger genomes and nuclear envelopes, the ancestral process of binary fission somehow gave rise to mitosis. **Figure 12.12** traces a

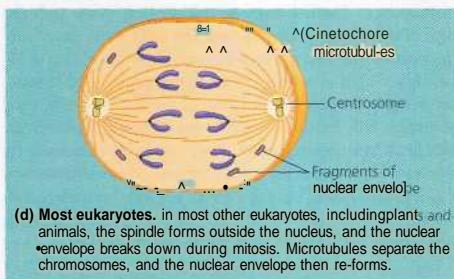

(a) Prokaryotes. During binary fission, the origins of the daughter chromosomes move to opposite ends of the cell. The mechanism is not fully understood, but proteins may anchor the daughter chromosomes to specific sites on the plasma membrane.

(b) Dinoflagellates. In unicellular protists called dinoflagellates, the nuclear envelope remains intact during cell division, and the chromosomes attach to the nuclear envelope. Microtubules pass through the nucleus inside cytoplasmic tunnels, reinforcing the spatial orientation of the nucleus, which then divides in a fission process reminiscent of bacterial division.

(c) Diatoms. In another group of unicellular protists, the diatoms, the nuclear envelope also remains intact during cell division. But in these organisms, the microtubules form a spindle *within* the nucleus. Microtubules separate the chromosomes, and the nucleus splits into two daughter nuclei.

(d) Most eukaryotes. In most other eukaryotes, including plants and animals, the spindle forms outside the nucleus, and the nuclear envelope breaks down during mitosis. Microtubules separate the chromosomes, and the nuclear envelope then re-forms.

A Figure 12.12 **A hypothetical sequence for the evolution of mitosis.** In modern organisms, researchers have observed mechanisms of cell division that appear to be intermediate between the binary fission of bacteria (a) and mitosis as it occurs in most eukaryotes (d). Except for (a), these schematic diagrams do not show cell walls.

hypothesis for the stepwise evolution of mitosis. Possible **intermediate** stages are represented by two unusual types of nuclear division found in certain modern unicellular protists. These two examples of nuclear division are thought to be cases where ancestral mechanisms have remained relatively unchanged over evolutionary time. In both types, the nuclear envelope remains intact. In dinoflagellates, replicated chromosomes are attached to the nuclear envelope and separate as the nucleus elongates prior to cell division. In diatoms, a spindle within the nucleus separates the chromosomes. In most eukaryotic cells, the nuclear envelope breaks down and a spindle separates the chromosomes.

Concept Check 12.2

- During which stages of a cell cycle would a chromosome consist of two identical chromatids?
- How many chromosomes are shown in the Figure 12.7 diagram? How many chromatids are shown?
- Compare cytokinesis in animal cells and plant cells.
- What is a function of nonkinetochore microtubules?
- Identify three similarities between bacterial chromosomes and eukaryotic chromosomes, considering both structure and behavior during cell division.

For suggested answers, see Appendix A.

Concept 12.3

The cell cycle is regulated by a molecular control system

The timing and rate of cell **division** in different parts of a plant or animal are crucial to normal growth, development, and maintenance. The frequency of cell division varies with the type of cell. For example, human skin cells divide frequently throughout life, whereas liver cells maintain the ability to divide but keep it in reserve until an appropriate need arises—say to repair a wound. Some of the most specialized cells, such as mature, fully formed nerve cells and muscle cells, do not divide at all in a mature human. These cell cycle differences result from regulation at the molecular level. The mechanisms of this regulation are of intense interest, not only for understanding the life cycles of normal cells but also for understanding how cancer cells manage to escape the usual controls.

Evidence for Cytoplasmic Signals

What drives the cell cycle? One reasonable hypothesis might be that each event in the cycle triggers the next. According to this hypothesis, for example, the replication of chromosomes

in the S phase might cause cell growth during the G₂ phase, which might in turn directly trigger the onset of mitosis. However, this apparently logical hypothesis is not in fact correct.

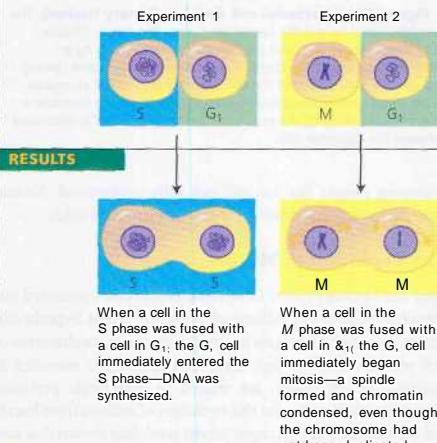

In the early 1970s, a variety of experiments suggested an alternative hypothesis; that the cell cycle is driven by specific molecular signals present in the cytoplasm. Some of the first strong evidence for this hypothesis came from experiments with mammalian cells grown in culture. In these experiments, two cells in different phases of the cell cycle were fused to form a single cell with two nuclei. If one of the original cells was in the S phase and the other was in G₁, the G₁ nucleus immediately entered the S phase, as though stimulated by chemicals present in the cytoplasm of the first cell. Similarly, if a cell undergoing mitosis (M phase) was fused with another cell in any stage of its cell cycle, even G₀, the second nucleus immediately entered mitosis, with condensation of the chromatin and formation of a mitotic spindle (Figure 12.13).

Figure 12.13

Inquiry Are there molecular signals in the cytoplasm that regulate the cell cycle?

EXPERIMENT

In each experiment, cultured mammalian cells at two different phases of the cell cycle were induced to fuse.

CONCLUSION

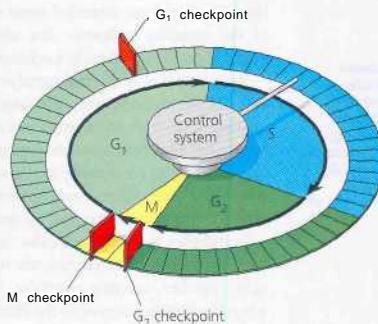

The results of fusing cells at two different phases of the cell cycle suggest that molecules present in the cytoplasm of cells in the S or M phase control the progression of phases.

The Cell Cycle Control System

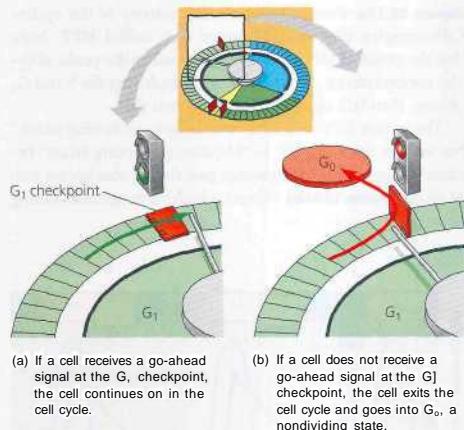

The experiment shown in Figure 12.13 and other experiments demonstrated that the sequential events of the cell cycle are directed by a distinct cell cycle control system, a cyclically operating set of molecules in the cell that both triggers and coordinates key events in the cell cycle. The cell cycle control system has been compared to the control device of an automatic washing machine (**Figure 12.14**). Like the washer's timing device, the cell cycle control system proceeds on its own, driven by a built-in clock. However, just as a washer's cycle is subject to both internal control (such as the sensor that detects when the tub is filled with water) and external adjustment (such as activation of the start mechanism), the cell cycle is regulated at certain checkpoints by both internal and external controls.

A checkpoint in the cell cycle is a critical control point where stop and go-ahead signals can regulate the cycle. (The signals are transmitted within the cell by the kinds of signal transduction pathways discussed in Chapter 11.) Animal cells generally have built-in stop signals that halt the cell cycle at checkpoints until overridden by go-ahead signals. Many signals registered at checkpoints come from cellular surveillance mechanisms inside the cell; the signals report whether crucial cellular processes up to that point have been completed correctly and thus whether or not the cell cycle should proceed. Checkpoints also register signals from outside the cell, as we will discuss later. Three major checkpoints are found in the G₁, G₂, and M phases (see Figure 12.14).

For many cells, the G₁ checkpoint—dubbed the "restriction point" in mammalian cells—seems to be the most important. If a cell receives a go-ahead signal at the G₁ checkpoint, it will usually complete the S, G₂, and M phases and divide. Alternatively,

A Figure 12.14 Mechanical analogy for the cell cycle control system. In this diagram of the cell cycle, the flat "stepping stones" around the perimeter represent sequential events. Like the control device of an automatic washer, the cell cycle control system proceeds on its own, driven by a built-in clock. However, the system is subject to regulation at various checkpoints, of which three are shown (red).

A. Figure 12.15 The G₁ checkpoint.

if it does not receive a go-ahead signal at that point, it will exit the cycle, switching into a nondividing state called the G₀ phase (**Figure 12.15**). Most cells of the human body are actually in the G₀ phase. As mentioned earlier, fully formed, mature nerve cells and muscle cells never divide. Other cells, such as liver cells, can be "called back" from the G₀ phase to the cell cycle by certain external cues, such as growth factors released during injury.

To understand how cell cycle checkpoints work, we first need to see what kinds of molecules make up the cell cycle control system (the molecular basis for the cell cycle clock) and how a cell progresses forward through the cycle. Then we will consider the internal and external checkpoint signals that can make the clock pause or continue.

The Cell Cycle Clock; Cyclins and Cyclin-Dependent Kinases

Rhythmic fluctuations in the abundance and activity of cell cycle control molecules pace the sequential events of the cell cycle. These regulatory molecules are proteins of two main types: kinases and cyclins. Protein kinases are enzymes that activate or inactivate other proteins by phosphorylating them (see Chapter 11). Particular protein kinases give the go-ahead signals at the G₁ and G₂ checkpoints.

The kinases that drive the cell cycle are actually present at a constant concentration in the growing cell, but much of the time they are in an inactive form. To be active, such a kinase must be attached to a cyclin, a protein that gets its name from its cyclically fluctuating concentration in the cell. Because of this requirement, these kinases are called cyclin-dependent kinases, or Cdks. The activity of a Cdk rises and falls with changes in the concentration of its cyclin partner.

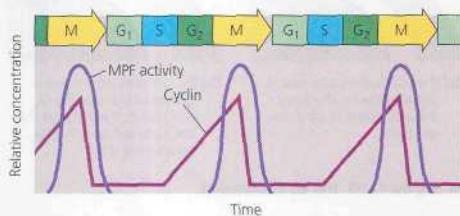

Figure 12.16a shows the fluctuating activity of the cyclin-Cdk complex that was discovered first, called MPF. Note that the peaks of MPF activity correspond to the peaks of cyclin concentration. The cyclin level rises during the S and G₂ phases, then falls abruptly during mitosis (M).

The initials MPF stand for "maturation-promoting factor," but we can think of MPF as "M-phase-promoting factor" because it triggers the cell's passage past the G₂ checkpoint into M phase (**Figure 12.16b**). When cyclins that accumulate during

G₂ associate with Cdk molecules, the resulting MPF complex initiates mitosis, phosphorylating a variety of proteins. MPF acts both directly as a kinase and indirectly by activating other kinases. For example, MPF causes phosphorylation of various proteins of the nuclear lamina (see Figure 6.10), which promotes fragmentation of the nuclear envelope during prometaphase of mitosis. There is also evidence that MPF contributes to molecular events required for chromosome condensation and spindle formation during prophase.

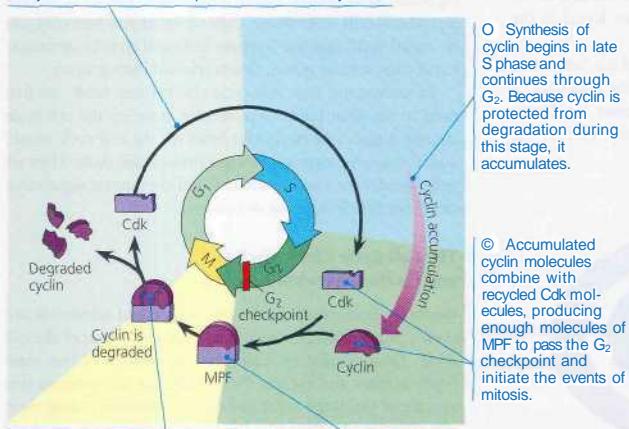

During anaphase, MPF helps switch itself off by initiating a process that leads to the destruction of its own cyclin. The noncyclin part of MPF, the Cdk, persists in the cell in inactive form until it associates with new cyclin molecules synthesized during the S and G₂ phases of the next round of the cycle.

What about the G₁ checkpoint? Recent research suggests the involvement of at least three Cdk proteins and several different cyclins at this checkpoint. The fluctuating activities of different cyclin-Cdk complexes seem to control all the stages of the cell cycle.

(a) Fluctuation of MPF activity and cyclin concentration during the cell cycle

Q During G₁, conditions in the cell favor degradation of cyclin, and the Cdk component of MPF is recycled.

Q During anaphase, the cyclin component of MPF is degraded, terminating the M phase. The cell enters the G₁ phase.

(b) Molecular mechanisms that help regulate the cell cycle

A. Figure 12.16 Molecular control of the cell cycle at the G₂ checkpoint. The steps of the cell cycle are timed by rhythmic fluctuations in the activity of cyclin-dependent kinases (Cdks). Here we focus on a cyclin-Cdk complex called MPF, which acts at the G₂ checkpoint as a go-ahead signal, triggering the events of mitosis.

Stop and Go Signs: Internal and External Signals at the Checkpoints

Research scientists are only in the early stages of working out the signaling pathways that link cyclin-dependent kinases to other molecules and events inside and outside the cell. For example, they know that in general, active Cdks function by phosphorylating substrate proteins that affect particular steps in the cell cycle. In many cases, though, scientists don't yet know what the various Cdks actually do. However, they have identified some steps of the signaling pathways that convey information to the cell cycle machinery.

An example of an internal signal occurs at the M phase checkpoint. Anaphase, the separation of sister chromatids, does not begin until all the chromosomes are properly attached to the spindle at the metaphase plate. Researchers have learned that kinetochores not yet attached to spindle microtubules send a molecular signal that causes the sister chromatids to remain together, delaying anaphase. Only when the kinetochores of all the chromosomes are attached to the spindle will the sister chromatids separate (owing to inactivation of the proteins holding them together). This mechanism ensures that daughter cells do not end up with missing or extra chromosomes.

By growing animal cells in culture, researchers have been able to identify many external factors, both chemical and physical, that can influence cell division. For example, cells fail to divide if an essential nutrient is left out of the culture medium. (This is analogous to trying to run an automatic washing machine without the water supply hooked up.) And even if all other conditions are favorable, most types of mammalian cells divide in culture only if the growth medium includes specific growth factors. As mentioned in Chapter 11, a growth factor is a protein released by certain cells that stimulates other cells to divide. While called a growth factor for historical reasons, a protein that promotes mitosis is sometimes more narrowly called a mitogen.

One such growth factor is *platelet-derived growth factor* (PDGF), which is made by blood cells called platelets. The experiment illustrated in Figure 12.17 demonstrates that PDGF is required for the division of fibroblasts in culture. Fibroblasts, a type of connective tissue cell, have PDGF receptors on their plasma membranes. The binding of PDGF molecules to these receptors (which are receptor tyrosine kinases; see Chapter 11) triggers a signal transduction pathway that allows the cells to pass the G₁ checkpoint and divide. PDGF stimulates fibroblast division not only in the artificial conditions of cell culture, but in an animal's body as well. When an injury occurs, platelets release PDGF in the vicinity. The resulting proliferation of fibroblasts helps heal the wound. Researchers have discovered at least 50 different growth factors that can trigger cells to divide. Different cell types respond specifically to a certain growth factor or combination of growth factors.

The effect of an external physical factor on cell division is clearly seen in density-dependent inhibition, a phenomenon in which crowded cells stop dividing (Figure 12.18a, on the next page). As first observed many years ago, cultured cells normally divide until they form a single layer of cells on the inner surface of the culture container, at which point the cells stop dividing. If some cells are removed, those bordering the open space begin dividing again and continue until the vacancy is filled. It was originally thought that a cell's physical contact with neighboring cells signaled it to stop dividing. However, while physical contact may have some influence, it turns out that the amount of required growth factors and nutrients available to each cell has a more important effect: Apparently, when a cell population reaches a certain density, the availability of nutrients becomes insufficient to allow continued cell growth and division.

Most animal cells also exhibit anchorage dependence (see Figure 12.18a). To divide, they must be attached to a substratum, such as the inside of a culture jar or the extracellular matrix of a tissue. Experiments suggest that anchorage is signaled to the cell cycle control system via pathways involving plasma membrane proteins and elements of the cytoskeleton linked to them.

Figure 12.17

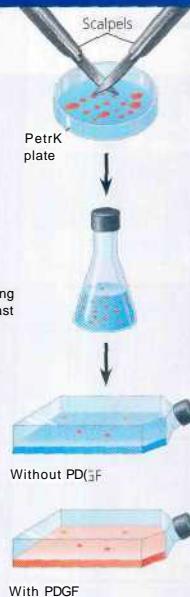

Inquiry Does platelet-derived growth factor (PDGF) stimulate the division of human fibroblast cells in culture?

EXPERIMENT

- 1 A sample of connective tissue was cut up into small pieces.

- 2 Enzymes were used to digest the extracellular matrix, resulting in a suspension of free fibroblast cells.

- 3 Cells were transferred to sterile culture vessels containing a basic growth medium consisting of glucose, amino acids, salts, and antibiotics (as a precaution against bacterial growth). PDGF was added to half the vessels. The culture vessels were incubated at 37°C.

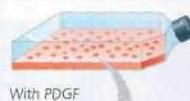

RESULTS

- (a) In a basic growth medium without PDGF (the control), cells failed to divide.

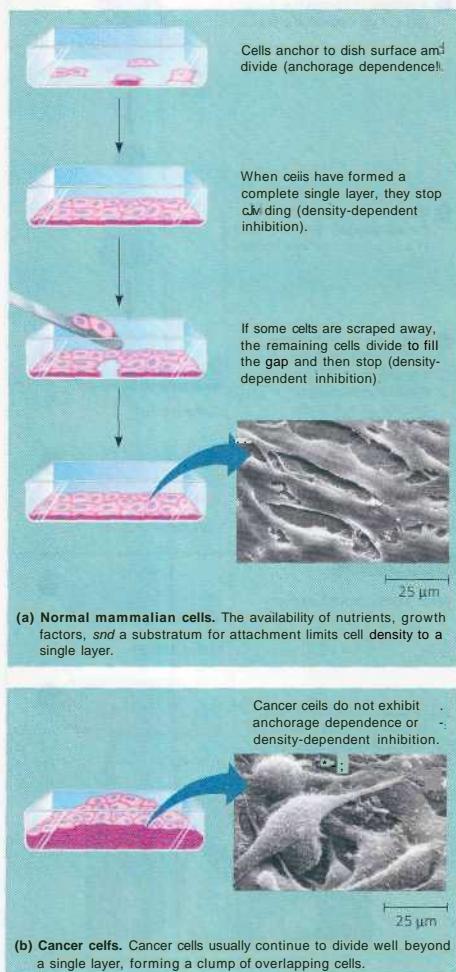

- (b) In a basic growth medium plus PDGF, cells proliferated. The SEM shows cultured fibroblasts.

10 μ m

CONCLUSION This experiment confirmed that PDGF stimulates the division of human fibroblast cells in culture.

Density-dependent inhibition and anchorage dependence appear to function in the body's tissues as well as in cell culture, checking the growth of cells at some optimal density and location. Cancer cells, which we discuss next, exhibit neither density-dependent inhibition nor anchorage dependence (Figure 12.18b).

A Figure 12.18 Density-dependent inhibition and anchorage dependence of cell division. Individual cells are shown disproportionately large in the drawings.

Loss of Cell Cycle Controls in Cancer Cells

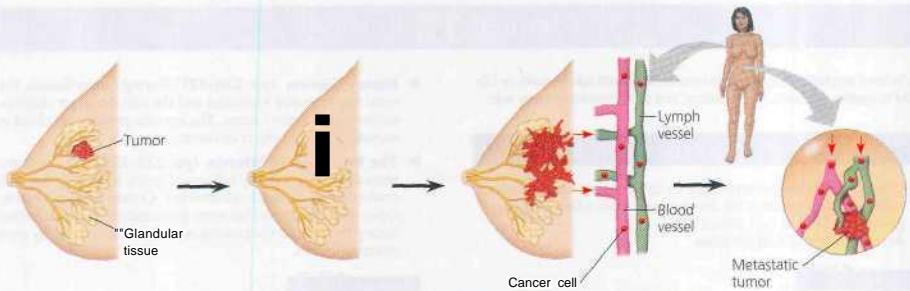

Cancer cells do not respond normally to the **bad%** control mechanisms. They divide excessively and invade other tissues. If unchecked, they can kill the organism.

By studying cells growing in culture, researchers have learned that cancer cells do not heed the normal signals that regulate the cell cycle. For example, as Figure 12.18b shows, cancer cells do not exhibit density-dependent inhibition when growing in culture; they do not stop dividing when growth factors are depleted. A logical hypothesis to explain this behavior is that cancer cells do not need growth factors in their culture medium in order to grow and divide. They may make a required growth factor themselves, or they may have an abnormality in the signaling pathway that conveys the growth factor's signal to the cell cycle control system even in the absence of that factor. Another possibility is an abnormal cell cycle control system. In fact, as you will learn in Chapter 19, these are all conditions that may lead to cancer.

There are other important differences between normal cells and cancer cells that reflect derangements of the cell cycle. If and when they stop dividing, cancer cells do so at random points in the cycle, rather than at the normal checkpoints. Moreover, in culture, cancer cells can go on dividing indefinitely if they are given a continual supply of nutrients; they are said to be "immortal." A striking example is a cell line that has been reproducing in culture since 1951. Cells of this line are called HeLa cells because their original source was a tumor removed from a woman named Henrietta Lacks. By contrast nearly all normal mammalian cells growing in culture divide only about 20 to 50 times before they stop dividing, age, and die. (We'll see a possible reason for this phenomenon when we discuss chromosome replication in Chapter 16.)

The abnormal behavior of cancer cells can be catastrophic when it occurs in the body. The problem begins when a single cell in a tissue undergoes transformation, the process that converts a normal cell to a cancer cell. The body's immune system normally recognizes a transformed cell as an insurgent and destroys it. However, if the cell evades destruction, it may proliferate and form a tumor, a mass of abnormal cells within otherwise normal tissue. If the abnormal cells remain at the original site, the lump is called a benign tumor. Most benign tumors do not cause serious problems and can be completely removed by surgery. In contrast, a malignant tumor becomes invasive enough to impair the functions of one or more organs (Figure 12.19). An individual with a malignant tumor is said to have cancer.

The cells of malignant tumors are abnormal in many ways besides their excessive proliferation. They may have unusual numbers of chromosomes (whether this is a cause or an effect of transformation is a current topic of debate). Their metabolism may be disabled, and they may cease to function in any constructive way. Also, owing to abnormal changes on the

1 A tumor grows from a single cancer cell.

2 Cancer cells invade neighboring tissue.

3 Cancer cells spread through lymph and blood vessels to other parts of the body.

4 A small percentage of cancer cells may survive and establish a new tumor in another part of the body.

A Figure 12.19 The growth and metastasis of a malignant breast tumor. The cells of malignant (cancerous) tumors grow in an uncontrolled way and can spread to neighboring tissues and, via lymph and blood vessels, to other parts of the body. The spread of cancer cells beyond their original site is called metastasis.

cells' surfaces, they lose or destroy their attachments to neighboring cells and the extracellular matrix and can spread into nearby tissues. Cancer cells may also secrete signal molecules that cause blood vessels to grow toward the tumor. A few tumor cells may separate from the original tumor, enter blood vessels and lymph vessels, and travel to other parts of the body. There, they may proliferate and form a new tumor. This spread of cancer cells to locations distant from their original site is called **metastasis** (see Figure 12.19).

A tumor that appears to be localized may be treated with high-energy radiation, which damages DNA in cancer cells much more than it does in normal cells, apparently because cancer cells have lost the ability to repair such damage. To treat known or suspected metastatic tumors, chemotherapy is used, in which drugs that are toxic to actively dividing cells are administered through the circulatory system. As you might expect, chemotherapeutic drugs interfere with specific steps in the cell cycle. For example, the drug Taxol freezes the mitotic spindle by preventing microtubule depolymerization, which stops actively dividing cells from proceeding past metaphase. The side effects of chemotherapy are due to the drugs' effects on normal cells. For example, nausea results from chemotherapy's effects on intestinal cells, hair loss from effects on hair follicle cells, and susceptibility to infection from effects on immune system cells.

Researchers are beginning to understand how a normal cell is transformed into a cancer cell. You will learn more about the molecular biology of cancer in Chapter 19. Though the causes of cancer are diverse, cellular transformation always

involves the alteration of genes that somehow influence the cell cycle control system. Our knowledge of how changes in the genome lead to the various abnormalities of cancer cells remains rudimentary, however.

Perhaps the reason we have so many unanswered questions about cancer cells is that there is still so much to learn about how normal cells function. The cell, life's basic unit of structure and function, holds enough secrets to engage researchers well into the future.

Concept Check 12.3

1. A researcher treats cells with a chemical that prevents DNA synthesis. This treatment traps the cells in which part of the cell cycle?
2. In Figure 12.13, why do the nuclei resulting from experiment 2 contain different amounts of DNA?
3. What is the go-ahead signal for a cell to pass the G₂ phase checkpoint and enter mitosis? (See Figure 12.16.)
4. What would happen if you performed the experiment in Figure 12.17 with cancer cells?
5. What phase of the cell cycle are most of your body cells in?
6. Compare and contrast a benign tumor and a malignant tumor.

For suggested answers, see Appendix A.

Chapter 12 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

- Unicellular organisms reproduce by cell division. Multicellular organisms depend on it for development from a fertilized egg, growth, and repair (pp. 218–219).

Activity Roles of Cell Division

Concept 12.1

Cell division results in genetically identical daughter cells

- Cells duplicate their genetic material before they divide, ensuring that each daughter cell receives an exact copy of the genetic material, DNA (p. 219).
- Cellular Organization of the Genetic Material** (p. 219) DNA is partitioned among chromosomes. Eukaryotic chromosomes consist of chromatin, a complex of DNA and protein that condenses during mitosis. In animals, gametes have one set of chromosomes and somatic cells have two sets.
- Distribution of Chromosomes During Cell Division** (pp. 219–220) In preparation for cell division, chromosomes replicate, each one then consisting of two identical sister chromatids. The chromatids separate during cell division, becoming the chromosomes of the new daughter cells. Eukaryotic cell division consists of mitosis (division of the nucleus) and cytokinesis (division of the cytoplasm).

Concept 12.2

The mitotic phase alternates with interphase in the cell cycle

- Phases of the Cell Cycle** (pp. 221–223) Between divisions, cells are in interphase: the G₁, S, and G₂ phases. The cell grows throughout interphase, but DNA is replicated only during the synthesis (S) phase. Mitosis and cytokinesis make up the mitotic (M) phase of the cell cycle. Mitosis is a continuous process, often described as occurring in five stages: prophase, prometaphase, metaphase, anaphase, and telophase.

Activity The Cell Cycle

- The Mitotic Spindle: A Closer Look** (pp. 221–225) The mitotic spindle is an apparatus of microtubules that controls chromosome movement during mitosis. The spindle arises from the centrosomes and includes spindle microtubules and asters. Some spindle microtubules attach to the kinetochores of chromosomes and move the chromosomes to the metaphase plate. In anaphase, sister chromatids separate and move along the kinetochore microtubules toward opposite ends of the cell. Meanwhile, nonkinetochore microtubules from opposite poles overlap and push against each other, elongating the cell. In telophase, genetically identical daughter nuclei form at opposite ends of the cell.

- Cytokinesis: A Closer Look** (pp. 224–226) Mitosis is usually followed by cytokinesis. Animal cells carry out cytokinesis by cleavage, and plant cells form a cell plate.

Activity Mitosis and Cytokinesis Animation

Activity Mitosis and Cytokinesis Video

Investigation How Much Time Do Cells Spend in Each Phase of Mitosis?

- Binary Fission** (pp. 226–227) During binary fission, the bacterial chromosome replicates and the two daughter chromosomes actively move apart. The specific proteins involved in this movement are a subject of current research.

- The Evolution of Mitosis** (pp. 227–228) Since prokaryotes preceded eukaryotes by billions of years, it is likely that mitosis evolved from bacterial cell division. Certain protists exhibit types of cell division that seem intermediate between bacterial binary fission and the process of mitosis carried out by most eukaryotic cells.

Concept 12.3

The cell cycle is regulated by a molecular control system

- Evidence for Cytoplasmic Signals** (p. 228) Molecules present in the cytoplasm regulate progress through the cell cycle.
- The Cell Cycle Control System** (pp. 229–232) Cyclic changes in regulatory proteins work as a cell cycle clock. The clock has specific checkpoints where the cell cycle stops until a go-ahead signal is received. The key molecules are cyclins and cyclin-dependent kinases (Cdks). Cell culture has enabled researchers to study the molecular details of cell division. Both internal signals and external signals control the cell cycle checkpoints via signal transduction pathways. Most cells exhibit density-dependent inhibition of cell division as well as anchorage dependence.

• Loss of Cell Cycle Controls in Cancer Cells

- (pp. 232–233) Cancer cells elude normal regulation and divide out of control, forming tumors. Malignant tumors invade surrounding tissues and can metastasize, exporting cancer cells to other parts of the body, where they may form secondary tumor.

Activity Causes of Cancer

TESTING YOUR KNOWLEDGE

Evolution Connection

The result of mitosis is that the daughter cells end up with the same number of chromosomes as the parent cell had. Another way to maintain the number of chromosomes would be to carry out cell division first and then duplicate the chromosomes in each daughter cell. What would be the problems with this alternative? Or do you think it would be an equally good way of organizing the cell cycle?

Scientific Inquiry

Microtubules are polar structures in that one end (called the + end) polymerizes and depolymerizes at a much higher rate than the other end (the — end). The experiment shown in Figure 12.8 clearly identifies these two ends.

- From the results, identify the + end and explain your reasoning.
- If the opposite end were the + end, what would the results be? Make a sketch.

- c. Redesign the model in the conclusion of Figure 12.8 to reflect your new version of the results.

Investigation How Much Time Do Cells Spend in Each Phase of Mitosis?

Science, Technology, and Society

Hundreds of millions of dollars are spent each year in the search for effective treatments for cancer; far less money is spent preventing cancer. Why do you think this is true? What kinds of lifestyle changes could we make to help prevent cancer? What kinds of prevention programs could be initiated or strengthened to encourage these changes? What factors might impede such changes and programs?

3

Genetics

AN INTERVIEW WITH Eric Lander

Genomics, the study of all the genes in an organism and how they function together, is a new field that is bringing about a revolution in biology. Having played a major role in the Human Genome Project, Eric Lander is a leader of this revolution. Dr. Lander is the founding director of the Broad Institute of MIT and Harvard, which uses genomics to develop new tools and approaches to understanding and treating disease. The institute includes the former Whitehead Center for Genome Research, which played a leading role in the sequencing of the human genome.

A graduate of Princeton, Dr. Lander earned a doctorate in mathematics at Oxford University, where he was a Rhodes Scholar. He then taught managerial economics at Harvard Business School until turning full time to biology in 1990. Among his many honors have been a MacArthur Foundation Fellowship and election to the U.S. National Academy of Sciences. Dr. Lander is a professor at both MIT and Harvard, and he has taught MIT's core introductory biology course for a decade.

How did you get into genetics?
In high school, I took biology, but I loved math, and I was a math major in college. I went on to get my Ph.D. in mathematics but decided I didn't want to be a pure mathematician. One day, my brother suggested I might be interested in the coding theory of the brain and sent me some papers on mathematical neurobiology. I realized that, to understand them, I had to learn something about cellular neurobiology. This required me to study cell biology. Next came molecular biology and finally, I really had to know genetics. So one thing led to another—and here I am still learning genetics!

What was the main purpose of the Human Genome Project?

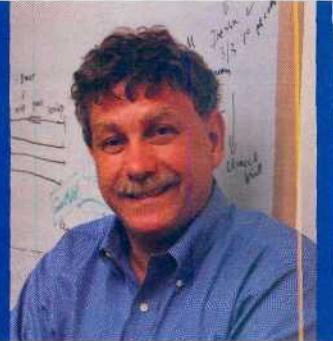

The ultimate purpose of the Human Genome Project was to read out and make freely available the complete DNA sequence of the human being. This information is fundamental to our biology. It contains the parts list in terms of which all our biological structures and processes must eventually be described.

You can study the detailed properties of individual genes, as biologists did before the Human Genome Project and still do, or you can study how all the components of the system interact. Important discoveries are made at both levels, but there are some things you only see when you step back. Imagine looking at a pointillist painting. Up close, the dots are interesting, but when you step back you can see patterns that weren't evident at first. Until the Human Genome Project, it hadn't been possible to step back and get the big picture of the human genome.

Analysis of the genome is unveiling a comprehensive picture of how the genes are turned on and off in different tissues and at different times, so we can see how genes collaborate in modules or circuits. It's an ensemble picture that we've just never had before.

What were the main challenges of the Human Genome Project?

The biggest challenge was the necessity of a 10,000-fold improvement in our methods for mapping and sequencing DNA—the project was that much more ambitious than anything ever done before! In any realistic sense, the scientific community was crazy to propose it. But realism is much overrated. Once we recognized how important the sequence would be to thousands of scientists, we began to ask why, exactly, we couldn't do it. Then we took on the barriers one at a time. We set intermediate goals, both to obtain some information that would be immediately useful and to show ourselves that we

were on the right track. And one after another, we were able to reach our goals: first, genetic maps we could use to trace the inheritance of diseases, then physical maps of the chromosomal DNA, and, finally, the nucleotide-by-nucleotide sequence of the whole genome.

It was a great experience. Everybody involved in the Human Genome Project knew we were working on something that would still be fundamental to science a hundred years from now. We felt it would be important to our children because the medicine of 50 years from now will be based on this work. And it was the work of no one individual, no one center, no one country. Overall, the project involved several thousand people at 20 centers all over the world—in the United States, the United Kingdom, France, Germany, Japan, and China. It was science at its best, an international collaboration of people working together for something bigger than themselves.

To achieve our goals, we constantly had to invent new methodologies, and we had to figure out how to automate as much as possible. Then we had to figure out how to analyze the data. My own background in mathematics actually turned out to be useful.

The genome sequences are just long chains of A's, C's, T's, and G's. How do you know which sections are genes?

Knowing the three billion letters of the human genome is still a far cry from understanding what they say. It's not easy to identify the genes within a very long sequence. This is particularly so in humans and other multicellular eukaryotes, which generally have huge amounts of noncoding DNA and gene-coding sequences split up into small segments (exons) interrupted by stretches of noncoding DNA (introns). In searching for human genes, we're looking for small signals in a sea of noise.

Computer programs can do a passable job of pick'ng out gene sequences, but only passable. The sequences you can look for include ATG, which starts the coding sequence of all genes, but, YIG is so common in the genome that it's not much of a signal. You can also look for places where that start signal is followed by a fairly long stretch of nucleotides before one of the direc-nucleotide stop signals appears, but that can easily occur by chance. So, using a computer to look for those kinds of signals alone does a pretty crummy job of identifying genes.

Happily, we have other tricks up our sleeves. One way to identify genes is to compare the genome to copies of messenger RNA molecules from cells (see Figure 5.25). Another powerful approach is to compare the human sequence to those of related species. Because many genes are crucial to an organism's survival, they tend to be conserved (not change very much) during evolution. So if we look at the portions of the human genome that are very similar in other mammals, they tend to contain genes. The task of finding all the genes is a fascinating puzzle that involves computer scientists, evolutionary biologists, molecular biologists, and others.

How many human genes are there?

My best guess today is that there are 20,000–25,000 protein-coding genes. One of the most surprising findings of the Human Genome Project was a gene count much lower than people had expected based on the total size of the human genome; not so many years ago,

textbooks gave 100,000 as the likely number of human genes. When we got the rough draft of the sequence, we thought there might be as many as 40,000 genes, but we soon learned that many of these were actually pseudogenes, which are defective, nonfunctional copies of true genes. The gene count has been falling and falling. Of course, genes for functional RNA molecules, such as rRNA, that are not translated into protein are also present in the genome, but they don't add up to a lot of territory, probably only a few thousand genes—although we're not certain.

How close are we to understanding the human genome?

The extent of our ignorance became clear from comparing the human genome with the mouse genome. When we lined up the two, we found that about 5% of the human genome showed strong similarity to that of the mouse, indicating strong evolutionary conservation since the last common ancestor of mouse and human. Thus, the sequences in this DNA must be functionally very important. But only about a third of the 5% could be accounted for by known genes and regulatory sequences, leaving a lot more that evolution "cares about" than we can explain today.

That's what I love about genomics. We're learning that there are vast tracts of biology we have missed. It's as if we suddenly could look at the whole Earth and see that, golly, there are several continents we hadn't known about. Genomics is revealing huge territories for the next generation of young scientists to explore.

"The Human Genome Project . . . was science at its best, an international collaboration of people working together for something bigger than themselves."

How is genomics affecting the study of evolution?

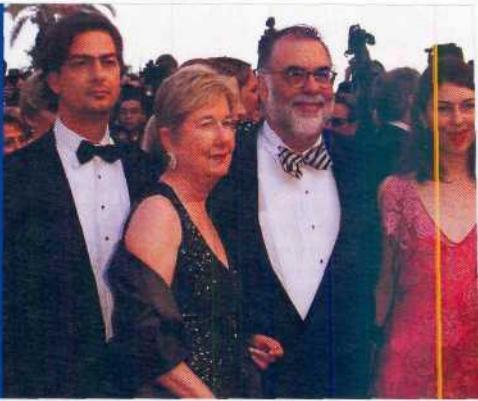

Evolutionary biology is being transformed by the availability of genomic data. Now we can sit down with the complete sequences of a number of organisms and begin to reconstruct their evolutionary relationships and histories in exquisite detail. We can see the forces at work in different lineages. For instance, we can see that in humans the most actively evolving genes are those involved in reproduction and the immune system. Scientists have long thought that genomes carried such information about evolution, but we're finally getting to see it laid out clearly. Evolution is, so to speak, an experimentalist that has been running experiments for three and a half billion years, since the origin of life on Earth. And, wonderfully, the genomes of today's organisms retain the lab notes of these experiments, so that we can go back and reconstruct the events that took place.

Let's talk about the application of genomics to medicine. What goes on at the Broad Institute?

The key challenge ahead is to understand the molecular basis of common human diseases such as diabetes, lung cancer, psychiatric diseases, and many others. Understanding molecular mechanisms is key to creating therapies. The sequence of the human genome has given us a great foundation for systematic understanding of disease—but it's just a start. We now need a full understanding of all the functional elements encoded in the human genome sequence and how they regulate genes; of all the common genetic variants in the human population and how they correlate with risk of disease; of the gene and protein expression patterns that reflect the activation of cellular pathways; and of all the genetic mutations that underlie cancers. In parallel, we need to develop ways to use this comprehensive picture to identify the right targets for drug development and other therapies.

The Broad Institute's mission is to help drive this next stage of biomedicine. The institute includes many kinds of scientists—biologists, chemists, physicians, mathematicians, and others—from across MIT and Harvard, including the Harvard hospitals. Together, we're developing new ways to generate biological information and new ways to apply it in medical studies. We also feel strongly about making all the data publicly available, so that anyone can use it to ask new questions.

13 Meiosis and Sexual Life Cycles

A Figure 13.1 Francis Ford Coppola and his family.

Key Concepts

- 13.1 Offspring acquire genes from parents by inheriting chromosomes
- 13.2 Fertilization and meiosis alternate in sexual life cycles
- 13.3 Meiosis reduces the number of chromosome sets from diploid to haploid
- 13.4 Genetic variation produced in sexual life cycles contributes to evolution

Overview

Heredity Similarity and Variation

Living organisms are distinguished by their ability to reproduce their own kind. Only oak trees produce oaks, and only elephants can make more elephants. Furthermore, offspring resemble their parents more than they do less closely related individuals of the same species. The transmission of traits from one generation to the next is called inheritance, or heredity (from the Latin *heres*, heir). Along with inherited similarity, there is also variation: Offspring differ somewhat in appearance from parents and siblings. Farmers have exploited these observations for thousands of years, breeding plants and animals for desired traits. Just as ancient is a curiosity about genetic similarities and differences among people, including family members (Figure 13.1). The mechanisms of heredity and variation, however, eluded biologists until the development of genetics in the 20th century.

Genetics is the scientific study of heredity and hereditary variation. In this unit, you will learn about genetics at the levels

of organism, cell, and molecule. On the practical side, you will learn how modern genetics is revolutionizing medicine and agriculture, and you will be asked to consider some social and ethical questions raised by our ability to manipulate DNA, the genetic material. At the end of the unit, you will learn about the contributions geneticists have made to solving the mystery of how multicellular animals and plants arise from a single cell II, the fertilized egg. In fact, genetic methods and discoveries are catalyzing progress in all areas of biology—from cell biology to physiology, evolutionary biology, ecology, and even behavior.

We begin our study of genetics in this chapter by examining how chromosomes pass from parents to offspring in sexual y reproducing organisms. The processes of meiosis (a special type of cell division) and fertilization (the fusion of sperm and egg) maintain a species' chromosome count during the sexual life cycle. We will describe the cellular mechanics of meiosis and how this process differs from mitosis. Finally, we will consider how both meiosis and fertilization contribute to genetic variation, such as the variation obvious in the Coppola family (see Figure 13.1).

Concept 13.1

Offspring acquire genes from parents by inheriting chromosomes

Family friends may tell you that you have your mother's freckles or your father's eyes. However, parents do not, in any literal sense, give their children freckles, eyes, hair, or any other traits. What, then, is actually inherited?

Inheritance of Genes

Parents endow their offspring with coded information in the form of hereditary units called genes. The tens of thousands of genes we inherit from our mothers and fathers constitute our genome. This genetic link to our parents accounts for family resemblances such as shared eye color or freckles. Our genes program the specific traits that emerge as we develop from fertilized eggs into adults.

Genes are segments of DNA. You learned in Chapters 1 and 5 that DNA is a polymer of four different kinds of monomers called nucleotides. Inherited information is passed on in the form of each gene's specific sequence of nucleotides, much as printed information is communicated in the form of meaningful sequences of letters. Language is symbolic. The brain translates words and sentences into mental images and ideas; for example, the object you imagine when you read "apple" looks nothing like the word itself. Analogously, cells translate genetic "sentences" into freckles and other features that bear no resemblance to genes. Most genes program cells to synthesize specific enzymes and other proteins whose cumulative action produces an organism's inherited traits. The programming of these traits in the form of DNA is one of the unifying themes of biology.

The transmission of hereditary traits has its molecular basis in the precise replication of DNA, which produces copies of genes that can be passed along from parents to offspring. In animals and plants, reproductive cells called gametes are the vehicles that transmit genes from one generation to the next. During fertilization, male and female gametes (sperm and eggs) unite, thereby passing on the genes of both parents to their offspring.

Except for tiny amounts of DNA in mitochondria and chloroplasts, the DNA of a eukaryotic cell is subdivided into chromosomes within the nucleus. Every living species has a characteristic number of chromosomes. For example, humans have 46 chromosomes in almost all of their cells. Each chromosome consists of a single long DNA molecule elaborately coiled in association with various proteins. One chromosome includes several hundred to a few thousand genes, each of which is a specific sequence of nucleotides within the DNA molecule. A gene's specific location along the length of a chromosome is called the gene's locus (plural, loci). Our genetic endowment consists of the genes carried on the chromosomes we inherited from our parents.

Comparison of Asexual and Sexual Reproduction

Only organisms that reproduce asexually produce offspring that are exact copies of themselves. In asexual reproduction, a single individual is the sole parent and passes copies of all its genes to its offspring. For example, single-celled eukaryotic organisms can reproduce asexually by mitotic cell division, in which DNA is copied and allocated equally to two daughter

-4 **Figure 13.2** The asexual reproduction of a hydra.

This relatively simple multicellular animal reproduces by budding. The bud, a localized mass of mitotically dividing cells, develops into a small hydra, which detaches from the parent (LM).

cells. The genomes of the offspring are virtually exact copies of the parent's genome. Some multicellular organisms are also capable of reproducing asexually. A hydra, which is related to the jellies (jellyfishes), can reproduce by budding (**Figure 13.2**). Because the cells of a bud are derived by mitosis in the parent, the "chip off the old block" is usually genetically identical to its parent. An individual that reproduces asexually gives rise to a clone, a group of genetically identical individuals. Genetic differences occasionally arise in asexually reproducing organisms as a result of changes in the DNA called mutations, which we will discuss in Chapter 17.

In sexual reproduction, two parents give rise to offspring that have unique combinations of genes inherited from the two parents. In contrast to a clone, offspring of sexual reproduction vary genetically from their siblings and both parents: They are variations on a common theme of family resemblance, not exact replicas. Genetic variation like that shown in Figure 13.1 is an important consequence of sexual reproduction. What mechanisms generate this genetic variation? The key is the behavior of chromosomes during the sexual life cycle.

Concept Check 13.1

- How are the traits of parents (such as hair color) transmitted to their offspring?
- In the absence of mutation, asexually reproducing organisms produce offspring that are genetically identical to each other and to their parents. Explain.
- In organisms that reproduce sexually, how similar are the offspring to their parents? Explain.

For suggested answers, see Appendix A.

Concept 13.2

Fertilization and meiosis alternate in sexual life cycles

A **life cycle** is the generation-to-generation sequence of stages in the reproductive history of an organism, from conception to production of its own offspring. In this section, we use humans as an example to track the behavior of chromosomes through sexual life cycles. We begin by considering the chromosome count in human somatic cells and gametes; we will then explore how the behavior of chromosomes relates to the human life cycle and other types of sexual life cycles.

Sets of Chromosomes in Human Cells

In humans, each **somatic cell**—any cell other than a gamete—has 46 chromosomes. During mitosis, the chromosomes become condensed enough to be visible in a light microscope. Because chromosomes differ in size, in the positions of their centromeres, and in the pattern of colored bands produced by certain stains, they can be distinguished from one another by microscopic examination when sufficiently condensed.

Careful examination of a micrograph of the 46 human chromosomes from a single cell in mitosis reveals that there are two chromosomes of each type. This becomes clear when images of the chromosomes are arranged in pairs, starting with the longest chromosomes. The resulting ordered display is called a **karyotype** (Figure 13.3). The two chromosomes composing a pair have the same length, centromere position, and staining pattern: These are called **homologous chromosomes**, or homologues. Both chromosomes of each pair carry genes controlling the same inherited characters. For example, if a gene for eye color is situated at a particular locus on a certain chromosome, then the homologue of that chromosome will also have a gene specifying eye color at the equivalent locus.

The two distinct chromosomes referred to as X and Y are an important exception to the general pattern of homologous chromosomes in human somatic cells. Human females have a homologous pair of X chromosomes (XX), but males have one X and one Y chromosome (XY). Only small parts of the X and Y are homologous. Most of the genes carried on the X chromosome do not have counterparts on the Y, and the Y chromosome has genes lacking on the X. Because they determine an individual's sex, the X and Y chromosomes are called **sex chromosomes**. The other chromosomes are called **autosomes**.

The occurrence of homologous pairs of chromosomes in each human somatic cell is a consequence of our sexual origins. We inherit one chromosome of each pair from each parent. So the 46 chromosomes in our somatic cells are actually two sets of 23 chromosomes—a maternal set (from our mother) and a paternal set (from our father). The number of chromosomes in a single set is represented by n . Any cell with two chromosome

Figure 13.3
Research Method Preparing a Karyotype

APPLICATION

A karyotype is a display of condensed chromosomes arranged in pairs. Karyotyping can be used to screen for abnormal numbers of chromosomes or defective chromosomes associated with certain congenital disorders, such as Down syndrome.

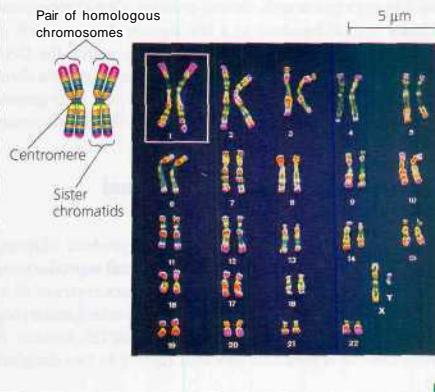

TECHNIQUE

Karyotypes are prepared from isolated somatic cells, which are treated with a drug to stimulate mitosis and then grown in culture for several days. A slide of cells arrested in metaphase is stained and then viewed with a microscope equipped with a digital camera. A digital photograph of the chromosomes is entered into a computer, and the chromosomes are electronically rearranged into pairs according to size and shape.

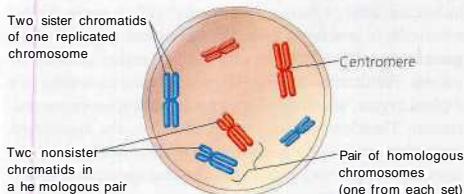

RESULTS

This karyotype shows the chromosomes from a normal human male. The patterns of stained bands help identify specific chromosomes and parts of chromosomes. Although difficult to discern in the karyotype, each metaphase chromosome consists of two, closely attached sister chromatids (see diagram).

Key

- Maternal set of chromosomes ($n = 3$)
- Paternal set of chromosomes ($n = 3$)

A Figure 13.4 Describing chromosomes. A cell with a diploid number of 6 ($2n = 6$) is depicted here in G_2 of interphase, following chromosome replication. (The chromosomes have been artificially color-coded.) Each of the six duplicated chromosomes consists of two sister chromatids joined at the centromere. Each homologous pair is composed of one chromosome from the maternal set (red) and one from the paternal set (blue). Each set is made up of three chromosomes. Non-sister chromatids are any two chromatids in a pair of homologous chromosomes that are not sister chromatids.

sets is called a diploid cell and has a diploid number of chromosomes, abbreviated $2n$. For humans, the diploid number is 46 ($2n = 46$), the number of chromosomes in our somatic cells. In a cell in which DNA synthesis has occurred, all the chromosomes are duplicated and thus each consists of two identical sister chromatids. **Figure 13.4** helps clarify the various terms that we use in describing duplicated chromosomes in a diploid cell. Study this figure so that you understand the differences between homologous chromosomes, sister chromatids, non-sister chromatids, and chromosome sets.

Unlike somatic cells, gametes (sperm and egg cells) contain a single chromosome set. Such cells are called haploid cells, and each has a haploid number of chromosomes (n). For humans, the haploid number is 23 ($n = 23$), the number of chromosomes found in a gamete. The set of 23 consists of the 22 autosomes plus a single sex chromosome. An unfertilized egg cell (also called an ovum) contains an X chromosome, but a sperm cell may contain an X or a Y chromosome.

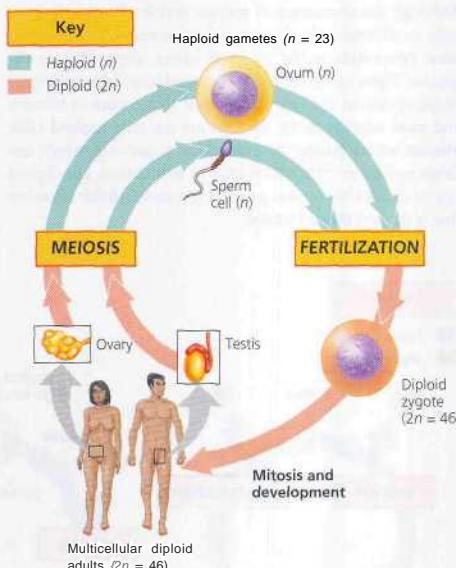

Note that each sexually reproducing species has a characteristic haploid number and diploid number. These may be higher than, lower than, or the same as the values for humans. Now let's extend the concepts of haploid and diploid to understand chromosome behavior during the human life cycle.

Behavior of Chromosome Sets in the Human Life Cycle

The human life cycle begins when a haploid sperm cell from the father fuses with a haploid ovum from the mother. This union of gametes, culminating in fusion of their nuclei, is

called fertilization. The resulting fertilized egg, or zygote, is diploid because it contains two haploid sets of chromosomes bearing genes representing the maternal and paternal family lines. As a human develops from a zygote to a sexually mature adult, mitosis generates all the somatic cells of the body. Both chromosome sets in the zygote and all the genes they carry are passed with precision to our somatic cells.

The only cells of the human body *not* produced by mitosis are the gametes, which develop in the gonads—ovaries in females and testes in males (**Figure 13.5**). Imagine what would happen if human gametes were made by mitosis: They would be diploid like the somatic cells. At the next round of fertilization, when two gametes fused, the normal chromosome number of 46 would double to 92 , and each subsequent generation would double the number of chromosomes yet again. This hypothetical situation of constantly increasing chromosome number in sexually reproducing organisms is avoided through

A Figure 13.5 The human life cycle. In each generation, the doubling of the number of chromosome sets that results from fertilization is offset by the halving of the number of sets that results from meiosis. For humans, the number of chromosomes in a haploid cell is 23 , consisting of one set ($n = 23$); the number of chromosomes in the diploid zygote and all somatic cells arising from it is 46 , consisting of two sets ($2n = 46$).

This figure introduces a color code that will be used for other life cycles later in this book. The teal-colored arrows highlight haploid stages of a life cycle, and the beige-colored arrows highlight diploid stages.

process of meiosis. This type of cell division reduces the number of sets of chromosomes from two to one in the gametes, compensating for the doubling that occurs at fertilization. In animals, meiosis occurs only in the ovaries or testes. As a result, each human sperm and ovum is haploid ($n = 23$). Fertilization restores the diploid condition by combining two haploid sets of chromosomes, and the human life cycle is repeated, generation after generation (see Figure 13.5). You will learn more about the production of sperm and ova in Chapter 46.

In general, the steps of the human life cycle are typical of many animals. Indeed, the processes of fertilization and meiosis are the unique trademarks of sexual reproduction. Fertilization and meiosis alternate in sexual life cycles, offsetting each other's effects on the chromosome number and thus perpetuating a species' chromosome count.

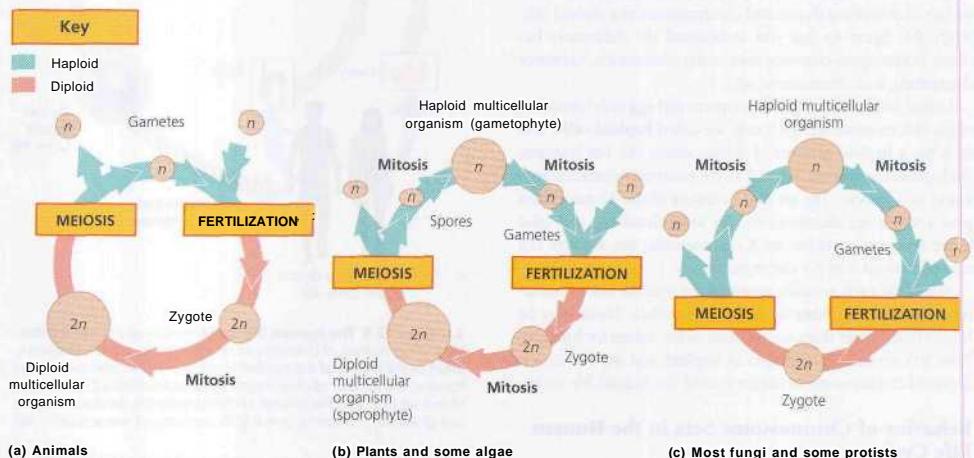

The Variety of Sexual Life Cycles

Although the alternation of meiosis and fertilization is common to all organisms that reproduce sexually, the timing of these two events in the life cycle varies, depending on the species. These variations can be grouped into three main types of life cycles. In the type of life cycle that occurs in humans and most other animals, gametes are the only haploid cells. Meiosis occurs during the production of gametes, which undergo no further cell division prior to fertilization. The diploid zygote divides by mitosis, producing a multicellular organism that is diploid (Figure 13.6a).

Plants and some species of algae exhibit a second type of life cycle called alternation of generations. This type of life cycle includes both diploid and haploid multicellular stages. The multicellular diploid stage is called the sporophyte. Meiosis in the sporophyte produces haploid cells called spores. Unlike a gamete, a spore gives rise to a multicellular individual without fusing with another cell. A spore divides mitotically to generate a multicellular haploid stage called the gametophyte. The haploid gametophyte makes gametes by mitosis. Fertilization among the haploid gametes results in a diploid zygote, which develops into the next sporophyte generation. Therefore, in this type of life cycle, the sporophyte generation produces a gametophyte as its offspring, and the gametophyte generation produces the next sporophyte generation (Figure 13.6b).

A third type of life cycle occurs in most fungi and some protists, including some algae. After gametes fuse and form a diploid zygote, meiosis occurs without a diploid offspring developing. Meiosis produces not gametes but haploid cells that then divide by mitosis and give rise to a haploid multicellular adult organism. Subsequently, the haploid organism carries out mitosis, producing the cells that develop into gametes. The only diploid stage in these species is the single-celled zygote (Figure 13.6c). (Note that either haploid or diploid cells can divide by mitosis, depending on the type of life cycle. Only diploid cells, however, can undergo meiosis.)

Though the three types of sexual life cycles differ in the timing of meiosis and fertilization, they share a fundamental

A Figure 13.6 Three types of sexual life cycles. The common feature of all three cycles is the alternation of meiosis and fertilization, key events that contribute to genetic variation among offspring. The cycles differ in the timing of these two key events.

result: Each cycle of chromosome halving and doubling contributes to genetic variation among offspring. A closer look at meiosis will reveal the sources of this variation.

Concept Check 13.2

- How does the karyotype of a human female differ from that of a human male?
- How does the alternation of meiosis and fertilization in the life cycles of sexually reproducing organisms maintain the normal chromosome count for each species?
- Dog sperm contain 39 chromosomes. What are the haploid number and diploid number for dogs?
- What process (meiosis or mitosis) is more directly involved in the production of gametes in animals? In plants and most fungi?

For suggested answers, see Appendix A.

Concept 13.3

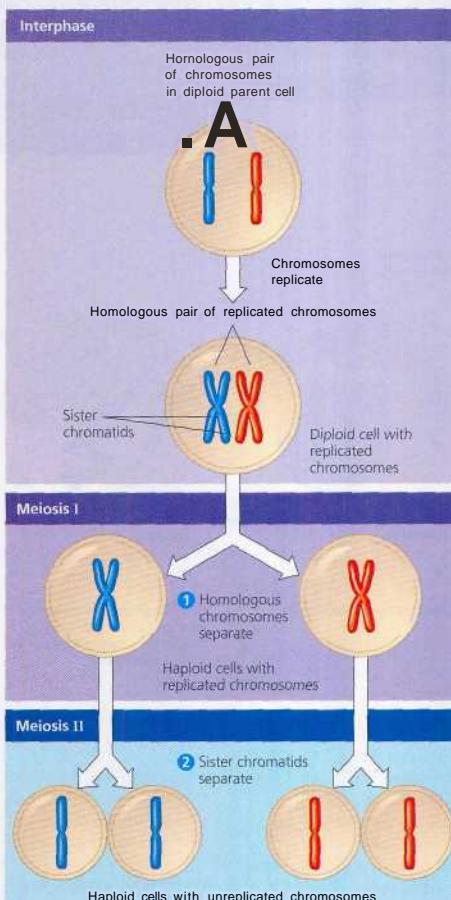

Meiosis reduces the number of chromosome sets from diploid to haploid

Many of the steps of meiosis closely resemble corresponding steps in mitosis. Meiosis, like mitosis, is preceded by the replication of chromosomes. However, this single replication is followed by two consecutive cell divisions, called meiosis I and meiosis II. These divisions result in four daughter cells (rather than the two daughter cells of mitosis), each with only half as many chromosomes as the parent cell.

The Stages of Meiosis

The overview of meiosis in **Figure 13.7** shows how both members of a single homologous pair of chromosomes in a diploid cell are replicated and the copies then sorted into four haploid daughter cells. Recall that sister chromatids are two copies of one chromosome, attached at the centromere; together they make up one duplicated chromosome (see Figure 13.4). In contrast, the two chromosomes of a homologous pair are individual chromosomes that were inherited from different parents; they are not usually connected to each other. Homologues appear alike in the microscope, but they may have different versions of genes at corresponding loci (for example, a gene for freckles on one chromosome and a gene for the absence of freckles at the same locus on the homologue).

Figure 13.8, on the next two pages, describes in detail the stages of the two divisions of meiosis for an animal cell whose diploid number is 6. Meiosis halves the total number of chro-

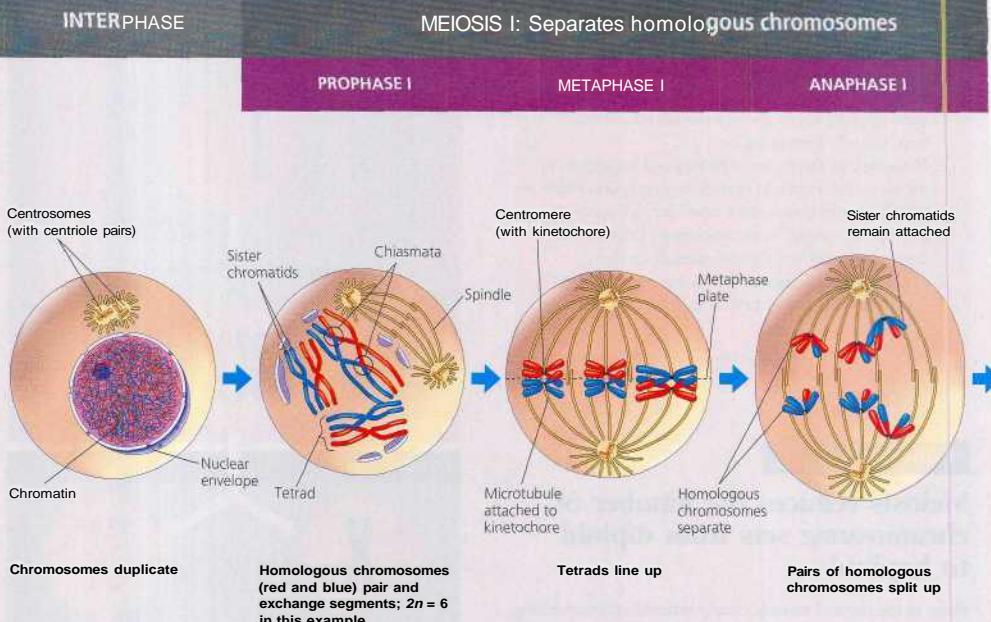

A Figure 13.7 Overview of meiosis: how meiosis reduces chromosome number. After the chromosomes replicate in interphase, the diploid cell divides twice, yielding four haploid daughter cells. This overview tracks just one pair of homologous chromosomes, which for the sake of simplicity are drawn in the condensed state throughout (they would not normally be condensed during interphase). The red chromosome was inherited from the female parent, the blue chromosome from the male parent.

mosomes in a very specific way reducing the number of sets from two to one, with each daughter cell receiving one set of chromosomes. Study Figure 13.8 thoroughly before going on to the next section.

Figure 13.8

Exploring The Meiotic Division of an Animal Cell

Interphase

- Chromosomes replicate during S phase but remain uncondensed.
- Each replicated chromosome consists of two genetically identical sister chromatids connected at the centromere.
- The centrosome replicates, forming two centrosomes.

Prophase I

- This phase typically occupies more than 90% of the time required for meiosis.
- Chromosomes begin to condense.
- Homologous chromosomes loosely pair along their lengths, precisely aligned gene by gene.

- In crossing over, the DNA molecules in nonsister chromatids break at corresponding places and then rejoin to the other's DNA.
- In synapsis, a protein structure called the synaptonemal complex forms between homologues, holding them tightly together along their lengths.

- The synaptonemal complex disassembles in late prophase, and each chromosome pair becomes visible in the microscope as a tetrad, a group of four chromatids.
- Each tetrad has one or more chiasmata, criss-crossed regions where crossing over has occurred; these hold the

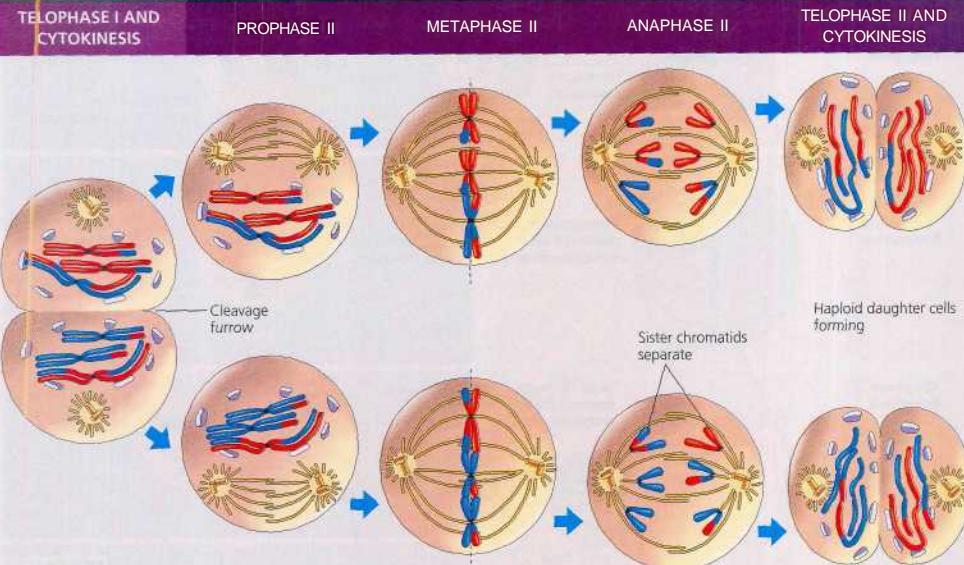

chromosome of each pair facing each pole.

- Both chromatids of a homologue are attached to kinetochore microtubules from one pole; those of the other homologue are attached to microtubules from the opposite pole.

Anaphase I

- The chromosomes move toward the poles, guided by the spindle apparatus.
- Sister chromatids remain attached at the centromere and move as a single unit toward the same pole.
- Homologous chromosomes, still in pairs, move toward opposite poles.

MEIOSIS II: Separates sister chromatids

Two haploid cells form; chromosomes are still double

During another round of cell division, the sister chromatids finally separate; four haploid daughter cells result, containing single chromosomes

Telophase I and Cytokinesis

- At the beginning of telophase I, each half of the cell has a complete haploid set of chromosomes, but each chromosome is still composed of two sister chromatids~
 - Cytokinesis (division of the cytoplasm) usually occurs simultaneously with Telophase I, forming two haploid daughter cells.
 - In animal cells, a cleavage furrow forms. (In plant cells, a cell plate forms.)
- t* In some but not all species, the chromosomes decondense and the nuclear envelope and nucleoli re-form.

- No chromosome replication occurs between the end of meiosis I and the beginning of meiosis II, as the chromosomes are already replicated.

Prophase II

- A spindle apparatus forms.
- In late prophase II (not shown here), chromosomes, each still composed of two chromatids, move toward the metaphase II plate.

Metaphase II

- The chromosomes are positioned on the metaphase plate as in mitosis.
- Because of crossing over in meiosis I, the two sister

chromatids of each chromosome are *not* genetically identical.

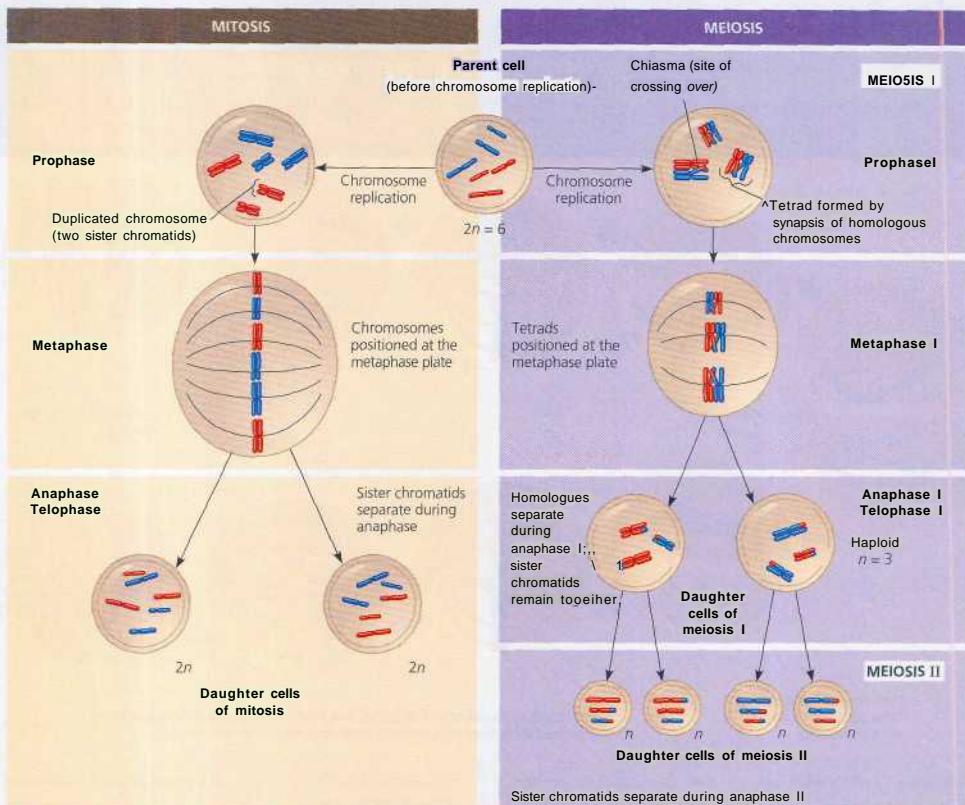

- The kinetochores of sister chromatids are attached to microtubules extending from opposite poles.

Anaphase II

- The centromeres of each chromosome finally separate, and the sister chromatids come apart.
- The sister chromatids of each chromosome now move as two individual chromosomes toward opposite poles.

Telophase II and Cytokinesis

- Nuclei form, the chromosomes begin decondensing, and cytokinesis occurs.
- The meiotic division of one parent cell produces four daughter cells, each with a haploid set of (unreplicated) chromosomes.
- Each of the four daughter cells is genetically distinct from the other daughter cells and from the parent cell.

SUMMARY

| Property | Mitosis | Meiosis |
|--|---|--|
| DNA replication | Occurs during interphase before mitosis begins | Occurs during interphase before meiosis I begins |
| Number of divisions | One, including prophase, metaphase, anaphase, and telophase | Two, each including prophase, metaphase, anaphase, and telophase |
| Synapsis of homologous chromosomes | Does not occur | Occurs during prophase I, forming tetrads (groups of four chromatids); is associated with crossing over between non-sister chromatids |
| Number of daughter cells and genetic composition | Two, each diploid ($2n$) and genetically identical to the parent cell | Four, each haploid (n), containing half as many chromosomes as the parent cell; genetically different from the parent cell and from each other |
| Role in the animal body | Enables multicellular adult to arise from zygote; produces cells for growth and tissue repair | Produces gametes; reduces number of chromosomes by half and introduces genetic variability among the gametes |

Hi HH

A Figure 13.9 A comparison of mitosis and meiosis.

A Comparison of Mitosis and Meiosis

Now let's summarize the key differences between meiosis and mitosis. Meiosis reduces the number of chromosome sets from two (diploid) to one (haploid), whereas mitosis conserves the number of chromosome sets. Therefore, mitosis produces daughter cells genetically identical to their parent cell and to each other, whereas meiosis produces cells that differ genetically from their parent cell and from each other.

Figure 13.9 compares mitosis and meiosis. Three events are unique to meiosis, and all three occur during meiosis I:

1. Synapsis and crossing over. During prophase I, duplicated homologous chromosomes line up and become physically connected along their lengths by a zipper-like protein structure, the *synaptonemal complex*; this process is called synapsis. Genetic rearrangement between nonsister chromatids, known as crossing over, also occurs during prophase I. Following disassembly of the synaptonemal complex in late prophase, the four chromatids of a homologous pair are visible in the light microscope as a tetrad. Each tetrad normally contains at least one X-shaped region called a chiasma (plural, *chiasmata*), the physical manifestation of crossing over. Synapsis and crossing over normally do not occur during mitosis.
2. Tetads on the metaphase plate. At metaphase I of meiosis, paired homologous chromosomes (tetads) are positioned on the metaphase plate, rather than individual replicated chromosomes, as in mitosis.
3. Separation of homologues. At anaphase I of meiosis, the duplicated chromosomes of each homologous pair move toward opposite poles, but the sister chromatids of each duplicated chromosome remain attached. In mitosis, sister chromatids separate.

Meiosis I is called the *reductional division* because it halves the number of chromosome sets per cell—a reduction from two sets (the diploid state) to one set (the haploid state). The sister chromatids then separate during the second meiotic division, meiosis II, producing haploid daughter cells. The mechanism for separating sister chromatids is virtually identical in meiosis II and mitosis.

Concept Check 13.3

1. Using the concept of chromosome sets, explain briefly how mitosis conserves chromosome number, whereas meiosis reduces the number of chromosomes by half.
2. How are the chromosomes in a cell at metaphase of mitosis similar to and different from the chromosomes in a cell at metaphase of meiosis II?

For suggested answers, see Appendix A.

Concept 13.4

Genetic variation produced in sexual life cycles contributes to evolution

How do we account for the genetic variation illustrated in Figure 13.1? As you will learn in later chapters, mutations are the original source of genetic diversity: These changes in an organism's DNA create different versions of genes. Once these differences arise, reshuffling of the versions during sexual reproduction produces the variation that results in each member of a species having its own unique combination of traits.

Origins of Genetic Variation Among Offspring

In species that reproduce sexually, the behavior of chromosomes during meiosis and fertilization is responsible for most of the variation that arises each generation. Let's examine three mechanisms that contribute to the genetic variation arising from sexual reproduction: independent assortment of chromosomes, crossing over, and random fertilization.

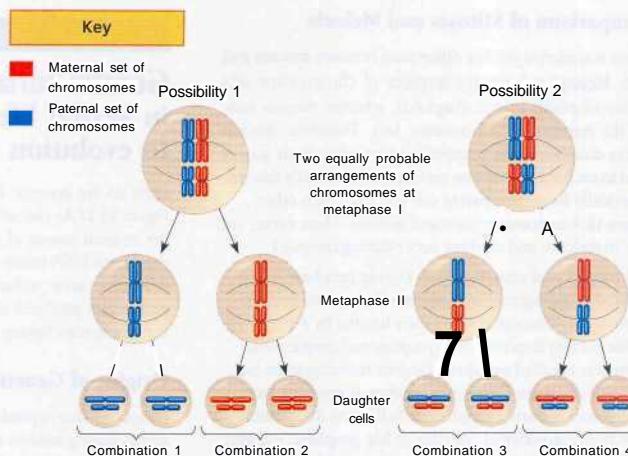

Independent Assortment of Chromosomes

One aspect of sexual reproduction that generates genetic variation is the random orientation of homologous pairs of chromosomes at metaphase of meiosis I. At metaphase I, the homologous pairs, each consisting of one maternal and one paternal chromosome, are situated on the metaphase plate. (Note that the terms *maternal* and *paternal* refer, respectively, to the mother and father of the individual whose cells are undergoing meiosis.) Each pair may orient with either its maternal or paternal homologue closer to a given pole—its orientation is as random as the flip of a coin. Thus, there is a 50% chance that a particular daughter cell of meiosis I will get the maternal chromosome of a certain homologous pair and a 50% chance that it will receive the paternal chromosome.

Because each homologous pair of chromosomes is positioned independently of the other pairs at metaphase I, the first meiotic division results in each pair sorting its maternal and paternal homologues into daughter cells independently of every other pair. This is called *independent assortment*. Each daughter cell represents one outcome of all possible combinations of maternal and paternal chromosomes. As shown in **Figure 13.10** on the next page, the number of combinations possible for daughter cells formed by meiosis of a diploid cell with two homologous pairs of chromosomes ($2^2 = 4$) is four. Note that only two of the four combinations of daughter cells shown in the figure would result from meiosis of a *single* diploid cell, because a single parent cell would have one or the other possible chromosomal arrangement at metaphase I, but not both. However, the population of daughter cells resulting from meiosis of a large

number of diploid cells contains all four types in approximately equal numbers. In the case of $n = 3$, eight combinations of chromosomes are possible for daughter cells. More generally, the number of possible combinations when chromosomes sort independently during meiosis is 2^n , where n is the haploid number of the organism.

In the case of humans, the haploid number (n) in the formula is 23. Thus, the number of possible combinations of maternal and paternal chromosomes in the resulting gametes is 2^{23} , or about 8 million. Each gamete that you produce in your lifetime contains one of roughly 8 million possible combinations of chromosomes inherited from your mother and father.

A Figure 13.10 The independent assortment of homologous chromosomes in meiosis.

Crossing Over

As a consequence of the independent assortment of chromosomes during meiosis, each of us produces a collection of gametes differing greatly in their combinations of the chromosomes we inherited from our two parents. Figure 13.10 suggests that each individual chromosome in a gamete is exclusively maternal or paternal in origin. In fact, this is *not* the case, because crossing over produces recombinant chromosomes, individual chromosomes that carry genes (DNA) derived from two different parents (Figure 13.11).

Crossing over begins very early in prophase I, as homologous chromosomes pair loosely along their lengths. Each gene on one homologue is aligned precisely with the corresponding gene on the other homologue. In a single crossover event, the DNA molecules of two *nonsister* chromatids—one maternal and one paternal chromatid of a homologous pair—are broken at the same place and then rejoined to each other's DNA. That is, the segment of each sister chromatid from the break point to the end is joined to the rest of the other chromatid. In effect, two homologous segments trade places, or cross over, producing chromosomes with new combinations of maternal and paternal genes (see Figure 13.11).

In humans, an average of one to three crossover events occur per chromosome pair, depending on the size of the chromosomes and the position of their centromeres. Recent research indicates that, in some species, crossing over may be essential for synapsis and the proper assortment of chromosomes in meiosis I. However, the exact relationship between crossing over and synapsis is not yet fully understood and seems to vary among species.

At metaphase II, chromosomes that contain one or more recombinant chromatids can be oriented in two alternative, nonequivalent ways with respect to other chromosomes,

because their sister chromatids are no longer identical twins. The independent assortment of these nonidentical sister chromatids during meiosis II increases even more the number of genetic types of daughter cells that can result from meiosis.

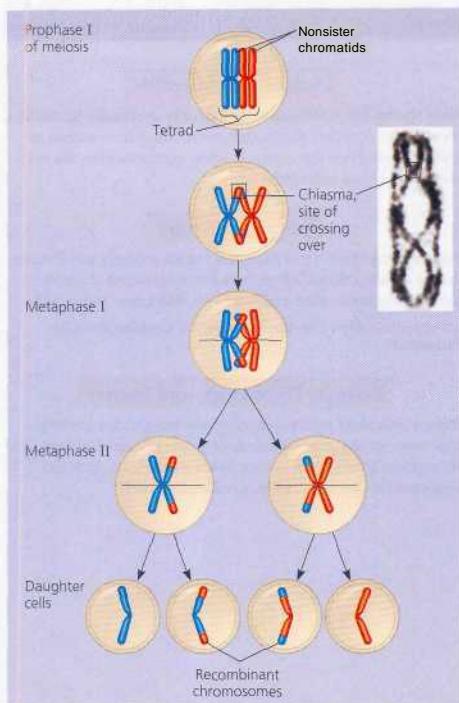

You will learn more about crossing over in Chapter 15. The important point for now is that crossing over, by combining DNA inherited from two parents into a single chromosome, is an important source of genetic variation in sexual life cycles

Random Fertilization

The random nature of fertilization adds to the genetic variation arising from meiosis. In humans, for instance, each male and female gamete represents one of approximately 8 million possible chromosome combinations due to independent assortment during meiosis. The fusion of a single male gamete with a single female gamete during fertilization will produce a zygote with any of about 64 trillion ($8\text{ million} \times 8\text{ million}$) diploid combinations. (If you calculate $2^{23} \times 2^{23}$ exactly, you will find that the total is actually over 70 trillion.) Adding in the variation brought about by crossing over, the number of possibilities is truly astronomical. No wonder brothers and sisters can be so different. You really *are* unique.

Evolutionary Significance of Genetic Variation Within Populations

Now that you've learned how new combinations of genes arise among offspring in a sexually reproducing population, let's see how the genetic variation in a population relates to evolution. Darwin recognized that a population evolves through the differential reproductive success of its variant members. On

A Figure 13.11 The results of crossing over during meiosis.

average, those individuals best suited to the local environment leave the most offspring, thus transmitting their genes. This natural selection results in the accumulation of those genetic variations favored by the environment. As the environment changes, the population may survive if, in each generation, at least some of its members can cope effectively with the new conditions. Different genetic variations may work better than those that previously prevailed. In this chapter, we have seen how sexual reproduction contributes to the genetic variation present in a population, which ultimately results from mutations.

Although Darwin realized that heritable variation is what makes evolution possible, he could not explain why offspring resemble—but are not identical to—their parents. Ironically, Gregor Mendel, a contemporary of Darwin, published a theory of inheritance that helps explain genetic variation, but his discoveries had no impact on biologists until 1900, more than 15 years after Darwin (1809–1882) and Mendel (1822–1884) had died. In the next chapter, you will learn how Mendel discovered the basic rules governing the inheritance of specific traits.

Concept Check 13.4

1. Fruit flies have a diploid number of 8, and honeybees have a diploid number of 32. Assuming no crossing over, is the genetic variation among offspring from the same two parents likely to be greater in fruit flies or honeybees? Explain.
2. Under what circumstances would crossing over during meiosis *not* contribute to genetic variation among daughter cells?

For suggested answers, see Appendix A.

Chapter 13 Review

SUMMARY OF KEY CONCEPTS

Concept 13.1

Offspring acquire genes from parents by inheriting chromosomes

I¹ **Inheritance of Genes** (p. 239) Each gene in an organism's DNA has a specific locus on a certain chromosome. We inherit one set of chromosomes from our mother and one set from our father.

• **Comparison of Asexual and Sexual Reproduction** (p. 239) In asexual reproduction, one parent produces genetically identical offspring by mitosis. Sexual reproduction combines sets of genes from two different parents, forming genetically diverse offspring.

Activity Asexual and Sexual Life Cycles

Concept 13.2

Fertilization and meiosis alternate in sexual life cycles

- **Sets of Chromosomes in Human Cells** (pp. 240–241) Normal human somatic cells have 46 chromosomes made up of two sets—one set of 23 chromosomes derived from each parent. In diploid cells ($2n = 46$), each of the 22 maternal autosomes has a homologous paternal chromosome. The 23rd pair, the sex chromosomes, determines whether the person is female (XX) or male (XY).
- **Behavior of Chromosome Sets in the Human Life Cycle** (pp. 241–242) At sexual maturity, ovaries and testes (the gonads) produce haploid gametes by meiosis, each gamete containing a single set of 23 chromosomes. During fertilization, an ovum and sperm unite, forming a diploid (2n) single-celled zygote, which develops into a multicellular organism by mitosis.
- **The Variety of Sexual Life Cycles** (pp. 242–243) Sexual life cycles differ in the timing of meiosis in relation to fertilization. Multicellular organisms may be diploid or haploid or may alternate between haploid and diploid generations.

Concept 13.3

Meiosis reduces the number of chromosome sets from diploid to haploid

- **The Stages of Meiosis** (pp. 243-245) The two cell divisions of meiosis produce four haploid daughter cells. The number of chromosome sets is reduced from diploid to haploid during meiosis I, the reductional division.
- **A Comparison of Mitosis and Meiosis** (pp. 246-247) Meiosis is distinguished from mitosis by three events of meiosis I; synapsis, which is associated with crossing over; positioning of paired homologous chromosomes (tetrads) on the metaphase plate; and movement of the two chromosomes of each homologous pair (not the sister chromatids) to opposite poles during anaphase I. Meiosis II separates the sister chromatids.

Activity Meiosis Animation

Concept 13.4

Genetic variation produced in sexual life cycles contributes to evolution

- **Origins of Genetic Variation Among Offspring** (pp. 247-249) The events of sexual reproduction that contribute to genetic variation in a population are independent assortment of chromosomes during meiosis, crossing over during meiosis I, and random fertilization of egg cells by sperm.
Activity Origins of Genetic Variation
Investigation How Can the Frequency of Crossing Over Be Estimated?
- **Evolutionary Significance of Genetic Variation Within Populations** (pp. 248-249) Genetic variation is the raw material for evolution by natural selection. Mutations are the original source of this variation; the production of new combinations of variant genes in sexual reproduction generates additional genetic diversity

TESTING YOUR KNOWLEDGE

Evolution Connection

Many species can reproduce either asexually or sexually. Speculate about the evolutionary significance of the switch from asexual to sexual reproduction that occurs in some organisms when the environment becomes unfavorable.

Scientific Inquiry

You prepare a karyotype of an animal you are studying and discover that its somatic cells each have three homologous sets of chromosomes, a condition called triploidy. What might have happened?

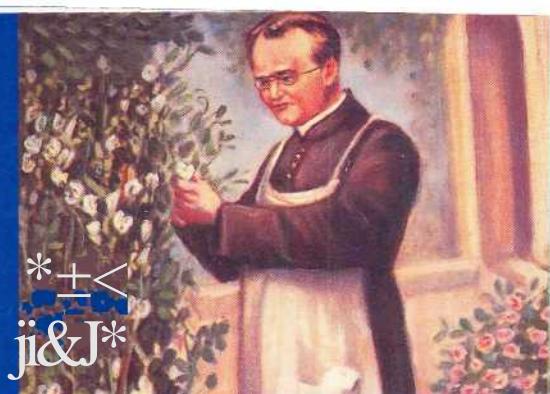

Investigation How Can the Frequency of Crossing Over Be Estimated?

Science, Technology, and Society

Starting with short pieces of needles from straight, fast-growing pine trees, we can grow thousands of genetically identical trees that are superior producers of lumber. What are the short-term and long-term benefits and drawbacks of this approach?

Mendel and the Gene Idea

A Figure 14.1 Gregor Mendel and his garden peas.

I Key Concepts

- 114.1 **Mendel** used the scientific approach to identify two laws of inheritance
- "14.2 The laws of probability govern Mendelian inheritance
- 14.3 Inheritance patterns are often more complex than predicted by simple Mendelian genetics
- 14.4 Many human traits follow Mendelian patterns of inheritance

Overview

Drawing from the Deck of Genes

Even of brown, blue, green, or gray; hair of black, brown, blond, or red—these are just a few examples of heritable variations that we may observe among individuals in a population. What genetic principles account for the transmission of such traits from parents to offspring?

One possible explanation of heredity is a "blending" hypothesis, the idea that genetic material contributed by the two parents mixes in a manner analogous to the way blue and yellow paints blend to make green. This hypothesis predicts that over many generations, a freely mating population will give rise to a uniform population of individuals. However, our everyday observations and the results of breeding experiments with animals and plants contradict such a prediction. The blending hypothesis also fails to explain other phenomena of inheritance, such as traits reappearing after skipping a generation.

An alternative to the blending model is a "panciculate" hypothesis of inheritance: the gene idea. According to this

model, parents pass on discrete heritable units—genes—that retain their separate identities in offspring. An organism's collection of genes is more like a deck of cards or a bucket of marbles than a pail of paint. Like cards and marbles, genes can be sorted and passed along, generation after generation, in undiluted form.

Modern genetics had its genesis in an abbey garden, where a monk named Gregor Mendel documented a particular mechanism of inheritance. The painting in **Figure 14.1** depicts Mendel working with his experimental organism, garden peas. Mendel developed his theory of inheritance several decades before the behavior of chromosomes was observed in the microscope and their significance understood. So in this chapter, we digress from the study of chromosomes to recount how Mendel arrived at his theory. We will also explore how to predict the inheritance of certain characteristics and consider inheritance patterns more complex than those Mendel observed in garden peas. Finally, we will see how the Mendelian model applies to the inheritance of human variations, including hereditary disorders such as sickle-cell disease.

Concept 14.1

Mendel used the scientific approach to identify two laws of inheritance

Mendel discovered the basic principles of heredity by breeding garden peas in carefully planned experiments. As we retrace his work, the key elements of the scientific process that were introduced in Chapter 1 will be evident.

Mendel's Experimental, Quantitative Approach

Mendel grew up on his parents' small farm in a region of Austria that is now part of the Czech Republic. At school in this agricultural area, Mendel and the other children received agricultural training along with basic education. Later, Mendel overcame financial hardship and illness to excel in high school and at the Olmutz Philosophical Institute.

In 1843, at the age of 21, Mendel entered an Augustinian monastery. After failing an examination to become a teacher, he went to the University of Vienna, where he studied from 1851 to 1853. These were very important years for Mendel's development as a scientist. Two professors were especially influential. One was the physicist Christian Doppler, who encouraged his students to learn science through experimentation and trained Mendel to use mathematics to help explain natural phenomena. The second was a botanist named Franz Unger, who aroused Mendel's interest in the causes of variation in plants. These influences came together in Mendel's subsequent experiments with garden peas.

After attending the university, Mendel was assigned to teach at a school where several other teachers shared his enthusiasm for scientific research. What's more, many university professors and researchers lived at the monastery with Mendel. Most important, the monks had a long-standing interest in the breeding of plants. Around 1857, Mendel began breeding garden peas in the abbey garden in order to study inheritance. In itself, this does not seem extraordinary. What was extraordinary was Mendel's fresh approach to very old questions about heredity.

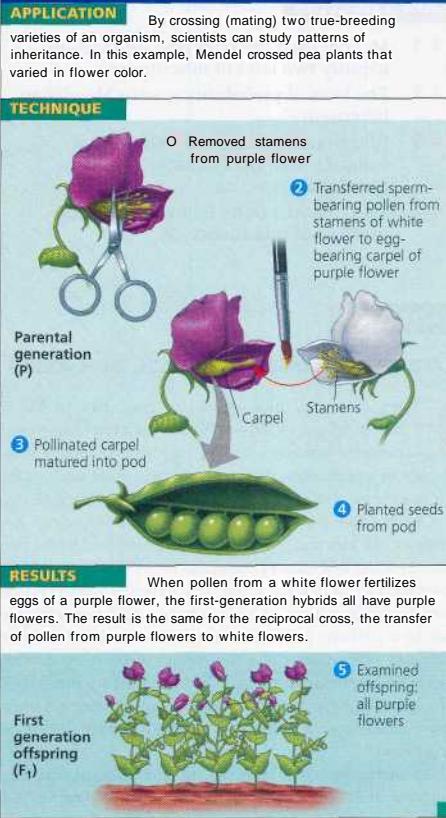

Mendel most likely chose to work with peas because they are available in many varieties. For example, one variety has purple flowers, while another variety has white flowers. A character is a heritable feature, such as flower color, that varies among individuals. Each variant for a character, such as purple or white color for flowers, is called a **trait**. (Some geneticists use the terms *character* and *trait* synonymously but in this book we distinguish between them.)

Another advantage in using peas was that Mendel could strictly control which plants mated with which. The reproductive organs of a pea plant are in its flowers, and each pea flower has both pollen-producing organs (stamens) and an egg-bearing organ (carpel). In nature, pea plants usually self-fertilize: Pollen grains released from the stamens land on the carpel of the same flower, and sperm from the pollen fertilize eggs in the carpel. To achieve cross-pollination (fertilization between different plants), Mendel removed the immature stamens of a plant before they produced pollen and then dusted pollen from another plant onto the altered flowers (**Figure 14.2**). Each resulting zygote then developed into a plant embryo encased in a seed (pea). Whether ensuring self-pollination or executing artificial cross-pollination, Mendel could always be sure of the parentage of new seeds.

Mendel chose to track only those characters that varied in an "either-or" manner rather than a "more-or-less" manner. For example, his plants had either purple flowers or white flowers; there was nothing intermediate between these two varieties. Had Mendel focused instead on characters that varied in a continuum among individuals—seed weight, for example—he would not have discovered the particulate nature of inheritance (you'll learn why later).

Mendel also made sure that he started his experiments with varieties that were true-breeding. When true-breeding plants self-pollinate, all their offspring are of the same variety. For example, a plant with purple flowers is true-breeding if

Figure 14.2
Research Method Crossing Pea Plants

th: seeds produced by self-pollination all give rise to plants that also have purple flowers.

In a typical breeding experiment, Mendel cross-pollinated two contrasting, true-breeding pea varieties—for example, purple-flowered plants and white-flowered plants (see Figure 14.2). This mating, or crossing, of two true-breeding varieties is called hybridization. The true-breeding parents are referred to as the P generation (parental generation), and their hybrid offspring are the F₁ generation (first filial generation, the word *filial* from the Latin word for "son"). Allowing these F₁ hybrids to self-pollinate produces an F₂ generation (second filial generation). Mendel usually followed traits for at least the P, F₁, and F₂ generations. Had Mendel stopped his experiments with the F₁ generation, the basic patterns of inheritance would have eluded him. It was mainly Mendel's quantitative analysis of F₂ plants that revealed the two fundamental principles of heredity that are now known as the law of segregation and the law of independent assortment.

The Law of Segregation

If the blending model of inheritance were correct, the F₁ hybrids from a cross between purple-flowered and white-flowered pea plants would have pale purple flowers, intermediate between the two varieties of the P generation. Notice in Figure 14.2 that the experiment produced a very different result: All the F₁ offspring had flowers just as purple as the purple-flowered parents. What happened to the white-flowered plants' genetic contribution to the hybrids? If it were lost, then the F₁ plants could produce only purple-flowered offspring in the F₂ generation. But when Mendel allowed the F₁ plants to self-pollinate and planted their seeds, the white-flower trait reappeared in the F₂ generation.

Mendel used very large sample sizes and kept accurate records of his results: 705 of the F₂ plants had purple flowers, and 224 had white flowers. These data fit a ratio of approximately three purple to one white (Figure 14.3). Mendel reasoned that the heritable factor for white flowers did not disappear in the F₁ plants, but only the purple-flower factor was affecting flower color in these hybrids. In Mendel's terminology, purple flower color is a *dominant* trait and white flower color is a *recessive* trait. The reappearance of white-flowered plants in the F₂ generation was evidence that the heritable factor causing recessive trait had not been diluted by coexisting with the purple-flower factor in the F₁ hybrids.

Mendel observed the same pattern of inheritance in six other characters, each represented by two different traits (Table 14.1, on the next page). For example, the parental pea seeds either had a smooth, round shape or were wrinkled. When Mendel crossed his two true-breeding varieties, all the F₁ hybrids produced round seeds; this is the dominant trait. In the F₂ generation, 75% of the seeds were

round and 25% were wrinkled—a 3:1 ratio, as in Figure 14.3. Now let's see how Mendel deduced the law of segregation from his experimental results. In our discussion, we will use modern terms instead of some of the terms used by Mendel (for example, we'll use "gene" instead of Mendel's "heritable factor").

Mendel's Model?

Mendel developed a hypothesis, or model, to explain the 3:1 inheritance pattern that he consistently observed among the F₂ offspring in his pea experiments. We describe four related concepts making up this model, the fourth of which is the law of segregation.

First, *alternative versions of genes account for variations in inherited characters*. The gene for flower color in pea plants, for example, exists in two versions, one for purple flowers and the other for white. These alternative versions of a gene are

Figure 14.3

Inquiry When F₁ pea plants with purple flowers are allowed to self-pollinate, what flower color appears in the F₂ generation?

EXPERIMENT

True-breeding purple-flowered pea plants and white-flowered pea plants were crossed (symbolized by x). The resulting F₁ hybrids were allowed to self-pollinate or were cross-pollinated with other F₁ hybrids. Flower color was then observed in the F₂ generation.

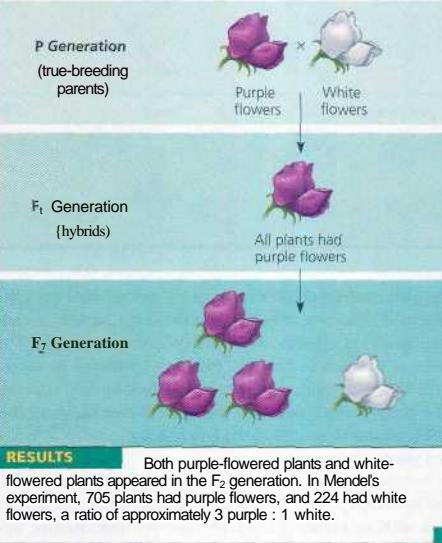

Table 14.1 The Results of Mendel's F₁ Crosses for Seven Characters in Pea Plants

| Character | Dominant Trait | × | Recessive Trait | F ₂ Generation Dominant:Recessive | Ratio |
|-----------------|----------------|---|-----------------|--|---------------|
| Flower color | Purple | × | White | 705:224 | 3:15:1 |
| | | | | | |
| Flower position | Axial | × | Terminal | 651:207 | 3:14:1 |
| | | | | | |
| Seed color | Yellow | × | Green | 6022:2001 | TTT:TTt:TT:tt |
| | | | | | |
| Seed shape | Round | × | Wrinkled | 5474:1850 | 2:Q61 |
| | | | | | |
| Pod shape | Inflated | × | Constricted | 882:299 | 2:95:1 |
| | | | | | |
| Pod color | Green | × | Yellow | 428:152 | 2:82:1 |
| | | | | | |
| Stem length | Tall | × | Dwarf | 787:277 | 2:84:1 |
| | | | | | |

now called alleles (**Figure 14.4**). Today, we can relate this concept to chromosomes and DNA. As noted in Chapter 13, each gene resides at a specific locus on a specific chromosome. The DNA at that locus, however, can vary somewhat in its sequence of nucleotides and hence in its information content. The purple-flower allele and the white-flower allele are two DNA variations possible at the flower-color locus on one of a pea plant's chromosomes.

Second, *for each character, an organism inherits two alleles, one from each parent*. Remarkably, Mendel made this deduction without knowing about the role of chromosomes. Recall from Chapter 13 that each somatic cell in a diploid

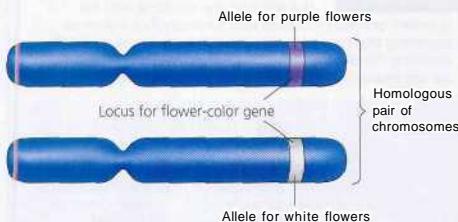

organism has two sets of chromosomes; one set inherited from each parent. Thus, a genetic locus is actually represented twice in a diploid cell. The two alleles at a particular locus may be identical, as in the true-breeding plants of Mendel's P generation. Or the alleles may differ, as in the F₁ hybrids (see Figure 14.4).

Third, *if the two alleles at a locus differ, then one, the dominant allele, determines the organism's appearance; the other, the recessive allele, has no noticeable effect on the organism's appearance*. Thus, Mendel's FT plants had purple flowers because the allele for that trait is dominant and the allele for white flowers is recessive.

The fourth and final part of Mendel's model, now known as the law of segregation, states that *the two alleles for a heritable character separate (segregate) during gamete formation and end up in different gametes*. Thus, an egg or a sperm gets only one of the two alleles that are present in the somatic cells of the organism. In terms of chromosomes, this segregation corresponds to the distribution of homologous chromosomes to different gametes in meiosis (see Figure 13.7). Note that if an organism has identical alleles for a particular character—that is, the organism is true-breeding for that character—then that allele is present in all gametes. But if different alleles are present, as in the F₂ hybrids, then 50% of the gametes receive the dominant allele and 50% receive the recessive allele.

Does Mendel's segregation model account for the 3:1 ratio he observed in the F₂ generation of his numerous crosses? For the flower-color character, the model predicts that the two different alleles present in an F₁ individual will segregate into gametes such that half the gametes will have the purple-flower allele and half will have the white-flower allele. During self-pollination, gametes of each class unite randomly. An egg with a purple-flower allele has an equal chance of being fertilized by a sperm with a purple-flower allele or one with a white-flower allele. Since the same is true for an egg with a white-flower allele, there are a total of four equally likely combinations of sperm and egg. **Figure 14.5** illustrates these combinations using a Punnett square, a handy diagrammatic

device for predicting the allele composition of offspring from a cross between individuals of known genetic makeup. Notice that we use a capital letter to symbolize a dominant allele and a lowercase letter for a recessive allele. In our example, P is the purple-flower allele, and p is the white-flower allele.

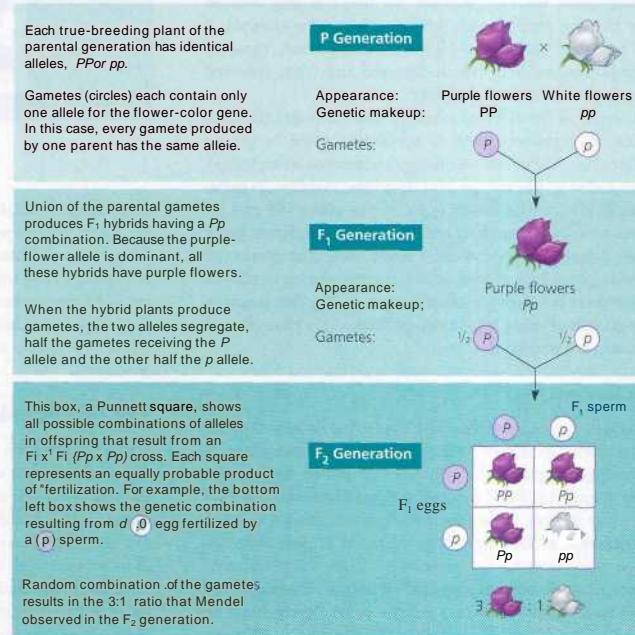

A Figure 14.4 Alleles, alternative versions of a gene. A somatic cell has two copies of each chromosome (forming a homologous pair) and thus two alleles of each gene, which may be identical or different. This figure depicts an *F₁* pea hybrid with an allele for purple flowers, inherited from one parent, and an allele for white flowers, inherited from the other parent.

What will be the physical appearance of these *F₂* offspring? One-fourth of the plants have inherited two purple-flower alleles; clearly, these plants will have purple flowers. One-half of the *F₂* offspring have inherited one purple-flower allele and one white-flower allele; these plants will also have purple flowers, the dominant trait. Finally, one-fourth of the *F₂* plants have inherited two white-flower alleles and will, in fact, express the recessive trait. Thus, Mendel's model accounts for the 3:1 ratio of traits that he observed in the *F₂* generation.

Useful Genetic Vocabulary

An organism having a pair of identical alleles for a character is said to be homozygous for the gene controlling that character. A pea plant that is true-breeding for purple flowers (PP) is an example. Pea plants with white flowers are also homozygous, but for the recessive allele (pp). If we cross dominant homozygotes with recessive homozygotes, as in the parental (P generation) cross of Figure 14.5, every offspring will have two different alleles—*Pp* in the case of the *F₁* hybrids of our flower-color experiment. An organism that has two different alleles for a gene is said to be heterozygous for that gene. Unlike

• Figure 14.5 Mendel's law of segregation. This diagram shows the genetic makeup of the generations in Figure 14.3. It illustrates Mendel's model for inheritance of the alleles of a single gene. Each plant has two alleles for the gene controlling flower color, one allele inherited from each parent. To construct a Punnett square, list all the possible female gametes along one side of the square and all the possible male gametes along an adjacent side. The boxes represent the offspring resulting from all the possible unions of male and female gametes.

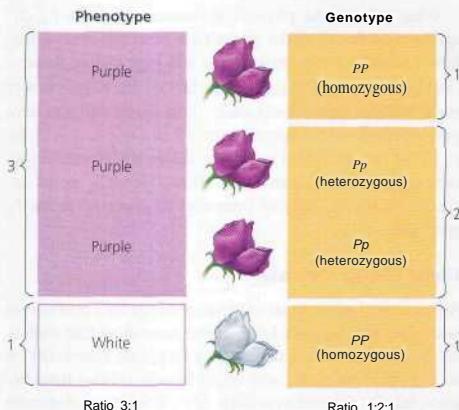

Figure 14.6 Phenotype versus genotype. Grouping F_2 offspring from a cross for flower color according to phenotype results in the typical 3:1 phenotypic ratio. In terms of genotype, however, there are actually two categories of purple-flowered plants, PP (homozygous) and Pp (heterozygous), giving a 1:2:1 genotypic ratio.

homozygotes, heterozygotes are not true-breeding because they produce gametes with different alleles—for example, P and p in the F_1 hybrids of Figure 14.5. As a result, those F_1 hybrids produce both purple-flowered and white-flowered offspring when they self-pollinate.

Because of the different effects of dominant and recessive alleles, an organism's traits do not always reveal its genetic composition. Therefore, we distinguish between an organism's traits, called its phenotype, and its genetic makeup, its genotype. In the case of flower color in pea plants, PP and Pp plants have the same phenotype (purple) but different genotypes. **Figure 14.6** reviews these terms. Note that phenotype refers to physiological traits as well as traits relating directly to appearance. For example, there is a pea variety that lacks the normal trait of being able to self-pollinate. This physiological variation is a phenotype.

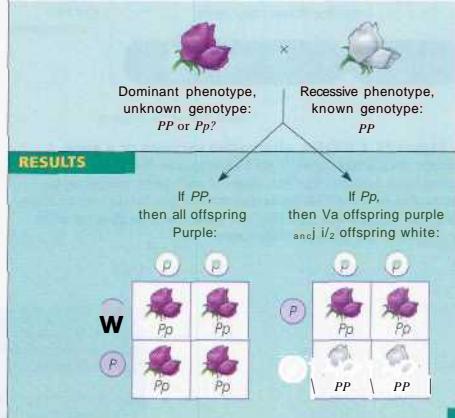

The Testcross

Suppose we have a pea plant that has purple flowers. We cannot tell from its flower color if this plant is homozygous or heterozygous because the genotypes PP and Pp result in the same phenotype. But if we cross this pea plant with one having white flowers, the appearance of the offspring will reveal the genotype of the purple-flowered parent (**Figure 14.7**). Because white flowers is a recessive trait, the white-flowered parent must be homozygous (pp). If all the offspring of the cross have purple flowers, then the other parent must be homozygous for the dominant allele, because a $PP \times pp$

Figure 14.7 Research Method The Testcross

APPLICATION An organism that exhibits a dominant trait, such as purple flowers in pea plants, can be either homozygous for the dominant allele or heterozygous. To determine the organism's genotype, geneticists can perform a testcross.

TECHNIQUE In a testcross, the individual with the unknown genotype is crossed with a homozygous individual expressing the recessive trait (white flowers in this example). By observing the phenotypes of the offspring resulting from this cross, we can deduce the genotype of the purple-flowered parent.

cross produces all Pp offspring. But if both the purple and the white phenotypes appear among the offspring, then the purple-flowered parent must be heterozygous. The offspring of a $Pp \times pp$ cross will have a 1:1 phenotypic ratio. This breeding of a recessive homozygote with an organism of dominant phenotype but unknown genotype is called a testcross. It was devised by Mendel and continues to be an important tool of geneticists.

The Law of Independent Assortment

Mendel derived the law of segregation by performing breeding experiments in which he followed only a *single* character, such as flower color. All the F_1 progeny produced in his crosses of true-breeding parents were monohybrids, meaning that they were heterozygous for one character. We refer to a cross between such heterozygotes as a *monohybrid cross*.

Mendel identified his second law of inheritance by following two characters at the same time. For instance, two of the seven characters Mendel studied were seed color and seed

shape. Seeds may be either yellow or green. They also may be either round (smooth) or wrinkled. From single-character crosses, Mendel knew that the allele for yellow seeds is dominant (Y) and that the allele for green seeds is recessive (y). For the seed-shape character, the allele for round is dominant (R), and the allele for wrinkled is recessive (r).

Imagine crossing two true-breeding pea varieties differing in *both* of these characters—a parental cross between a plant with yellow-round seeds ($YYRR$) and a plant with green-wrinkled seeds ($yyrr$). The F_1 plants will be **dihybrids**, heterozygous for both characters ($YyRr$). But are these two characters, seed color and seed shape, transmitted from parents to offspring as a package? Put another way, will the Y and R alleles always stay together, generation after generation? Or are seed color and seed shape inherited independently of each other? **Figure 14.8** illustrates how a *dihybrid cross*, a cross between F_1 dihybrids, can determine which of these two hypotheses is correct.

The F_1 plants, of genotype $YyRr$, exhibit both dominant phenotypes, yellow seeds with round shapes, no matter which hypothesis is correct. The key step in the experiment is to see what happens when F_1 plants self-pollinate and produce F_2 offspring. If the hybrids must transmit their alleles in the same combinations in which they were inherited from the P generation, then there will only be two classes of gametes: YR and yr . This hypothesis predicts that the phenotypic ratio of the F_2 generation will be 3:1, just as in a monohybrid cross (see Figure 14.8).

The alternative hypothesis is that the two pairs of alleles segregate independently of each other. In other words, genes are packaged into gametes in all possible allelic combinations, as long as each gamete has one allele for each gene. In our example, four classes of gametes would be produced by an F_1 plant in equal quantities: YR , Yr , yR , and yr . If sperm of the four classes are mixed with eggs of the four classes, there will be 16 (4×4) equally probable ways in which the alleles can combine in the F_2 generation, as shown in the Punnett square on the right in Figure 14.8. These combinations make up four phenotypic categories with a ratio of 9:3:3:1 (nine yellow-round to three green-round to three yellow-wrinkled to one green-wrinkled). When Mendel did the

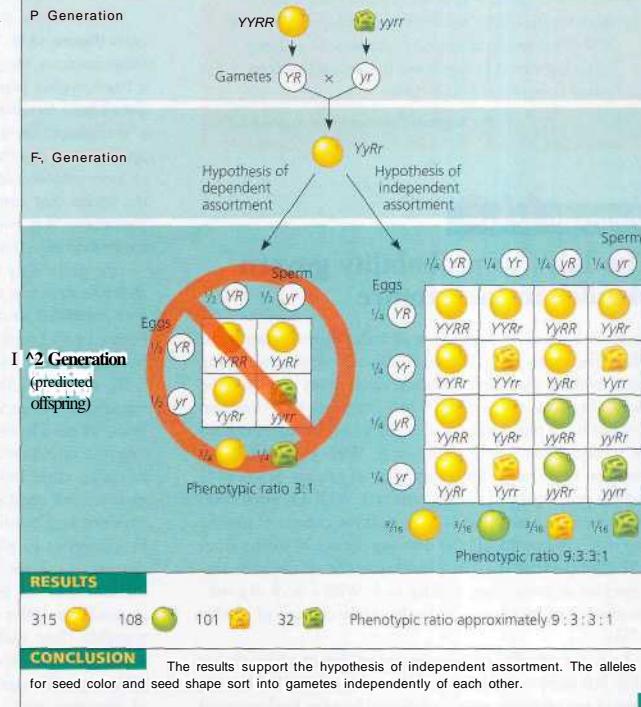

experiment and "scored" (classified) the F_2 offspring, his results were close to the predicted 9:3:3:1 phenotypic ratio, supporting the hypothesis that each character—seed color or seed shape—is inherited independently of the other character.

Mendel tested his seven pea characters in various dihybrid combinations and always observed a 9:3:3:1 phenotypic ratio in the F_2 generation. Notice in Figure 14.8, however, that, if you consider the two characters separately, there is a 3:1 phenotypic ratio for each: three yellow to one green; three round to one wrinkled. As far as a single character is concerned, the alleles segregate as if this were a monohybrid cross. The results of Mendel's dihybrid experiments are the basis for what we

Figure 14.8
Inquiry Do the alleles for seed color and seed shape sort into gametes independently (together) or independently?

EXPERIMENT

Two true-breeding pea plants—one with yellow-round seeds and the other with green-wrinkled seeds—were crossed, producing dihybrid F_1 plants. Self-pollination of the F_1 dihybrids, which are heterozygous for both characters, produced the F_2 generation. The two hypotheses predict different phenotypic ratios. Note that yellow color (Y) and round shape (R) are dominant.

now call the law of independent assortment, which states that *each pair of alleles segregates independently of other pairs of alleles during gamete formation*.

Strictly speaking, this law applies only to genes (allele pairs) located on different chromosomes—that is, on chromosomes that are not homologous. Genes located near each other on the same chromosome tend to be inherited together and have more complex inheritance patterns than predicted by the law of independent assortment. We will describe such inheritance patterns in Chapter 15. All the pea characters studied by Mendel were controlled by genes on different chromosomes (or behaved as though they were); this fortuitous situation greatly simplified interpretation of his multi-character pea crosses. All the examples we consider in the rest of this chapter involve genes located on different chromosomes.

Concept Check 14.1

1. Briefly describe how the experimental results shown in Figure 14.3 support Mendel's "panicle"¹ hypothesis of inheritance.
2. Pea plants heterozygous for flower position and stem length (*AaTt*) are allowed to self-pollinate, and 400 of the resulting seeds are planted. How many offspring would be predicted to be dwarf with terminal flowers? (See Table 14.1.)

For suggested answers, see Appendix A.

Concept 14.2

The laws of probability govern Mendelian inheritance

Mendel's laws of segregation and independent assortment reflect the same rules of probability that apply to tossing coins, rolling dice, and drawing cards from a deck. The probability scale ranges from 0 to 1. An event that is certain to occur has a probability $p = 1$, while an event that is certain *not* to occur has a probability of 0. With a coin that has heads on both sides, the probability of tossing heads is 1, and the probability of tossing tails is 0. With a normal coin, the chance of tossing heads is $\frac{1}{2}$, and the chance of tossing tails is $\frac{1}{2}$. The probability of drawing the ace of spades from a 52-card deck is $\frac{1}{52}$. The probabilities of all possible outcomes for an event must add up to 1. With a deck of cards, the chance of picking a card other than the ace of spades is $\frac{51}{52}$.

Tossing a coin illustrates an important lesson about probability. For every LOSS, the probability of heads is $\frac{1}{2}$. The outcome of any particular toss is unaffected by what has happened

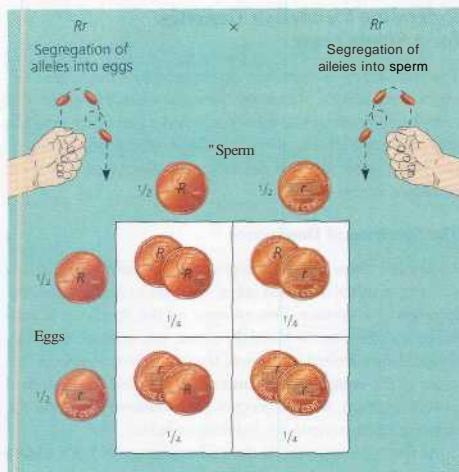

on previous trials. We refer to phenomena such as coin tosses as independent events. Each toss of a coin, whether done sequentially with one coin or simultaneously with many, is independent of every other toss. And like two separate coin tosses, the alleles of one gene segregate into gametes independently of another gene's alleles (the law of independent assortment). Two basic rules of probability can help us predict the outcome of the fusion of such gametes in simple monohybrid crosses and more complicated crosses.

The Multiplication and Addition Rules Applied to Monohybrid Crosses

HOW^T do we determine the probability that two or more independent events will occur together in some specific combination? For example, what is the chance that two coins tossed simultaneously will both land heads up? The *multiplication rule* states that to determine this probability, we multiply the probability of one event (one coin coming up heads) by the probability of the other event (the other coin coming up heads). By the multiplication rule, then, the probability that, both coins will land heads up is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$.

We can apply the same reasoning to an F₁ monohybridic cross (Figure 14.9). With seed shape in pea plants as the heritable character, the genotype of F₁ plants is *Rr*. Segregation in a heterozygous plant is like flipping a coin: Each egg produced has a $\frac{1}{2}$ chance of carrying the dominant allele (R) and a $\frac{1}{2}$ chance of carrying the recessive allele (r). The same odds apply to each sperm cell produced. For a particular F₂ plant to have wrinkled seeds, the recessive trait, both the egg and the sperm that come together must carry the r allele. The probability that two r alleles will be present in gametes at fertilization is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$ (the probability that the egg will have an r) \times $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$ (the probability that the sperm will have an r). Thus, the multiplication rule tells us that the probability of an F₂ plant with wrinkled seeds (*rr*) is $\frac{1}{4}$ (see the Punnett square in Figure 14.9). Likewise, the probability of an F₂ plant carrying both dominant alleles for seed shape (*RR*) is $\frac{1}{4}$.

To figure out the probability that an F₂ plant from a monohybrid cross will be heterozygous rather than homozygous, we need to invoke a second rule. Notice in Figure 14.9 that the dominant allele can come from the egg and the recessive allele from the sperm, or vice versa. That is, F₂ gametes can combine to produce *Rr* offspring in two independent and mutually exclusive ways: For any particular heterozygous F₂ plant, the dominant allele can come from the egg or the sperm, but not from both. According to the *addition rule*, the probability that any one of two or more mutually exclusive events will occur is calculated by adding together their individual probabilities. As we have just seen, the multiplication rule gives us the individual probabilities to add together. The probability for one possible way of obtaining an F₂ heterozygote—the dominant allele from

A. Figure 14.9 Segregation of alleles and fertilization as chance events. When a heterozygote (Rr) forms gametes, segregation of alleles is like the toss of a coin. We can determine the probability for any genotype among the offspring of two heterozygotes by multiplying together the individual probabilities of an egg and sperm having a particular allele (R or r in this example).

the egg and the recessive allele from the sperm—is Yf. The probability for the other possible way—the recessive allele from the egg and the dominant allele from the sperm—is also ¹A (see Figure 14.9). Using the rule of addition, then, we can calculate the probability of an F₂ heterozygote as $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$.

Solving Complex Genetics Problems with the Rules of Probability

We can also apply the rules of probability to predict the outcome of crosses involving multiple characters. Recall that each allelic pair segregates independently during gamete formation (the law of independent assortment). Thus, a dihybrid or other multi-character cross is equivalent to two or more independent monohybrid crosses occurring simultaneously. By applying what we have learned about monohybrid crosses, we can determine the probability of specific genotypes occurring in the F₂ generation without having to construct unwieldy Punnett squares.

Consider the dihybrid cross between YyRr heterozygotes shown in Figure 14.8. We will focus first on the seed-color character. For a monohybrid cross of Yy plants, the probabilities of the offspring genotypes are ¹A for YY, ¹H for Yy, and ¹Vf for yy. The same probabilities apply to the offspring genotypes for seed shape: ¹fa RR, ¹Hr Rr, and ¹A rr. Knowing these

probabilities, we can simply use the multiplication rule to determine the probability of each of the genotypes in the F₂ generation. For example, the probability of an F₂ plant having the YYRR genotype is ¹A X ¹H = ¹V. This corresponds to the upper left box in the Punnett square on the right in Figure 14.8. To give another example, the probability of an F₂ plant with the YyRR genotype is ¹V (Yy) X ¹H (RR) = ¹V. If you look closely at the Punnett square on the right in Figure 14.8, you will see that 2 of the 16 boxes (YR) correspond to the YyRR genotype.

Now let's see how we can combine the multiplication and addition rules to solve even more complex problems in Mendelian genetics. For instance, imagine a cross of two pea varieties in which we track the inheritance of three characters. Suppose we cross a trihybrid with purple flowers and yellow, round seeds (heterozygous for all three genes) with a plant with purple flowers and green, wrinkled seeds (heterozygous for flower color but homozygous recessive for the other two characters). Using Mendelian symbols, our cross is PpYyRr X Ppyyrr. What fraction of offspring from this cross would be predicted to exhibit the recessive phenotypes for at least two of the three characters?

To answer this question, we can start by listing all genotypes that fulfill this condition: ppYYRr, ppYyrr, PpYYrr, PpYyrr, and ppyyrr. (Because the condition is *at least* two recessive traits, the last genotype, which produces all three recessive phenotypes, counts.) Next, we calculate the probability for each of these genotypes resulting from our PpYyRr X PpYyrr cross by multiplying together the individual probabilities for the allele pairs, just as we did in our dihybrid example. Note that in a cross involving heterozygous and homozygous allele pairs (for example, Yy X yy), the probability of heterozygous offspring is ¹H and the probability of homozygous offspring is ¹H. Finally, we use the addition rule to add together the probabilities for all the different genotypes that fulfill the condition of at least two recessive traits, as shown below.

| | | |
|--------|--|------------------|
| ppyyRr | ¹ A (probability of pp) x ¹ Vf (yy) x ¹ /2 (Rr) | = ¹ V |
| ppYyrr | ¹ V-i x ¹ A x ¹ H | = ¹ V |
| PpYYrr | ¹ V, X ¹ A x ¹ A | = ¹ V |
| PpYyrr | ¹ % X ¹ Yi x ¹ A | = ¹ V |
| ppyyrr | ¹ V i x ¹ V i x ¹ V i | = ¹ V |

Chance of at least two recessive traits = ¹V or ¹V

With practice, you'll be able to solve genetics problems faster by using the rules of probability than by filling in Punnett squares.

We cannot predict with certainty the exact numbers of progeny of different genotypes resulting from a genetic cross. But the rules of probability give us the chance of various outcomes. Usually, the larger the sample size, the closer the results will conform to our predictions. The reason Mendel counted

so many offspring from his crosses is that he understood this statistical feature of inheritance and had a keen sense of the rules of chance.

Concept Check 14.2

- For any gene with a dominant allele C and recessive allele c, what proportions of the offspring from a $CC \times Cc$ cross are expected to be homozygous dominant, homozygous recessive, and heterozygous?
- An organism with the genotype $BbDD$ is mated to one with the genotype $BBDd$. Assuming independent assortment of these two genes, write the genotypes of all possible offspring from this cross and calculate the chance of each genotype occurring using the rules of probability.
- What is the probability that an offspring from the cross in question 2 will exhibit either of the two recessive traits coded by the b and d alleles? Explain.

For suggested answers, see Appendix A.

Concept 14.3

Inheritance patterns are often more complex than predicted by simple Mendelian genetics

In the 20th century, geneticists extended Mendelian principles not only to diverse organisms, but also to patterns of inheritance more complex than Mendel actually described. It was brilliant (and lucky) that Mendel chose pea plant characters that turned out to have a relatively simple genetic basis: Each character he studied is determined by one gene, for which there are only two alleles, one completely dominant to the other.* But these conditions are not met by all heritable characters, even in garden peas. The relationship between genotype and phenotype is rarely so simple. This does not diminish the utility of Mendelian genetics (also called Mendelism), however, because the basic principles of segregation and independent assortment apply even to more complex patterns of inheritance. In this section, we will extend Mendelian genetics to hereditary patterns that were not reported by Mendel.

* There is one exception: **Geneticists** have found that Mendel's flower-position character is actually determined by two genes.

Extending Mendelian Genetics for a Single Gene

The inheritance of characters determined by a single gene deviates from simple Mendelian patterns when alleles are not completely dominant or recessive, when a particular gene has more than two alleles, or when a single gene produces multiple phenotypes. We will describe examples of each of these situations in this section.

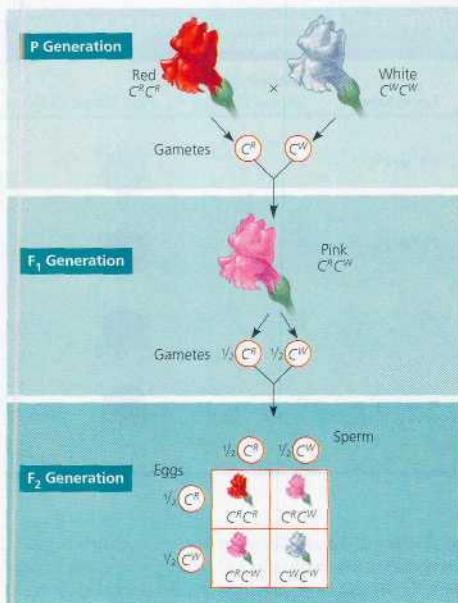

The Spectrum of Dominance

Alleles can show different degrees of dominance and recessiveness in relation to each other. We refer to this range as the *spectrum of dominance*. One extreme on this spectrum is seen in the Y_1 offspring of Mendel's classic pea crosses. These Y_1 plants always looked like one of the two parental varieties because of the complete dominance of one allele over another. In this situation, the phenotypes of the heterozygote and the dominant homozygote are indistinguishable.

At the other extreme is the codominance of both alleles; that is, the two alleles both affect the phenotype in separate, distinguishable ways. For example, the human MN blood group is determined by codominant alleles for two specific molecules located on the surface of red blood cells, the M and N molecules. A single gene locus, at which two allelic variations are possible, determines the phenotype of this blood group. Individuals homozygous for the M allele (MM) have red blood cells with only M molecules; individuals homozygous for the N allele (NN) have red blood cells with only N molecules. But both M and N molecules are present on the red blood cells of individuals heterozygous for the M and N alleles (MN). Note that the MN phenotype is *not* intermediate between the M and N phenotypes. Rather, both the M and N phenotypes are exhibited by heterozygotes, since both molecules are present.

The alleles for some characters fall in the middle of the spectrum of dominance. In this case, the F_1 hybrids have a phenotype somewhere in between the phenotypes of the two parental varieties. This phenomenon, called the incomplete dominance of either allele, is seen when red snapdragons are crossed with white snapdragons: All the F_1 hybrids have pink flowers (Figure 14.10). This third phenotype results from flowers of the heterozygotes having less red pigment than the red homozygotes (unlike the situation in Mendel's pea plants, where the Pp heterozygotes make enough pigment for the flowers to be a purple color indistinguishable from those of PP plants).

At first glance, incomplete dominance of either allele seems to provide evidence for the blending hypothesis of inheritance, which would predict that the red or white trait could never be retrieved from the pink hybrids. In fact, interbreeding F_1 hybrids produces F_2 offspring with a phenotypic ratio of one red to two pink to one white. (Because

A Figure 14.10 Incomplete dominance in snapdragon color. When red snapdragons are crossed with white ones, the F₁ hybrids have pink flowers. Segregation of alleles into gametes of the F₁ plants results in an F₂ generation with a 1:2:1 ratio for both genotype and phenotype. Superscripts indicate alleles for flower color: C^R for red and C^W for white.

heterozygotes have a separate phenotype, the genotypic and phenotypic ratios for the F₂ generation are the same, 1:2:1. The segregation of the red-flower and white-flower alleles in the gametes produced by the pink-flowered plants confirms that the alleles for flower color are heritable factors that maintain their identity in the hybrids; that is, inheritance is particulate.

The Relation Between Dominance and Phenotype. We've now seen that the relative effects of two alleles range from complete dominance of one allele, through incomplete dominance of either allele, to codominance of both alleles. It is important to understand that an allele is not termed *dominant* because it somehow subdues a recessive allele. Recall that **alleles** are simply variations in a gene's nucleotide sequence. When a dominant allele coexists with a recessive allele in a heterozygote, they do not actually interact at all. It is in the pathway from genotype to phenotype that dominance and recessiveness come into play.

To illustrate the relation between dominance and phenotype, we can use one of Mendel's characters—round versus wrinkled pea seed shape. The dominant allele (round) codes for the **synthesis** of an enzyme that helps convert sugar to starch in the seed. The recessive allele (wrinkled) codes for a defective form of this enzyme. Thus, in a recessive homozygote, sugar accumulates in the seed because it is not converted to starch. As the seed develops, the high sugar concentration causes the osmotic uptake of water, and the seed swells. Then when the mature seed dries, it develops wrinkles. In contrast, if a dominant allele is present, sugar is converted to starch, the seeds do not take up excess water, and so the seeds do not wrinkle when they dry. One dominant allele results in enough of the enzyme to convert sugar to starch, and thus dominant homozygotes and heterozygotes have the same phenotype: round seeds.

A closer look at the relation between dominance and phenotype reveals an intriguing fact: For any character, the observed dominance/recessiveness relationship of alleles depends on the level at which we examine phenotype. **Tay-Sachs disease**, an inherited disorder in humans, provides an example. The **brain** cells of a baby with Tay-Sachs disease are unable to metabolize certain lipids because a crucial enzyme does not work properly. As these lipids accumulate in brain cells, an infant begins to suffer seizures, blindness, and degeneration of motor and mental performance. An affected child dies within a few years.

Only children who inherit two copies of the Tay-Sachs allele (homozygotes) have the disease. Thus, at the *organismal* level, the Tay-Sachs allele qualifies as recessive. However, the activity level of the H₂lipid-metabolizing enzyme in heterozygotes is intermediate between that in **individuals** homozygous for the normal allele and that in individuals with Tay-Sachs disease. The intermediate phenotype observed at the *biochemical* level is characteristic of incomplete dominance of either allele. Fortunately, the heterozygote condition does not lead to disease symptoms, apparently because half the normal enzyme activity is sufficient to prevent lipid accumulation in the brain. Extending our analysis to yet another level, we find that heterozygous individuals produce equal numbers of normal and dysfunctional enzyme molecules. Thus, at the *molecular* level, the normal allele and the Tay-Sachs allele are codominant. As you can see, whether alleles appear to be completely dominant, incompletely dominant, or codominant relative to each other depends on which phenotypic trait is considered.

Frequency of Dominant Alleles. Although you might assume that the dominant allele for a particular character would be more common in a population than the recessive allele for that character, this is not necessarily the case. For example, about one baby out of 400 in the United States is born with extra fingers or toes, a condition known as

polydactyly. The allele for the unusual trait of polydactyly is dominant to the allele for the more common trait of five digits per appendage. In other words, 399 out of every 400 people are recessive homozygotes for this character; the recessive allele is far more prevalent than the dominant allele in the population. In Chapter 23, you will learn how the relative frequencies of alleles in a population are affected by natural selection.

Multiple Alleles

Only two alleles exist for the pea characters that Mendel studied, but most genes actually exist in populations in more than two allelic forms. The ABO blood group in humans, for instance, is determined by multiple alleles of a single gene. There are four possible phenotypes for this character: A person's blood group may be either A, B, AB, or O. These letters refer to two carbohydrates—A and B—that may be found on the surface of red blood cells. A person's blood cells may have carbohydrate A (type A blood), carbohydrate B (type B), both (type AB), or neither (type O), as shown schematically in Table 14.2.

The four blood groups result from various combinations of three different alleles for the enzyme (*I*) that attaches the A or B carbohydrate to red blood cells. The enzyme encoded by the I^A allele adds the A carbohydrate, whereas the enzyme encoded by I^B adds the B carbohydrate (the superscripts indicate the carbohydrate). The enzyme encoded by the *i* allele adds neither A nor B. Because each person carries two alleles, six genotypes are possible, resulting in four phenotypes (see Table 14.2). Both the I^A and I^B alleles are dominant to the *i* allele. Thus, $I^A I^A$ and $I^A i$ individuals have type A blood, and $I^B I^B$ and $I^B i$ individuals have type B blood. Recessive homozygotes, ii , have type O blood, because their red blood cells have neither the A nor the B carbohydrate. The I^A and I^B alleles are codominant; both are expressed in the phenotype of $I^A I^B$ heterozygotes, who have type AB blood.

Matching compatible blood groups is critical for safe blood transfusions. For example, if a type A person receives blood from a type B or type AB donor, the recipient's immune system recognizes the "foreign" B substance on the donated blood cells and attacks them. This response causes the donated blood cells to clump together, potentially killing the recipient (see Chapter 43).

Pleiotropy

So far, we have treated Mendelian inheritance as though each gene affects one phenotypic character. Most genes, however, have multiple phenotypic effects, a property called pleiotropy (from the Greek *pleion*, more). For example, pleiotropic alleles are responsible for the multiple symptoms associated with certain hereditary diseases in humans, such as cystic fibrosis

Table 14.2 Determination of ABO Blood Group by Multiple Alleles

| Genotype | Phenotype (Blood Group) | Red Blood Cells |
|----------------------|----------------------------|-----------------|
| $I^A I^A$ or $I^A i$ | A | |
| $I^B I^B$ or $I^B i$ | B | |
| $I^A I^B$ | AB | |
| ii | O | |

and sickle-cell disease, discussed later in this chapter. Considering the intricate molecular and cellular interactions responsible for an organism's development and physiology, it is not surprising that a single gene can affect a number of characteristics in an organism.

Extending Mendelian Genetics for Two or More Genes

Dominance relationships, multiple alleles, and pleiotropy all have to do with the effects of the alleles of a single gene. We now consider two situations in which two or more genes are involved in determining a particular phenotype.

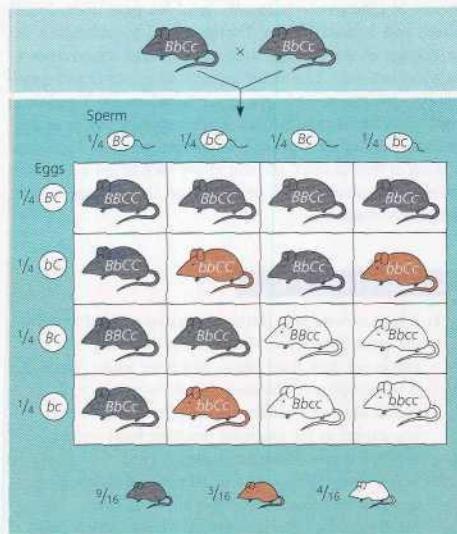

Epistasis

In epistasis (from the Greek for "stopping"), a gene at one locus alters the phenotypic expression of a gene at a second locus. An example will help clarify this concept. In mice and many other mammals, black coat color is dominant to brown. Let's designate *B* and *b* as the two alleles for this character. For a mouse to have brown fur, its genotype must be *bb*. But there is more to the story. A second gene determines whether or not pigment will be deposited in the hair. The dominant allele, symbolized by *C* (for color), results in the deposition of either black or brown pigment, depending on the genotype at the first locus. But if the mouse is homozygous recessive for the second locus (*cc*), then the coat is white (albino), regardless of the genotype at the black/brown locus. The gene for pigment deposition is said to be epistatic to the gene that codes for black or brown pigment.

What happens if we mate black mice that are heterozygous for both genes ($BbCc$)? Although the two genes affect the same phenotypic character (coat color), they follow the law of independent assortment. Thus, our breeding experiment represents an Yi dihybrid cross, like those that produced a 9:3:3:1 ratio in Mendel's experiments. We can use a Punnett square to represent the genotypes of the F_2 offspring (Figure 14.11). As a result of epistasis, the phenotypic ratio among the F_2 offspring is 9 black to 3 brown to 4 (3 + 1) white. Other types of epistatic interactions produce different ratios, but all are modified versions of 9:3:3:1.

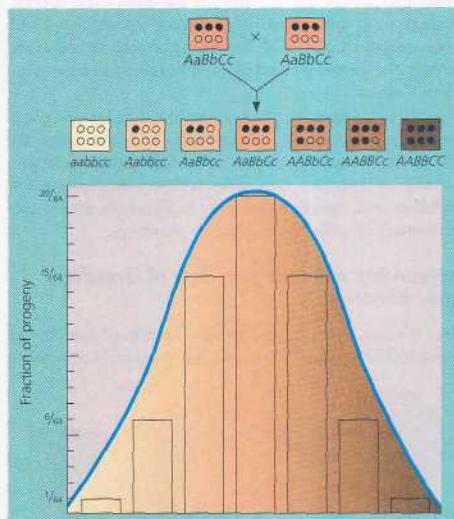

Polygenic Inheritance

Mendel studied characters that could be classified on an either-or basis, such as purple versus white flower color. But for many characters, such as human skin color and height, an either-or classification is impossible because the characters vary in the population along a continuum (in gradations). These are called quantitative characters. Quantitative variation usually indicates polygenic inheritance, an additive effect of two or more genes on a single phenotypic character (the converse of pleiotropy, where a single gene affects several phenotypic characters).

A Figure 14.11 An example of epistasis. This Punnett square illustrates the genotypes and phenotypes predicted for offspring of matings between two black mice of genotype $BbCc$. The C/c gene, which is epistatic to the B/b gene, controls whether or not pigment of any color will be deposited in the hair.

There is evidence, for instance, that skin pigmentation in humans is controlled by at least three separately inherited genes (probably more, but we will simplify). Let's consider three genes, with a dark-skin allele for each gene (A, B, or C) contributing one "unit" of darkness to the phenotype and being incompletely dominant to the other allele (a, b, or c). An $AABBCC$ person would be very dark, while an $aabbcc$ individual would be very light. An $AaBbCc$ person would have skin of an intermediate shade. Because the alleles have a cumulative effect, the genotypes $AaBbCc$ and $AABbcc$ would make the same genetic contribution (three units) to skin darkness. Figure 14.12 shows how this polygenic inheritance could result in a bell-shaped curve, called a normal distribution, for skin darkness among the progeny of hypothetical matings between individuals heterozygous for all three genes. (You are probably familiar with the concept of a normal distribution for class curves of test scores.) Environmental factors, such as exposure to the sun, also affect the skin-color phenotype and help make the graph a smooth curve rather than a stair-like histogram.

4 Figure 14.12 A simplified model for polygenic inheritance of skin color. According to this model, three separately inherited genes affect the darkness of skin. The heterozygous individuals ($AaBbCc$), represented by the two rectangles at the top of this figure, each carry three dark-skin alleles (black circles) and three light-skin alleles (open circles). The variations in genotype and skin color that can occur among offspring from a large number of hypothetical matings between these heterozygotes are shown above the graph. The y-axis represents the fraction of progeny with each skin color. The resulting histogram is smoothed into a bell-shaped curve by environmental factors that affect skin color.

Nature and Nurture: The Environmental Impact on Phenotype

Another departure from simple Mendelian genetics arises when the phenotype for a character depends on environment as well as on genotype. A single tree, locked into its inherited genotype, has leaves that vary in size, shape, and greenness, depending on exposure to wind and sun. For humans, nutrition influences height, exercise alters build, sun-tanning darkens the skin, and experience improves performance on intelligence tests. Even identical twins, who are genetic equals, accumulate phenotypic differences as a result of their unique experiences.

Whether human characteristics are more influenced by genes or the environment—nature or nurture—is a very old and hotly contested debate that we will not attempt to settle here. We can say, however, that a genotype generally is not associated with a rigidly defined phenotype, but rather with a range of phenotypic possibilities due to environmental influences. This phenotypic range is called the norm of reaction for a genotype (**Figure 14.13**). For some characters, such as the ABO blood group, the norm of reaction has no breadth whatsoever; that is, a given genotype mandates a very specific phenotype. In contrast, a person's blood count of red and white cells varies quite a bit, depending on such factors as the altitude, the customary level of physical activity, and the presence of infectious agents.

Generally, norms of reaction are broadest for polygenic characters. Environment contributes to the quantitative nature of these characters, as we have seen in the continuous variation of skin color. Geneticists refer to such characters as multifactorial, meaning that many factors, both genetic and environmental, collectively influence phenotype.

Integrating a Mendelian View of Heredity and Variation

Over the past several pages, we have broadened our view of Mendelian inheritance by exploring the spectrum of dominance

A Figure 14.13 The effect of environment on phenotype.

The outcome of a genotype lies within its norm of reaction, a phenotypic range that depends on the environment in which the genotype is expressed. For example, hydrangea flowers of the same genetic variety range in color from blue-violet to pink, depending on the acidity of the soil.

as well as multiple alleles, pleiotropy, epistasis, polygenic inheritance, and the phenotypic impact of the environment. How can we integrate these refinements into a comprehensive theory of Mendelian genetics? The key is to make the transition from the reductionist emphasis on single genes and *ph**i*-notypic characters to the emergent properties of the organism as a whole, one of the themes of this book.

The term *phenotype* can refer not only to specific characters, such as flower color and blood group, but also to an *organism* in its entirety—all aspects of its physical appearance, internal anatomy, physiology, and behavior. Similarly, the term *genotype* can refer to an organism's entire genetic makeup, not just its alleles for a single genetic locus. In most cases, a genes impact on phenotype is affected by other genes and by the environment. In this integrated view of heredity and variation, an organism's phenotype reflects its overall genotype and unique environmental history.

Considering all that can occur in the pathway from genotype to phenotype, it is indeed impressive that Mendel could uncover the fundamental principles governing the transmission of individual genes from parents to offspring. Mendel's two laws, segregation and independent assortment, explain heritable variations in terms of alternative forms of gene= (hereditary "particles") that are passed along, generation after generation, according to simple rules of probability. This theory of inheritance is equally valid for peas, flies, fishes, birds, and human beings. Furthermore, by extending the principles of segregation and independent assortment to help explain such hereditary patterns as epistasis and quantitative characters, we begin to see how broadly Mendelian applies. From Mendel's abbey garden came a theory of particulate inheritance that anchors modern genetics. In the last section of this chapter, we will apply Mendelian genetics to human inheritance, with emphasis on the transmission of hereditary diseases.

Concept Check 14.3

1. A rooster with gray feathers is mated with a hen of the same phenotype. Among their offspring, 15 chicks are gray, 6 are black, and 8 are white. What is the simplest explanation for the inheritance of these colors in chickens? What phenotypes would you expect in the offspring resulting from a cross between a gray rooster and a black hen?
2. In humans, tall parents tend to have tall children, and short parents tend to have short children. Adult heights, however, vary in the population over a wide range, following a normal bell-shaped curve. Explain these observations.

For suggested answers, see Appendix A.

Concept 14.4

Many human traits follow Mendelian patterns of inheritance

Whereas peas are convenient subjects for genetic research, humans are not. The human generation span is about 20 years, and human parents produce relatively few offspring compared to peas and most other species. Furthermore, breeding experiments like the ones Mendel performed are unacceptable with humans. In spite of these difficulties, the study of human genetics continues to advance, spurred on by the desire to understand our own inheritance. New techniques in molecular biology have led to many breakthrough discoveries, as we will see in Chapter 20, but basic Mendelism endures as the foundation of human genetics.

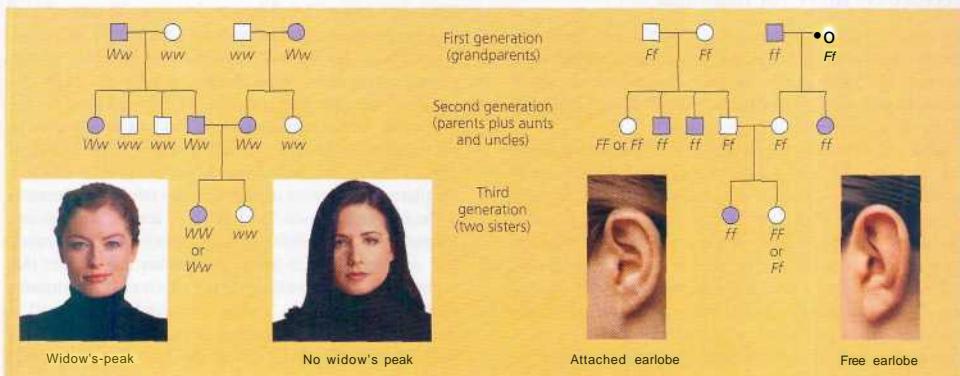

Pedigree Analysis

Unable to manipulate the mating patterns of people, geneticists must analyze the results of matings that have already occurred. They do so by collecting information about a family's

history for a particular trait and assembling this information into a family tree describing the interrelationships of parents and children across the generations—the family pedigree.

Figure 14.14a shows a three-generation pedigree that traces the occurrence of a pointed contour of the hairline on the forehead. This trait, called a widow's peak, is due to a dominant allele, W. Because the widow's-peak allele is dominant, all individuals who lack a widow's peak must be homozygous recessive (ww). The two grandparents with widow's peaks must have the Ww genotype, since some of their offspring are homozygous recessive. The offspring in the second generation who *do* have widow's peaks must also be heterozygous, because they are the products of $Ww \times ww$ matings. The third generation in this pedigree consists of two sisters. The one who has a widow's peak could be either homozygous (WW) or heterozygous (Ww), given what we know about the genotypes of her parents (both Ww).

Figure 14.14b is a pedigree of the same family, but this time we focus on a recessive trait, attached earlobes. We'll use F for the recessive allele and f for the dominant allele, which results in free earlobes. As you work your way through the pedigree, notice once again that you can apply what you have learned about Mendelian inheritance to fill in the genotypes for most individuals.

(a) Dominant trait (widow's peak). This pedigree traces the trait called widow's peak through three generations of a family. Notice in the third generation that the second-born daughter lacks a widow's peak, although both of her parents had the trait. Such a pattern of inheritance supports the hypothesis that the trait is due to a dominant allele. If the trait were due to a recessive allele, and both parents had the recessive phenotype, then *all* of their offspring would also have the recessive phenotype.

(b) Recessive trait (attached earlobe). This is the same family, but in this case we are tracing the inheritance of a recessive trait, attached earlobes. Notice that the first-born daughter in the third generation has attached earlobes, although both of her parents lack that trait (they have free earlobes). Such a pattern is easily explained if the attached-lobe phenotype is due to a recessive allele. If it were due to a dominant allele, then at least one parent would also have had the trait.

A Figure 14.14 Pedigree analysis. In these family trees, squares represent males and circles represent females. A horizontal line connecting a male and female ($Lh-O$) indicates a mating, with offspring listed below in their order of birth from left to right. Shaded squares and circles represent individuals who exhibit the trait being traced.

An important application of a pedigree is to help us predict the future. Suppose that the couple represented in the second generation of Figure 14.14 decide to have one more child. What is the probability that the child will have a widow's peak? This is equivalent to a Mendelian T_1 monohybrid cross ($Ww \times Ww$), and thus the probability that a child will inherit a dominant allele and have a widow's peak is $\frac{1}{2}$ ($\frac{1}{2}WW + \frac{1}{2}Ww$). What is the probability that the child will have attached earlobes? Again, we can treat this as a monohybrid cross ($Ff \times Ff$), but this time we want to know the chance that the offspring will be homozygous recessive (ff). That probability is $\frac{1}{4}$. Finally, what is the chance that the child will have a widow's peak *and* attached earlobes? Assuming that the genes for these two characters are on different chromosomes, the two pairs of alleles will assort independently in this dihybrid cross ($WwFf \times WwFf$). Thus, we can use the multiplication rule: $\frac{1}{2}A \times \frac{1}{4}V = \frac{1}{8}AV$ (chance of widows peak and attached earlobes).

Pedigrees are a more serious matter when the alleles in question cause disabling or deadly hereditary diseases instead of innocuous human variations such as hairline or earlobe configuration. However, for disorders inherited as simple Mendelian traits, the same techniques of pedigree analysis apply.

Recessively Inherited Disorders

Thousands of genetic disorders are known to be inherited as simple recessive traits. These disorders range in severity from relatively mild, such as albinism (lack of pigmentation, which results in susceptibility to skin cancers and vision problems), to life-threatening, such as cystic fibrosis.

How can we account for the recessive behavior of the alleles causing these disorders? Recall that genes code for proteins of specific function. An allele that causes a genetic disorder codes either for a malfunctioning protein or for no protein at all. In the case of disorders classified as recessive, heterozygotes are normal in phenotype because one copy of the normal allele produces a sufficient amount of the specific protein. Thus, a recessively inherited disorder shows up only in the homozygous individuals who inherit one recessive allele from each parent. We can symbolize the genotype of such individuals as aa and the genotypes of individuals with the normal phenotype as either AA or Aa . Although phenotypically normal with regard to the disorder, heterozygotes (Aa) may transmit the recessive allele to their offspring and thus are called carriers.

Most people who have recessive disorders are born to parents who are carriers of the disorder but themselves have a normal phenotype. A mating between two carriers corresponds to a Mendelian F_1 monohybrid cross ($Aa \times Aa$); the genotypic ratio for the offspring is $1 AA : 2 Aa : 1 aa$. Thus, each child has a $\frac{1}{4}$ chance of inheriting a double dose of the recessive allele and being affected by the disorder.

From the genotypic ratio, we also can see that out of three offspring with the *normal* phenotype (one AA plus two Aa), two are predicted to be heterozygous carriers, a $\frac{2}{3}$ chance. Recessive homozygotes could also result from $Aa \times aa$ and $aa \times aa$ matings, but if the disorder is lethal before reproductive age or results in sterility, no aa individuals will reproduce. Even if recessive homozygotes are able to reproduce, such individuals will still account for a much smaller percentage of the population than heterozygous carriers (for reasons we will examine in Chapter 23).

In general, a genetic disorder is not evenly distributed among all groups of humans. For example, the incidence of Tay-Sachs disease, which we described earlier in this chapter, is disproportionately high among Ashkenazic Jews, Jewish people whose ancestors lived in central Europe. In that population, Tay-Sachs disease occurs in one out of 3,600 births, about 100 times greater than the incidence among non-Jews or Mediterranean (Sephardic) Jews. Such an uneven distribution results from the different genetic histories of the world's peoples during less technological times, when populations were more geographically (and hence genetically) isolated. We will now examine two other recessively inherited diseases, which are also more prevalent in some groups than others.

Cystic Fibrosis

The most common lethal genetic disease in the United States is **cystic fibrosis**, which strikes one out of every 2,500 people of European descent but is much rarer in other groups. Among people of European descent, one out of 25 (4%) is a carrier of the cystic fibrosis allele. The normal allele for this gene codes for a membrane protein that functions in chloride ion transport between certain cells and the extracellular fluid. These chloride transport channels are defective or absent in the plasma membranes of children who inherit two recessive alleles for cystic fibrosis. The result is an abnormally high concentration of extracellular chloride, which causes the mucus that coats certain cells to become thicker and stickier than normal. The mucus builds up in the pancreas, lungs, digestive tract, and other organs, leading to multiple (pleiotropic) effects, including poor absorption of nutrients from the intestines, chronic bronchitis, foul stools, and recurrent bacterial infections. Recent research indicates that the extracellular chloride also contributes to infection by disabling a natural antibiotic made by some body cells. When immune cells come to the rescue, their remains add to the mucus, creating a vicious cycle.

If untreated, most children with cystic fibrosis die before their fifth birthday. Gentle pounding on the chest to clear mucus from clogged airways, daily doses of antibiotics to prevent infection, and other preventive treatments can prolong life. In the United States, more than half of the people with cystic fibrosis now survive into their late 20s or even 30s and beyond.

Sickle-Cell Disease

The most common inherited disorder among people of African descent is **sickle-cell disease**, which affects one out of 400 African-Americans. Sickle-cell disease is caused by the substitution of a single amino acid in the hemoglobin protein of red blood cells. When the oxygen content of an affected individual's blood is low (at high altitudes or under physical stress, for instance), the sickle-cell hemoglobin molecules aggregate into long rods that deform the red cells into a sickle shape (see Figure 5.21). Sickled cells may clump and clog small blood vessels, often leading to other symptoms throughout the body, including physical weakness, pain, organ damage, and even paralysis. The multiple effects of a double dose of the sickle-cell allele are another example of pleiotropy. Regular blood transfusions can ward off brain damage in children with sickle-cell disease, and new drugs can help prevent or treat other problems, but there is no cure.

Although two sickle-cell alleles are necessary for an individual to manifest full-blown sickle-cell disease, the presence of one sickle-cell allele can affect the phenotype. Thus, at the organismal level, the normal allele is incompletely dominant to the sickle-cell allele. Heterozygotes, said to have *sickle-cell trait*, are usually healthy but they may suffer some sickle-cell symptoms during prolonged periods of reduced blood oxygen. At the molecular level, the two alleles are codominant; both normal and abnormal (sickle-cell) hemoglobins are made in heterozygotes.

About one out of ten African-Americans has sickle-cell trait, an unusually high frequency of heterozygotes for an allele with severe detrimental effects in homozygotes. One explanation for this is that a single copy of the sickle-cell allele reduces the frequency and severity of malaria attacks, especially among young children. The malaria parasite spends part of its life cycle in red blood cells (see Figure 28.11), and the presence of even heterozygous amounts of sickle-cell hemoglobin results in lower parasite densities and hence reduced malaria symptoms. Thus, in tropical Africa where infection with the malaria parasite is common, the sickle-cell allele is both boon and bane. The relatively high frequency of African-Americans with sickle-cell trait is a vestige of their African roots.

Hating of Close Relatives

When a disease-causing recessive allele is rare, it is relatively unlikely that two carriers of the same harmful allele will meet and mate. However, if the man and woman are close relatives (for example, siblings or first cousins), the probability of passing on recessive traits increases greatly. These are called consanguineous ("same blood") matings, and they are indicated in pedigrees by double lines. Because people with recent common ancestors are more likely to carry the same recessive alleles than are unrelated people, it is more likely that a mating of close relatives will produce offspring homozygous for recessive traits—

including harmful ones. Such effects can be observed in many types of domesticated and zoo animals that have become inbred.

There is debate among geneticists about the extent to which human consanguinity increases the risk of inherited diseases. Many deleterious alleles have such severe effects that a homozygous embryo spontaneously aborts long before birth. Still, most societies and cultures have laws or taboos forbidding marriages between close relatives. These rules may have evolved out of empirical observation that in most populations, stillbirths and birth defects are more common when parents are closely related. Social and economic factors have also influenced the development of customs and laws against consanguineous marriages.

Dominantly Inherited Disorders

Although many harmful alleles are recessive, a number of human disorders are due to dominant alleles. One example is *achondroplasia*, a form of dwarfism with a prevalence of one among every 25,000 people. Heterozygous individuals have the dwarf phenotype (Figure 14.15). Therefore, all people who are not achondroplastic dwarfs—99.99% of the population—are homozygous for the recessive allele. Like the presence of extra fingers or toes mentioned earlier, achondroplasia is a trait for

which the recessive allele is much more prevalent than the corresponding dominant allele.

Dominant alleles that cause a lethal disease are much less common than recessive alleles that do so. All such lethal alleles arise by mutations (changes to the DNA) in a sperm or egg; presumably, such mutations occur equally often whether the mutant allele is dominant or recessive. However, if a lethal dominant allele causes the death of offspring before they mature and can reproduce, the allele will not be passed on to future generations. In contrast, a lethal recessive allele can be perpetuated from generation to generation by heterozygous carriers who have normal phenotypes. These carriers can reproduce and pass on the recessive allele. Only homozygous recessive offspring will have the lethal disease.

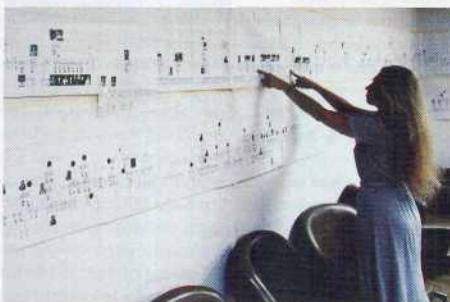

A lethal dominant allele can escape elimination if it causes death only at a relatively advanced age. By the time the symptoms become evident, the individual may have already

A Figure 14.15 Achondroplasia. The late David Rappaport, an actor, had achondroplasia, a form of dwarfism that is caused by a dominant allele.

transmitted the lethal allele to his or her children. For example, Huntington's disease, a degenerative disease of the nervous system, is caused by a lethal dominant allele that has no obvious phenotypic effect until the individual is about 35 to 45 years old. Once the deterioration of the nervous system begins, it is irreversible and inevitably fatal. Any child born to a parent who has the allele for Huntington's disease has a 50% chance of inheriting the allele and the disorder. (The mating can be symbolized as $Aa \times aa$, with A being the dominant allele that causes Huntington's disease.) In the United States, this devastating disease afflicts about one in 10,000 people.

Until relatively recently, the onset of symptoms was the only way to know if a person had inherited the Huntington's allele. This is no longer the case. By analyzing DNA samples from a large family with a high incidence of the disorder, geneticists tracked the Huntington's allele to a locus near the tip of chromosome 4 (**Figure 14.16**). This information led to development of a test that can detect the presence of the Huntington's allele in an individual's genome. (The methods that make such tests possible are discussed in Chapter 20.) For those with a family history of Huntington's disease, the availability of this test poses an agonizing dilemma: Under what circumstances is it beneficial for a presently healthy person to find out whether he or she has inherited a fatal and not yet curable disease? Some individuals may want to be tested for the disease before planning a family.

A Figure 14.16 Large families as excellent case studies of human genetics. Here, Nancy Wexler, of Columbia University and the Hereditary Disease Foundation, studies a huge pedigree that traces Huntington's disease through several generations of one large family in Venezuela. Classical Mendelian analysis of this family, coupled with the techniques of molecular biology, enabled scientists to develop a test for the presence of the dominant allele that causes Huntington's disease—a test that can be used before symptoms appear. Dr. Wexler's mother died of Huntington's disease, and thus there is a 50% chance that Dr. Wexler inherited the dominant allele that causes the disease. To date she has shown no symptoms.

Multifactorial Disorders

The hereditary diseases we have discussed so far are sometimes described as simple Mendelian disorders because they result from abnormality of one or both alleles at a single genetic locus. Many more people are susceptible to diseases that have a multifactorial basis—a genetic component plus a significant environmental influence. Heart disease, diabetes, cancer, alcoholism, certain mental illnesses such as schizophrenia and manic-depressive disorder, and many other diseases are multifactorial. In many cases, the hereditary component is polygenic. For example, many genes affect cardiovascular health, making some of us more prone than others to heart attacks and strokes. But our lifestyle intervenes tremendously between genotype and phenotype for cardiovascular health and other multifactorial characters. Exercise, a healthful diet, abstinence from smoking, and an ability to handle stressful situations all reduce our risk of heart disease and some types of cancer.

At present, so little is understood about the genetic contributions to most multifactorial diseases that the best public health strategy is to educate people about the importance of environmental factors and to promote healthful behavior.

Genetic Testing and Counseling

A preventive approach to simple Mendelian disorders is possible when the risk of a particular genetic disorder can be assessed before a child is conceived or during the early stages of the pregnancy. Many hospitals have genetic counselors who can provide information to prospective parents concerned about a family history for a specific disease.

Counseling Based on Mendelian Genetics and Probability Rules

Consider the case of a hypothetical couple, John and Carol. Both had a brother who died from the same recessively inherited lethal disease. Before conceiving their first child, John and Carol seek genetic counseling to determine the risk of having a child with the disease. From the information about their brothers, we know that both parents of John and both parents of Carol must have been carriers of the recessive allele. Thus, John and Carol are both products of $Aa \times Aa$ crosses, where a symbolizes the allele that causes this particular disease. We also know that John and Carol are not homozygous recessive (aa), because they do not have the disease. Therefore, their genotypes are either AA or Aa .

Given a genotypic ratio of $1AA:2Aa:1aa$ for offspring of an $Aa \times Aa$ cross, John and Carol each have a $\frac{1}{2}$ chance of being carriers (Aa). According to the rule of multiplication, the overall probability of their firstborn having the disorder is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$ (the chance that John is a carrier) multiplied by $\frac{1}{2}$ (the chance that Carol is a carrier) multiplied by $\frac{1}{4}$ (the chance of two carriers having a child with the disease), which equals $\frac{1}{16}$.

Suppose that Carol and John decide to have a child—after all, there is an $\frac{1}{4}$ chance that their baby will not have the disorder. U, despite these odds, their child is born with the disease, thⁿ we would know that both John and Carol are, in fact, carriers (Aa genotype). If both John and Carol are carriers, there is a $\frac{1}{4}$ chance that any subsequent child this couple has will have the disease.

When we use Mendel's laws to predict possible outcomes of matings, it is important to remember that each child represents an independent event in the sense that its genotype is unaffected by the genotypes of older siblings. Suppose that John and Carol have three more children, and *all three* have the hypothetical hereditary disease. There is only one chance in 64 ($\frac{1}{4} \times \frac{1}{4} \times \frac{1}{4}$) that such an outcome will occur. Despite this run of misfortune, the chance that still another child of this couple will have the disease remains $\frac{1}{4}$.

Tests for Identifying Carriers

Because most children with recessive disorders are born to parents with normal phenotypes, the key to assessing more accurately the genetic risk for a particular disease is determining whether the prospective parents are heterozygous carriers of the recessive allele. For an increasing number of heritable disorders, tests are available that can distinguish individuals of normal phenotype who are dominant homozygotes from those who are heterozygotes. There are now tests that can identify carriers of the alleles for Tay-Sachs disease, sickle-cell disease, and the most common form of cystic fibrosis.

These tests for identifying carriers enable people with family histories of genetic disorders to make informed decisions about having children. But these new methods for genetic screening pose potential problems, if confidentiality is breached, will carriers be stigmatized? Will they be denied health or life insurance, even though they themselves are healthy? Will misinformed employers equate "carrier" with disease? And will sufficient genetic counseling be available to help a large number of individuals understand their test results? New biotechnology offers possibilities for reducing human suffering, but not before key ethical issues are resolved. The dilemmas posed by human genetics reinforce one of this book's themes: the immense social implications of biology.

Fetal Testing

Suppose a couple learns that they are both Tay-Sachs carriers, but they decide to have a child anyway. Tests performed in conjunction with a technique known as **amniocentesis** can determine, beginning at the 14th to 16th week of pregnancy, whether the developing fetus has Tay-Sachs disease (Figure 14.17a, on the next page). To perform this procedure, a physician inserts a needle into the uterus and extracts about 10 milliliters of amniotic fluid, the liquid that bathes the fetus. Some genetic disorders can be detected from the presence of

certain chemicals in the amniotic fluid itself. Tests for other disorders, including Tay-Sachs disease, are performed on cells grown in the laboratory, descendants of the fetal cells sloughed off into the amniotic fluid. These cultured cells can also be used for karyotyping to identify certain chromosomal defects (see Figure 13.3).

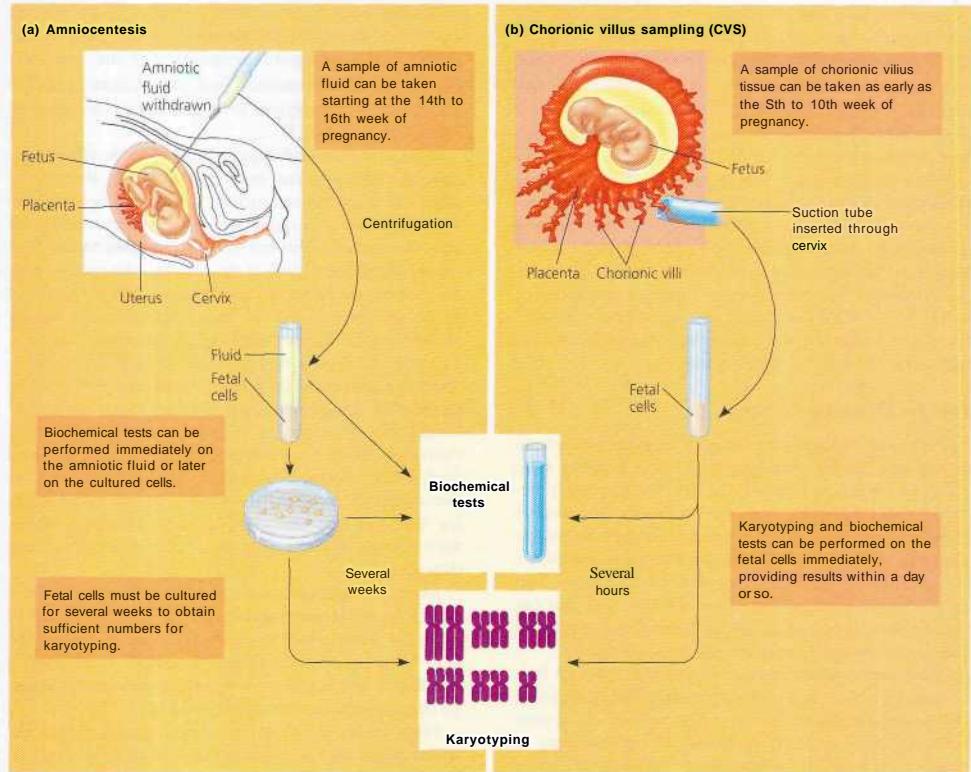

In an alternative technique called **chorionic villus sampling** (CVS), a physician inserts a narrow tube through the cervix into the uterus and suctions out a tiny sample of tissue from the placenta, the organ that transmits nutrients and fetal wastes between the fetus and the mother (Figure 14.17b). The cells of the chorionic villi of the placenta, the portion sampled, are derived from the fetus and have the same genotype as the new individual. These cells are proliferating rapidly enough to allow karyotyping to be carried out immediately. This rapid analysis is an advantage over amniocentesis, in which the cells must be cultured for several weeks before karyotyping. Another advantage of CVS is that it can be performed as early as the eighth to tenth week of pregnancy. However, CVS is not suitable for tests requiring amniotic fluid, and it is less widely available than amniocentesis. Recently, medical scientists have developed methods for isolating fetal cells that have escaped into the mother's blood. Although very few in number, these cells can be cultured and then tested.

Imaging techniques allow a physician to examine a fetus directly for major anatomical abnormalities. In the ultrasound technique, sound waves are used to produce an image of the fetus by a simple noninvasive procedure. In *jeioscopy*, a needle-thin tube containing a viewing scope and fiber optics (to transmit light) is inserted into the uterus.

Ultrasound has no known risk to either mother or fetus, but amniocentesis and fetoscopy cause complications, such as maternal bleeding or even fetal death, in about 1% of cases. For this reason, these techniques generally are used only when the chance of a genetic disorder or other type of birth defect is relatively great. If the fetal tests reveal a serious disorder, the parents face the difficult choice of terminating the pregnancy or preparing to care for a child with a genetic disorder.

Newborn Screening

Some genetic disorders can be detected at birth by simple tests that are now routinely performed in most hospitals in the United States. One common screening program is for phenylketonuria (PKU), a recessively inherited disorder that occurs in about one out of every 10,000 to 15,000 births in the United States. Children with this disease cannot properly break down the amino acid phenylalanine. This compound and its by-product, phenylpyruvate, can accumulate to toxic levels in the blood, causing mental retardation. However, if the deficiency is detected in the newborn, a special diet low in phenylalanine can usually promote normal development and

A Figure 14.17 Testing a fetus for genetic disorders. Biochemical tests may detect substances associated with particular disorders. Karyotyping shows whether the chromosomes of the fetus are normal in number and appearance.

prevent retardation. Unfortunately, very few other genetic disorders are treatable at the present time.

Screening of newborns and fetuses for serious inherited diseases, tests for identifying carriers, and genetic counseling—all these tools of modern medicine rely on the Mendelian model of inheritance. We owe the “gene idea”—the concept of particulate heritable factors transmitted according to simple rules of chance—to the elegant quantitative experiments of Gregor Mendel. The importance of his discoveries was overlooked by most biologists until early in the 20th century, several decades after his findings were reported. In the next chapter, you will learn how Mendel’s laws have their physical basis in the behavior of chromosomes during sexual life cycles and how the synthesis of Mendelism and a chromosome theory of inheritance catalyzed progress in genetics.

Concept Check 14.4

- Beth and Tom each have a sibling with cystic fibrosis, but neither Beth nor Tom nor any of their parents have the disease. Calculate the probability that if this couple has a child, the child will have cystic fibrosis. What would be the probability if a test revealed that Tom is a carrier but Beth is not?
- Joan was born with six toes on each foot, a dominant trait called polydactyly. Two of her five siblings and her mother, but not her father, also have extra digits. What is Joan’s genotype for the number-of-digits character? Explain your answer. Use *D* and *d* to symbolize the alleles for this character.

For suggested answers, see Appendix A.

Chapter 14 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 14.1

Mendel used the scientific approach to identify two laws of inheritance

- **Mendel's Experimental, Quantitative Approach** (pp. 252–253) Gregor Mendel formulated a particulate theory of inheritance based on experiments with garden peas, carried out in the 1860s. He showed that parents pass on to their offspring discrete genes that retain their identity through the generations.
- **The Law of Segregation** (pp. 253–256) This law states that the two alleles of a gene separate (segregate) during gamete formation, so that a sperm or an egg carries only one allele of each pair. Mendel proposed this law to explain the 3:1 ratio of F₂ phenotypes he observed when monohybrids self-pollinated. According to Mendel's model, genes have alternative forms (alleles), and each organism inherits one allele for each gene from each parent. If the two alleles of a gene are different, expression of one (the dominant allele) masks the phenotypic effect of the other (the recessive allele). Homozygous individuals have identical alleles of a given gene and are true-breeding. Heterozygous individuals have two different alleles of a given gene.

Activity *Monozygotic Cross*

- **The Law of Independent Assortment** (pp. 256–258) This law states that each pair of alleles segregates into gametes independently of other pairs. Mendel proposed this law based on dihybrid crosses between plants heterozygous for two genes. Alleles of each gene segregate into gametes independently of alleles of other genes. The offspring of a dihybrid cross (the F₂ generation) have four phenotypes in a 9:3:3:1 ratio.

Activity *Dihybrid Cross*

Concept 14.2

The laws of probability govern Mendelian inheritance

- **The Multiplication and Addition Rules Applied to Monohybrid Crosses** (pp. 258–259) The multiplication rule states that the probability of a compound event is equal to the product of the individual probabilities of the independent single events. The addition rule states that the probability of an event that can occur in two or more independent, mutually exclusive ways is the sum of the individual probabilities.

Activity *Gregor's Garden*

- **Solving Complex Genetics Problems with the Rules of Probability** (pp. 259–260) A dihybrid or other multi-character cross is equivalent to two or more independent monohybrid crosses occurring simultaneously. In calculating the chances for the various offspring genotypes from such crosses, each character first is considered separately and then the individual probabilities are multiplied together.

Concept 14.3

Inheritance patterns are often more complex than predicted by simple Mendelian genetics

- **Extending Mendelian Genetics for a Single Gene** (pp. 260–262) For a gene with complete dominance of one allele, the heterozygous phenotype is the same as that for the

homozygous dominant phenotype. For a gene with codominance of both alleles, both phenotypes are expressed in heterozygotes. For a gene with incomplete dominance of either allele, the heterozygous phenotype is intermediate between the two homozygous phenotypes. Many genes exist in multiple (more than two) alleles in a population. Pleiotropy is the ability of a single gene to affect multiple phenotypic characters.

Activity *Incomplete Dominance*

Extending Mendelian Genetics for Two or More Genes

(pp. 262–263) In epistasis, one gene affects the expression of another gene. In polygenic inheritance, a single phenotypic character is affected by two or more genes. Characters influenced by multiple genes are often quantitative, meaning that they vary continuously.

• **Nature and Nurture: The Environmental Impact on Phenotype** (p. 264) The expression of a genotype can be affected by environmental influences. The phenotypic range of a particular genotype is called its norm of reaction. Polygenic characters that are also influenced by the environment are called multifactorial characters.

• **Integrating a Mendelian View of Heredity and Variation** (p. 264) An organism's overall phenotype, including its physical appearance, internal anatomy, physiology, and behavior, reflects its overall genotype and unique environmental history. Even in more complex inheritance patterns, Mendel's fundamental laws of segregation and independent assortment still apply.

Concept 14.4

Many human traits follow Mendelian patterns of inheritance

• **Pedigree Analysis** (pp. 265–266) Family pedigrees can be used to deduce the possible genotypes of individuals and make predictions about future offspring. Predictions are usually statistical probabilities rather than certainties.

• **Recessively Inherited Disorders** (pp. 266–267) Tay-Sachs disease, cystic fibrosis, sickle-cell disease, and many other genetic disorders are inherited as simple recessive traits. Most affected individuals (with the homozygous recessive genotype) are children of phenotypically normal, heterozygous carriers.

• **Dominantly Inherited Disorders** (pp. 267–268) Lethal dominant alleles are eliminated from the population if affected people die before reproducing. Nonlethal dominant alleles and lethal ones that strike relatively late in life, such as the allele that causes Huntington's disease, are inherited in a Mendelian way.

• **Multifactorial Disorders** (p. 268) Many human diseases, such as most forms of cancer and heart disease, have both genetic and environmental components. These do not follow simple Mendelian inheritance patterns.

• **Genetic Testing and Counseling** (pp. 268–270) Using family histories, genetic counselors help couples determine the odds that their children will have genetic disorders. For a growing number of diseases, tests that identify carriers define the odds more accurately. Once a child is conceived, amniocentesis and chorionic villus sampling can help determine whether a suspected genetic disorder is present. Further genetic tests can be performed after a child is born.

Investigation *How Do You Diagnose a Genetic Disorder?*

Genetics Problems

1. In some plants, a true-breeding, red-flowered strain gives all pink flowers when crossed with a white-flowered strain: RR (red) X rr (white) -* Rr (pink). If flower position (axial or terminal) is inherited as it is in peas (see Table 14.1), what will be the ratios of genotypes and phenotypes of the F₂ generation resulting from the following cross: axial-red (true-breeding) X terminal-white? What will be the ratios in the F₂ generation?
2. Flower position, stem length, and seed shape were three characters that Mendel studied. Each is controlled by an independently assorting gene and has dominant and recessive expression as follows:

| Character | Dominant | Recessive |
|-----------------|-----------|--------------|
| Flower position | Axial (A) | Terminal (a) |
| Stem length | Tall (T) | Dwarf (t) |
| Seed shape | Round (R) | Wrinkled (r) |

If a plant that is heterozygous for all three characters is allowed to self-fertilize, what proportion of the offspring would you expect to be as follows? (Note: Use the rules of probability instead of a huge Punnett square.)

- a. homozygous for the three dominant traits
 - b. homozygous for the three recessive traits
 - c. heterozygous for all three characters
 - d. homozygous for axial and tall, heterozygous for seed shape
3. A black guinea pig crossed with an albino guinea pig produces 12 black offspring. When the albino is crossed with a second black one, 7 blacks and 5 albinos are obtained. What is the best explanation for this genetic situation? Write genotypes for the parents, gametes, and offspring.
4. In sesame plants, the one-pod condition (P) is dominant to the three-pod condition (p), and normal leaf (L) is dominant to wrinkled leaf (l). Pod type and leaf type are inherited independently. Determine the genotypes for the two parents for all possible matings producing the following offspring:
- a. 318 one-pod, normal leaf: 98 one-pod, wrinkled leaf
 - b. 323 three-pod, normal leaf: 106 three-pod, wrinkled leaf
 - c. 401 one-pod, normal leaf
 - d. 150 one-pod, normal leaf : 147 one-pod, wrinkled leaf: 51 three-pod, normal leaf : 48 three-pod, wrinkled leaf
 - e. 223 one-pod, normal leaf: 72 one-pod, wrinkled leaf: 76 three-pod, normal leaf: 27 three-pod, wrinkled leaf
5. A man with type A blood marries a woman with type B blood. Their child has type O blood. What are the genotypes of these individuals? What other genotypes, and in what frequencies, would you expect in offspring from this marriage?
6. Phenylketonuria (PKU) is an inherited disease caused by a recessive allele. If a woman and her husband, who are both carriers, have three children, what is the probability of each of the following?

- a. All three children are of normal phenotype.
- b. One or more of the three children have the disease.
- c. All three children have the disease.
- d. At least one child is phenotypically normal.

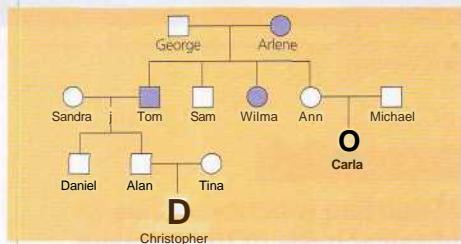

(Note: Remember that the probabilities of all possible outcomes always add up to 1.)

7. The genotype of F₁ individuals in a tetrahybrid cross is AaBbCcDd. Assuming independent assortment of these four genes, what are the probabilities that $\frac{1}{2}$ offspring will have the following genotypes?
- a. aabbccdd
 - b. AaBbCcDd
 - c. AaBBCcDD
 - d. AaBbccDd
 - e. AaBBCcdd
8. What is the probability that each of the following pairs of parents will produce the indicated offspring? (Assume independent assortment of all gene pairs.)
- a. AABCC X aabbc -* AaBbCc
 - b. AABbCc X AaBbCc -> AAbbCC
 - c. AaBbCc X AaBbCc -* AaBbCc
 - d. aaBBCC X AABbcc -+ AaBbCc
9. Karen and Steve each have a sibling with sickle-cell disease. Neither Karen nor Steve nor any of their parents have the disease, and none of them have been tested to reveal sickle-cell trait. Based on this incomplete information, calculate the probability that if this couple has a child, the child will have sickle-cell disease.
10. In 1981, a stray black cat with unusual rounded, curled-back ears was adopted by a family in California. Hundreds of descendants of the cat have since been born, and cat fanciers hope to develop the curl cat into a show breed. Suppose you owned the first curl cat and wanted to develop a true-breeding variety. How would you determine whether the curl allele is dominant or recessive? How would you obtain true-breeding curl cats? How could you be sure they are true-breeding?
11. Imagine that a newly discovered, recessively inherited disease is expressed only in individuals with type O blood, although the disease and blood group are independently inherited. A normal man with type A blood and a normal woman with type B blood have already had one child with the disease. The woman is now pregnant for a second time. What is the probability that the second child will also have the disease? Assume that both parents are heterozygous for the gene that causes the disease.
12. In tigers, a recessive allele causes an absence of fur pigmentation (a white tiger) and a cross-eyed condition. If two phenotypically normal tigers that are heterozygous at this locus are mated, what percentage of their offspring will be cross-eyed? What percentage will be white?
13. In corn plants, a dominant allele I inhibits kernel color, while the recessive allele i permits color when homozygous.

At a different locus, the dominant allele P causes purple kernel color, while the homozygous recessive genotype pp causes red kernels. If plants heterozygous at both loci are crossed, what will be the phenotypic ratio of the offspring?

14. The pedigree below traces the inheritance of alkaptонuria, a biochemical disorder. Affected individuals, indicated here by the colored circles and squares, are unable to break down a substance called alkaptone, which colors the urine and stains body tissues. Does alkaptонuria appear to be caused by a dominant allele or by a recessive allele? Fill in the genotypes of the individuals whose genotypes can be deduced. What genotypes are possible for each of the other individuals?

15. A man has six fingers on each hand and six toes on each foot. His wife and their daughter have the normal number of digits. Extra digits is a dominant trait. What fraction of this couple's children would be expected to have extra digits?
16. Imagine that you are a genetic counselor, and a couple planning to start a family come to you for information. Charles was married once before, and he and his first wife had a child with cystic fibrosis. The brother of his current wife Elaine died of cystic fibrosis. What is the probability that Charles and Elaine will have a baby with cystic fibrosis? (Neither Charles nor Elaine has cystic fibrosis.)
17. In mice, black color (*B*) is dominant to white (*b*). At a different locus, a dominant allele (*A*) produces a band of yellow just below the tip of each hair in mice with black fur. This gives a frosted appearance known as agouti. Expression of the

recessive allele (*a*) results in a solid coat color. If mice that are heterozygous at both loci are crossed, what is the expected phenotypic ratio of their offspring?

For Genetics Problems answers, see Appendix A.
Go to the website or CD-ROM for more quiz questions.

Evolution Connection

Over the past half century, there has been a trend in the United States and other developed countries for people to marry and start families later in life than did their parents and grandparents. Speculate on the effects this trend may have on the incidence (frequency) of late-acting dominant lethal alleles in the population.

Scientific Inquiry

You are handed a mystery pea plant with long stems and axial flowers and asked to determine its genotype as quickly as possible. You know the allele for tall stems (*T*) is dominant to that for dwarf stems (*t*) and that the allele for axial flowers (*A*) is dominant to that for terminal flowers (*a*).

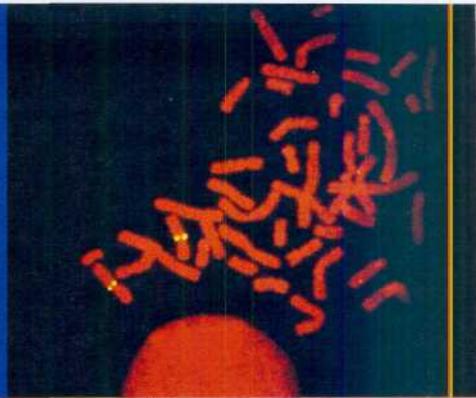

- What are *all* the possible genotypes for your mystery plant?
- Describe the *one* cross you would do, out in your garden, to determine the exact genotype of your mystery plant.
- While waiting for the results of your cross, you predict the results for each possible genotype listed in part a. How do you do this?
- Make your predictions using the following format: If the genotype of my mystery plant is _____, the plants resulting from my cross will be _____.
- If $\frac{1}{4}$ of your offspring plants have tall stems with axial flowers and $\frac{1}{4}$ have tall stems with terminal flowers, what must be the genotype of your mystery plant?
- Explain why the activities you performed in parts c and d were not "doing a cross."

Investigation *How Do You Diagnose a Genetic Disorder?*

Science, Technology, and Society

Imagine that one of your parents had Huntington's disease. What is the probability that you, too, will someday manifest the disease? There is no cure for Huntington's. Would you want to be tested for the Huntington's allele? Why or why not?

15 The Chromosomal Basis of Inheritance

A Figure 15.1 Chromosomes tagged to reveal a specific gene (yellow).

Key Concepts

- 15.1 Mendelian inheritance has its physical basis in the behavior of chromosomes
- 15.2 Linked genes tend to be inherited together because they are located near each other on the same chromosome
- 15.3 Sex-linked genes exhibit unique patterns of inheritance
- 15.4 Alterations of chromosome number or structure cause some genetic disorders
- 15.5 Some inheritance patterns are exceptions to the standard chromosome theory

Overview

Locating Genes on Chromosomes

Today, we can show that genes—Gregor Mendel's "hereditary factors"—are located on chromosomes. We can see the location of a particular gene by tagging isolated chromosomes with a fluorescent dye that highlights that gene. For example, the yellow dots in **Figure 15.1** mark the locus of a specific gene on a homologous pair of human chromosomes. (Because the chromosomes in this light micrograph have already replicated, we see two dots per chromosome, one on each sister chromatid.) A century or so ago, however, the relation of genes and chromosomes was not immediately obvious. Many biologists remained skeptical about Mendel's laws of segregation and independent assortment until evidence accumulated that these principles of heredity had a physical basis in the behavior of chromosomes. In this chapter, which integrates and extends what you learned in the past two chapters, we describe the chromosomal basis for the transmission of genes from parents to offspring, along with some important exceptions.

Concept 15.1

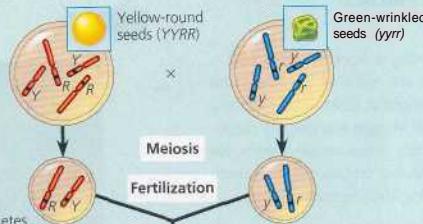

Mendelian inheritance has its physical basis in the behavior of chromosomes

Using improved techniques of microscopy, cytologists worked out the process of mitosis in 1875 and meiosis in the 1890s. Then, around 1900, cytology and genetics converged as biologists began to see parallels between the behavior of chromosomes and the behavior of Mendel's "factors" during sexual life cycles: Chromosomes and genes are both present in pairs in diploid cells; homologous chromosomes separate and alleles segregate during the process of meiosis; and fertilization restores the paired condition for both chromosomes and genes. Around 1902, Walter S. Sutton, Theodor Boveri, and others independently noted these parallels, and the chromosome theory of inheritance began to take form. According to this theory, Mendelian genes have specific loci (positions) on chromosomes, and it is the chromosomes that undergo segregation and independent assortment.

Figure 15.2 shows that the behavior of homologous chromosomes during meiosis can account for the segregation of the alleles at each genetic locus to different gametes. The figure also shows that the behavior of nonhomologous chromosomes can account for the independent assortment of the alleles for two or more genes located on different chromosomes. By carefully studying this figure, which traces the same dihybrid pea cross you learned about in Figure 14.8, you can see how the behavior of chromosomes during meiosis in the F₁ generation and subsequent random fertilization gives rise to the F₂ phenotypic ratio observed by Mendel.

P Generation

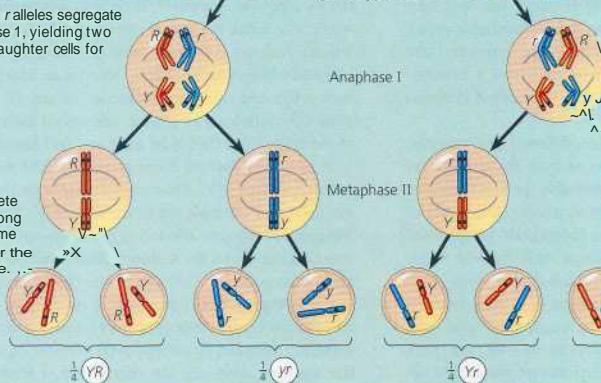

Starting with two true-breeding pea plants, we follow two genes through the F₁ and F₂ generations. The two genes specify seed color (allele Y for yellow and allele y for green) and seed shape (allele R for round and allele r for wrinkled). These two genes are on different chromosomes. (Peas have seven chromosome pairs, but only two pairs are illustrated here.)

F₁ Generation

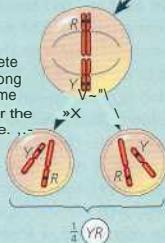

LAW OF SEGREGATION
The two alleles for each gene separate during gamete formation. As an example, follow the fate of the long chromosomes (carrying R and r). Read the numbered explanations below.

- ① The R and r alleles segregate at anaphase I, yielding two types of daughter cells for this locus.

- ② Each gamete gets one long chromosome with either the R or r allele.

Gametes

F₂ Generation

- ③ Fertilization recombines the F₁ alleles at random.

Fertilization among the F₁ plants

- ④ Fertilization results in the 9:3:3:1 phenotypic ratio in the F₂ generation.

Figure 15.2 The chromosomal basis of Mendel's laws. Here we correlate the results of one of Mendel's dihybrid crosses (see Figure 14.8) with the behavior of chromosomes during meiosis (see Figure 13.8). The arrangement of chromosomes at metaphase I of meiosis and their movement during anaphase I account for the segregation and independent assortment of the alleles for seed color and shape. Each cell that undergoes meiosis in an F₁ plant produces two kinds of gametes. Overall, however, F₁ plants produce equal numbers of all four kinds of gametes because the alternative chromosome arrangements at metaphase I are equally likely.

Morgan's Experimental Evidence: Scientific Inquiry

The first solid evidence associating a specific gene with a specific chromosome came from the work of Thomas Hunt Morgan, an experimental embryologist at Columbia University early in the 20th century. Although Morgan was initially skeptical about both Mendelism and the chromosome theory, his early experiments provided convincing evidence that chromosomes are indeed the location of Mendel's heritable factors.

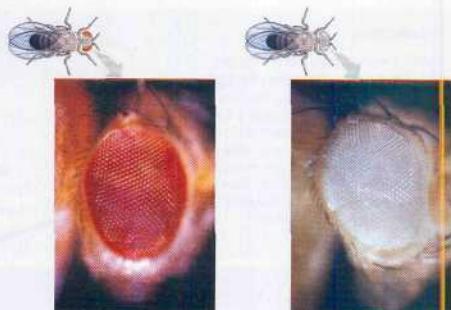

Morgan's Choice of Experimental Organism

Many times in the history of biology, important discoveries have come to those insightful enough or lucky enough to choose an experimental organism suitable for the research problem being tackled. Mendel chose the garden pea because a number of distinct varieties were available. For his work, Morgan selected a species of fruit fly, *Drosophila melanogaster*, a common, generally innocuous insect that feeds on the fungi growing on fruit. Fruit flies are prolific breeders; a single mating will produce hundreds of offspring, and a new generation can be bred every two weeks. These characteristics make the fruit fly a convenient organism for genetic studies. Morgan's laboratory soon became known as "the fly room."

Another advantage of the fruit fly is that it has only four pairs of chromosomes, which are easily distinguishable with a light microscope. There are three pairs of autosomes and one pair of sex chromosomes. Female fruit flies have a homologous pair of X chromosomes, and males have one X chromosome and one Y chromosome.

While Mendel could readily obtain different pea varieties, there were no convenient suppliers of fruit fly varieties for Morgan to employ. Indeed, he was probably the first person to want different varieties of this common insect. After a year of breeding flies and looking for variant individuals, Morgan was rewarded with the discovery of a single male fly with white eyes instead of the usual red. The normal phenotype for a character (the phenotype most common in natural populations), such as red eyes in *Drosophila*, is called the **wild type** (**Figure 15.3**). Traits that are alternatives to the wild type, such as white eyes in *Drosophila*, are called **mutant phenotypes** because they are due to alleles assumed to have originated as changes, or mutations, in the wild-type allele.

Morgan and his students invented a notation for symbolizing alleles in *Drosophila* that is still widely used for fruit flies. For a given character in flies, the gene takes its symbol from the first mutant (non-wild type) discovered. Thus, the allele for white eyes in *Drosophila* is symbolized by *w*. A superscript + identifies the allele for the wild-type trait—*w*⁺ for the allele for red eyes, for example. Over the years, different gene notation systems have been developed for different organisms. For example, human genes are usually written in all capitals, such as *HD* for the allele for Huntington's disease.

A Figure 15.3 Morgan's first mutant. Wild-type *Drosophila* flies have red eyes (left). Among his flies, Morgan discovered a mutant male with white eyes (right). This variation made it possible for Morgan to trace a gene for eye color to a specific chromosome (LMs).

Correlating Behavior of a Gene's Alleles with Behavior of a Chromosome Pair

Morgan mated his white-eyed male fly with a red-eyed female. All the F₁ offspring had red eyes, suggesting that the wild-type allele is dominant. When Morgan bred the F₁ flies to each other, he observed the classical 3:1 phenotypic ratio among the F₂ offspring. However, there was a surprising additional result: The white-eye trait showed up only in males. All the F₂ females had red eyes, while half the males had red eyes and half had white eyes. Therefore, Morgan concluded that somehow a fly's eye color was linked to its sex. (If the eye-color gene were unrelated to gender, one would have expected half of the white-eyed flies to be male and half female.)

A female fly has two X chromosomes (XX), while a male fly has an X and a Y (XY). The correlation between the trait of white eye color and the male sex of the affected F₂ flies suggested to Morgan that the gene affected in his white-eyed mutant was located exclusively on the X chromosome, with no corresponding allele present on the Y chromosome. His reasoning can be followed in **Figure 15.4**. For a male, a single copy of the mutant allele would confer white eyes; since a male has only one X chromosome, there can be no wild-type allele (w⁺) present to offset the recessive allele. On the other hand, a female could have white eyes only if both her X chromosomes carried the recessive mutant allele (w). This was impossible for the F₂ females in Morgan's experiment because all the f₁ fathers had red eyes.

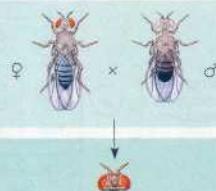

Morgan's finding of the correlation between a particular trait and an individual's sex provided support for the chromosome theory of inheritance: namely, that a specific gene is carried on a specific chromosome (in this case, the eye-color gene on the X chromosome). In addition, Morgan's work indicated that genes located on a sex chromosome exhibit unique inheritance patterns, which we will discuss later in this chapter. Recognizing the importance of Morgan's early work, many bright students were attracted to his fly room.

Figure 15.4

Scientific Inquiry In a cross between a wild-type male fruit fly and a mutant white-eyed female, what color eyes will the F_1 and F_2 offspring have?

EXPERIMENT

Morgan mated a wild-type (red-eyed) female with a mutant white-eyed male. The F_1 offspring all had red eyes.

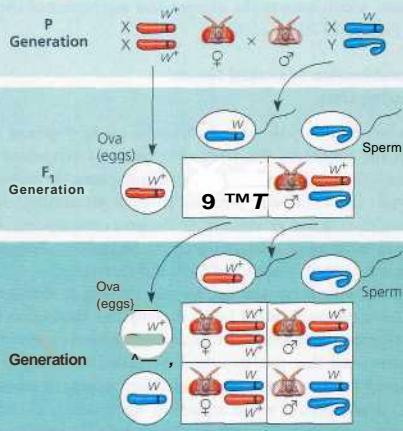

Morgan then bred an F_1 red-eyed female to an F_1 red-eyed male to produce the F_2 generation.

RESULTS

The F_2 generation showed a typical Mendelian 3:1 ratio of red eyes to white eyes. However, no females displayed the white-eye trait; they all had red eyes. Half the males had white eyes, and half had red eyes.

**CONCLUSION**

Since all F_2 offspring had red eyes, the mutant white-eye trait (w) must be recessive to the wild-type red-eye trait (w^+). Since the recessive trait—white eyes—was expressed only in males in the F_2 generation, Morgan hypothesized that the eye-color gene is located on the X chromosome and that there is no corresponding locus on the Y chromosome, as diagrammed here.

**Concept Check 15.1**

- "Which one of Mendel's laws relates to the inheritance of alleles for a single character? Which law relates to the inheritance of alleles for two characters in a dihybrid cross? What is the physical basis of these laws?"
- If the eye-color locus in *Drosophila* were located on an autosome, what would be the sex and phenotype of all the F_2 offspring produced by the crosses in Figure 15.4?

For suggested answers, see Appendix A.

Concept 15.2

linked genes tend to be inherited together because they are located near each other on the same chromosome

The number of genes in a cell is far greater than the number of chromosomes; in fact, each chromosome has hundreds or thousands of genes. Genes located on the same chromosome that tend to be inherited together in genetic crosses are said to be linked genes. When geneticists follow linked genes in breeding experiments, the results deviate from those expected from Mendel's law of independent assortment.

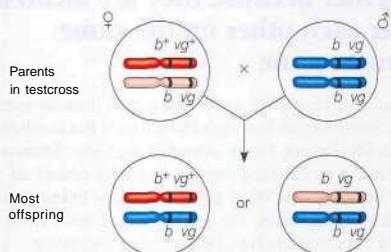

How Linkage Affects Inheritance: Scientific Inquiry

To see how linkage between genes affects the inheritance of two different characters, let's examine another of Morgan's *Drosophila* experiments. In this case, the characters are body color and wing size, each with two different phenotypes. Wild-type flies have gray bodies and normal-sized wings. In addition to these flies, "Morgan had doubly mutant flies with black bodies and vestigial wings (much smaller than normal wings). The alleles for these traits are represented by the following symbols: b^+ = gray b = black; vg^+ = normal wings, vg = vestigial wings. The mutant alleles are recessive to the wild-type alleles, and neither gene is on a sex chromosome.

In studying these two genes, Morgan carried out the crosses shown in Figure 15.5 (p. 279). He first mated true-breeding wild-type flies ($b^+ b^+ vg^+ vg^+$) with black, vestigial-winged ones ($b b vg vg$) to produce heterozygous F_1 dihybrids ($b^+ b vg^+ vg$), all of which were wild-type in appearance. He then crossed female dihybrids with true-breeding males of the double-mutant phenotype ($b b vg vg$). In this second cross, which corresponds to a Mendelian testcross, we know the genotype of the female parent ($b^+ b vg^+ vg$), and we also know which allele combinations are "parental," meaning derived

from the parents in the P generation: b^+ with vg^+ and b with vg . We don't know, however, whether the two genes are located on the same or different chromosomes. In the testcross, all the sperm will donate recessive alleles (b and vg); so the phenotypes of the offspring will depend on the ova's alleles. Therefore, from the phenotypes of the offspring, we can determine whether or not the parental allele combinations, b^+ with vg^+ and b with vg , stayed together during formation of the F₁ female's ova.

When Morgan "scored" (classified according to phenotype) 2,300 offspring from the testcross matings, he observed a much higher proportion of parental phenotypes than would be expected if the two genes assort independently (see Figure 15.5). Based on these results, Morgan reasoned that body color and wing size are usually inherited together in specific combinations (the parental combinations) because the genes for these characters are on the same chromosome:

However, if the genes for body color and wing size were always inherited together in those parental combinations, no nonparental phenotypes would have been observed among the offspring of Morgan's testcross. In fact, both of the nonparental phenotypes *were* produced in Morgan's experiments (see Figure 15.5), suggesting that the body-color and wing-size genes are only partially linked genetically. To understand this result, we need to further explore genetic recombination, the production of offspring with combinations of traits differing from those found in either parent.

Genetic Recombination and Linkage

In Chapter 13, you learned that meiosis and random fertilization generate genetic variation among offspring of sexually reproducing organisms. Here we will examine the chromosomal basis of recombination in relation to the genetic findings of Mendel and Morgan.

Recombination of Unlinked Genes: Independent Assortment of Chromosomes

Mendel learned from crosses in which he followed two characters that some offspring have combinations of traits that do

not match either parent in the parental (P) generation. For example, we can represent the cross between a pea plant with yellow-round seeds that is heterozygous for both seed color and seed shape ($YyRr$) and a plant with green-wrinkled seeds (homozygous for both recessive alleles, $yyrr$) by the following Punnett square:

| Gametes from yellow-round heterozygous parent ($YyRr$) | | | |
|--|------|-------------------------|-----------------------|
| Gametes from green-wrinkled homozygous recessive parent ($yyrr$) | | | |
| | | Parental-type offspring | Recombinant offspring |
| YR | yr | $YyRr$ | $yyRr$ |
| Yr | Yr | $YyRr$ | $YyRr$ |
| Yr | Yr | $YyRr$ | $YyRr$ |
| YR | YR | $YyRr$ | $YyRr$ |

Notice in this Punnett square that one-half of the offspring are expected to inherit a phenotype that matches one of the parental phenotypes. These offspring are called *parental types*. But two nonparental phenotypes are also found among the offspring. Because these offspring have new combinations of seed shape and color, they are called *recombinant types*, or *recombinants* for short. When 50% of all offspring are recombinants, as in this example, geneticists say that there is a 50% frequency of recombination. The predicted phenotypic ratios among the offspring are similar to what Mendel actually found in $YyRr \times yyrr$ crosses.

A 50% frequency of recombination is observed for any two genes that are located on different chromosomes. The physical basis of recombination between unlinked genes is the random orientation of homologous chromosomes at metaphase I of meiosis, which leads to the independent assortment of alleles (see Figures 15.2 and 13.10).

Recombination of Linked Genes: Crossing Over

Now let's return to Morgan's fly room to see how we can explain the results of the *Drosophila* testcross illustrated in Figure 15.5. Recall that most of the offspring from the testcross for body color and wing size had parental phenotypes, suggesting that the two genes were on the same chromosome, but a small number of offspring were recombinants. Although there was linkage, it appeared to be incomplete.

Faced with these results, Morgan proposed that some process must occasionally break the physical connection between genes on the same chromosome. Subsequent experiments demonstrated that this process, now called *crossing over*, accounts for the recombination of linked genes. In crossing over, which occurs while replicated homologous chromosomes are paired during prophase of meiosis I, one maternal

CONCLUSION

If these two genes were on different chromosomes, the alleles from the F_1 dihybrid would sort into gametes independently, and we would expect to see equal numbers of the four types of offspring. If these two genes were on the same chromosome, we would expect each allele combination, $b^+ vg^+$ and $b vg$, to stay together as gametes formed. In this case, only offspring with parental phenotypes would be produced. Since most offspring had a parental phenotype, Morgan concluded that the genes for body color and wing size are located on the same chromosome. However, the production of a small number of offspring with nonparental phenotypes indicated that some mechanism occasionally breaks the linkage between genes on the same chromosome.

md one paternal chromatic! break at corresponding points and then are rejoined to each other (see Figure 13.11). In effect, the end portions of two nonsister chromatids trade places each time a crossover occurs.

The recombinant chromosomes resulting from crossing over may bring alleles together in new combinations, and the subsequent events of meiosis distribute the recombinant chromo-

somes to gametes. **Figure 15.6** (p. 280) shows how crossing over in a dihybrid female fly resulted in recombinant ova and ultimately recombinant offspring in Morgan's testcross. Most of the ova had a chromosome with either the $b^+ vg^+$ or $b vg$ parental genotype for body color and wing size, but some ova had a recombinant chromosome ($b^+ vg$ or $b vg^{nh}$). Fertilization of these various classes of ova by homozygous recessive sperm ($b vg$) produced an offspring population in which 17% exhibited a nonparental, recombinant phenotype (see Figure 15.6). As we discuss next, the percentage of recombinant offspring, the **recombination frequency**, is related to the distance between linked genes.

**Linkage Mapping Using Recombination Data:
Scientific Inquiry**

The discovery of linked genes and recombination due to crossing over led one of Morgan's students, Alfred H. Sturtevant, to a method for constructing a genetic map, an ordered list of the genetic loci along a particular chromosome.

Sturtevant hypothesized that recombination frequencies calculated from experiments like the one in Figures 15.5 and 15.6 depend on the distances between genes on a chromosome. He assumed that crossing over is a random event, and thus the chance of crossing over is approximately equal at all points along a chromosome. Based on these assumptions, Sturtevant predicted that *the farther apart two genes are, the higher the probability that a crossover will occur between them and therefore the higher the recombination frequency*. His reasoning was simple: The greater the distance between two genes, the more points there are between them where crossing over can occur. Using recombination data from various fruit fly crosses,

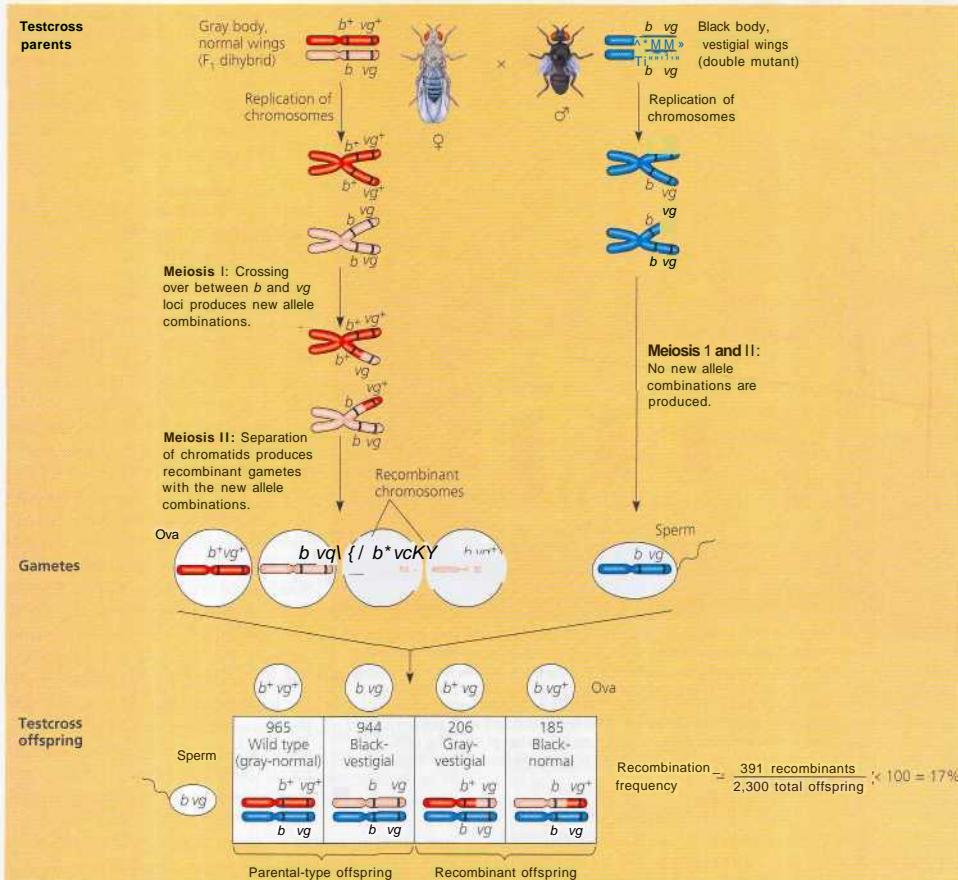

Sturtevant proceeded to assign relative positions to genes on the same chromosomes—that is, to *map* genes.

A genetic map based on recombination frequencies is specifically called a linkage map. **Figure 15.7** (p. 281) shows Sturtevant's linkage map of three genes: the body-color (b) and wing-size (vg) genes depicted in Figure 15.6 and a third gene, called cinnabar (en). Cinnabar is one of many *Drosophila* genes

affecting eye color. Cinnabar eyes, a mutant phenotype, are a brighter red than the wild-type color. The recombination frequency between *en* and *b* is 9%; that between *en* and *vg*, 9.5%; and that between *b* and *vg*, 17%. In other words, crossovers between *en* and *b* and between *en* and *vg* are about half as frequent as crossovers between *b* and *vg*. Only a map that locates *en* about midway between *b* and *vg* is consistent with these data, as you can prove to yourself by drawing alternative maps.

Sturtevant expressed the distances between genes in **map units**, defining one map unit as equivalent to a 1% recombination frequency. Today map units often are called *centimorgans* in honor of Morgan.

In practice, the interpretation of recombination data is more complicated than this example suggests. For example, some genes on a chromosome are so far from each other that a crossover between them is virtually certain. The observed

A Figure 15.6 Chromosomal basis for recombination of linked genes. In these diagrams re-creating the testcross in Figure 15.5, we track chromosomes as well as genes. The maternal chromosomes are color-coded to

distinguish one homologue from the other. Because crossing over between the *b* and *vg* loci occurs in some, but not all, ovum-producing cells, more ova with parental-type chromosomes than with recombinant ones are produced in the

mating females. Fertilization of the ova by sperm of genotype *b* *vg* gives rise to some recombinant offspring. The recombination frequency is the percentage of recombinant flies in the total pool of offspring.

Figure 15.7**Research Method Constructing a Linkage Map****APPLICATION**

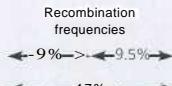

A linkage map shows the relative locations of genes along a chromosome.

TECHNIQUE

A linkage map is based on the assumption that the probability of a crossover between two genetic loci is proportional to the distance separating the loci. The recombination frequencies used to construct a linkage map for a particular chromosome are obtained from experimental crosses, such as the cross depicted in Figure 15.6. The distances between genes are expressed as map units (centimorgans), with one map unit equivalent to a 1% recombination frequency. Genes are arranged in the chromosome in the order that best fits the data.

RESULTS

In this example, the observed recombination frequencies between three *Drosophila* gene pairs (*b-cn* 9%, *cn-vg* 9.5%, and *b-vg* 17%) best fit a linear order in which *en* is positioned about halfway between the other two genes:

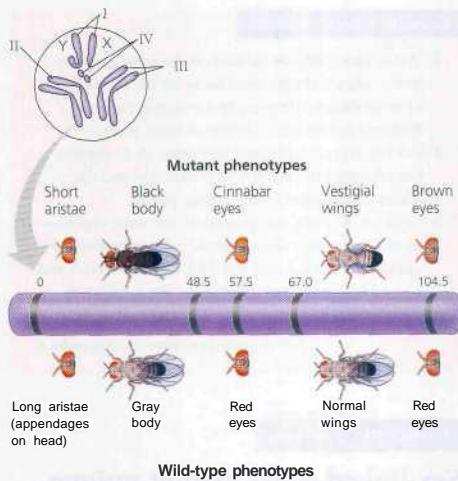

Chromosome

The *b-vg* recombination frequency is slightly less than the sum of the *b-cn* and *cn-vg* frequencies because double crossovers are fairly likely to occur between *b* and *vg* in matings tracking these two genes. A second crossover would "cancel out" the first and thus reduce the observed *b-vg* recombination frequency.

frequency of recombination in crosses involving two such genes can have a maximum value of 50%, a result indistinguishable from that for genes on different chromosomes. In this case, the physical connection between genes on the same chromosome is not reflected in the results of genetic crosses. Despite being on the same chromosome and thus being *physically linked*, the genes are *genetically unlinked*; alleles of such genes assort independently as if they were on different chromosomes. In fact, the genes for two of the pea characters that Mendel studied—seed color and flower color—are now known to be on the same chromosome, but the distance between them is so great that linkage is not observed in genetic crosses. Genes located far apart on a chromosome are mapped by adding the recombination frequencies from crosses involving each of the distant genes and a number of genes lying between them.

Using recombination data, Sturtevant and his colleagues were able to map numerous *Drosophila* genes in linear arrays. They found that the genes clustered into four groups of

**A Figure 15.8 A partial genetic (linkage) map of a**

Drosophila chromosome. This simplified map shows just a few of the genes that have been mapped on *Drosophila* chromosome II. The number at each gene locus indicates the number of map units between that locus and the locus for aristae length (left). Notice that more than one gene can affect a given phenotypic characteristic, such as eye color. Also, note that in contrast to the homologous autosomes (II-IV), the X and Y sex chromosomes (I) have distinct shapes.

linked genes. Because microscopists had found four pairs of chromosomes in *Drosophila* cells, this clustering of genes was additional evidence that genes are located on chromosomes. Each chromosome has a linear array of specific gene loci (Figure 15.8).

Because a linkage map is based on recombination frequencies, it gives only an approximate picture of a chromosome. The frequency of crossing over is not actually uniform over the length of a chromosome, as Sturtevant assumed, and therefore map units do not correspond to actual physical distances (in nanometers, for instance). A linkage map does portray the order of genes along a chromosome, but it does not accurately portray the precise locations of those genes. Other methods enable geneticists to construct **cytogenetic maps** of chromosomes, which locate genes with respect to chromosomal features, such as stained bands, that can be seen in the microscope. The ultimate maps, which we will discuss in Chapter 20, show the physical distances between gene loci in DNA nucleotides. Comparing a linkage map with such a physical map or with a cytogenetic map of the same chromosome, we find that the linear order of genes is identical in all the maps, but the spacing between genes is not.

Concept Check 15.2

- When two genes are located on the same chromosome, what is the physical basis for the production of recombinant offspring in a testcross between a dihybrid parent and a double-mutant parent?
- For each type of offspring in Figure 15.5, explain the relationship between its phenotype and the alleles contributed by the female parent.
- Genes A, B, and C are located on the same chromosome. Testcrosses show that the recombination frequency between A and B is 28% and between A and C is 12%. Can you determine the linear order of these genes?

For suggested answers, see Appendix A.

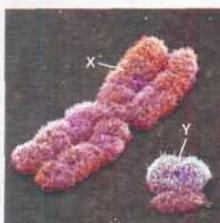

Concept 15.3

Sex-linked genes exhibit unique patterns of inheritance

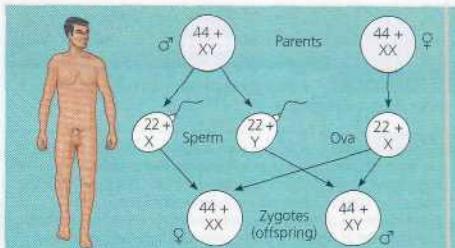

As you learned earlier, Morgan's discovery of a trait (white eyes) that correlated with the sex of flies was a key episode in the development of the chromosome theory of inheritance. In this section, we consider the role of sex chromosomes in inheritance in more detail. We begin by reviewing the chromosomal basis of sex determination in humans and some other animals.

The Chromosomal Basis of Sex

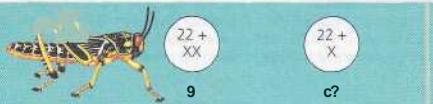

Whether we are male or female is one of our more obvious phenotypic characters. Although the anatomical and physiological differences between women and men are numerous, the chromosomal basis for determining sex is rather simple. In humans and other mammals, there are two varieties of sex chromosomes, designated X and Y. A person who inherits two X chromosomes, one from each parent, usually develops as a female. A male develops from a zygote containing one X chromosome and one Y chromosome (Figure 15.9a). The Y chromosome is much smaller than the X chromosome (see the micrograph to the left), and only relatively short segments at either end of the Y chromosome are homologous with corresponding regions of the X. These homologous regions allow the X and Y chromosomes in males to pair and behave like homologous chromosomes during meiosis in the testes.

In both testes and ovaries, the two sex chromosomes segregate during meiosis, and each gamete receives one. Each ovum contains one X chromosome. In contrast, sperm fall into two categories: Half the sperm cells a male produces contain an X chromosome, and half contain a Y chromosome. We

(a) **The X-Y system.** In mammals, the sex of an offspring depends on whether the sperm cell contains an X chromosome or a Y.

(b) **The X-0 system.** In grasshoppers, roaches, and some other insects, there is only one type of sex chromosome, the X. Females are XX; males have only one sex chromosome (XO). Sex of the offspring is determined by whether the sperm cell contains an X chromosome or no sex chromosome.

(c) **The Z-W system.** In birds, some fishes, and some insects, the sex chromosome present in the ovum (not the sperm) determines the sex of offspring. The sex chromosomes are designated Z and W. Females are ZW and males are ZZ.

(d) **The haplo-diploid system.** There are no sex chromosomes in most species of bees and ants. Females develop from fertilized ova and are thus diploid. Males develop from unfertilized eggs and are thus haploid; they have no fathers.

A Figure 15.9 Some chromosomal systems of sex determination. Numerals indicate the number of autosomes. In *Drosophila*, males are XY, but sex depends on the ratio between the number of X chromosomes and the number of autosome sets, not simply on the presence of a Y chromosome.

In both testes and ovaries, the two sex chromosomes segregate during meiosis, and each gamete receives one. Each ovum contains one X chromosome. In contrast, sperm fall into two categories: Half the sperm cells a male produces contain an X chromosome, and half contain a Y chromosome. We

can trace the sex of each offspring to the moment of conception: If a sperm cell bearing an X chromosome happens to fertilize an ovum, the zygote is XX, a female; if a sperm cell containing a Y chromosome fertilizes an ovum, the zygote is XY, a male (see Figure 15.9a). Thus sex determination is a matter of chance—a fifty-fifty chance. Besides the mammalian X-Y system, three other chromosomal systems for determining sex are shown in Figure 15.9, in parts b-d.

In humans, the anatomical signs of sex begin to emerge when the embryo is about two months old. Before then, the rudiments of the gonads are generic—they can develop into either ovaries or testes, depending on hormonal conditions within the embryo. Which of these two possibilities occurs depends on whether or not a Y chromosome is present. In 1990, a British research team identified a gene on the Y chromosome required for the development of testes. They named the gene *SRY*, for sex-determining region of Y. In the absence of *SRY*, the gonads develop into ovaries. The researchers emphasized that the presence (or absence) of *SRY* is just a trigger. The biochemical, physiological, and anatomical features that distinguish males and females are complex, and many genes are involved in their development. *SRY* codes for a protein that regulates other genes. Researchers have subsequently identified a number of additional genes on the Y chromosome that are required for normal testis functioning. In the absence of these genes, an XY individual is male but does not produce normal sperm.

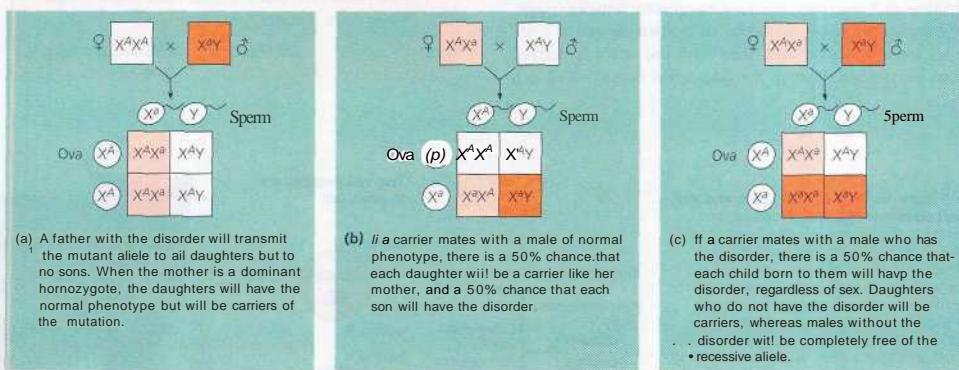

Inheritance of Sex-Linked Genes

In addition to their role in determining sex, the sex chromosomes, especially X chromosomes, have genes for many

characters unrelated to sex. A gene located on either sex chromosome is called a **sex-linked gene**, although in humans the term has historically referred specifically to a gene on the X chromosome. (Note the distinction between the terms *sex-linked gene*, referring to a gene on a sex chromosome, and *linked genes*, referring to genes on the same chromosome that tend to be inherited together.) Sex-linked genes in humans follow the same pattern of inheritance that Morgan observed for the eye-color locus in *Drosophila* (see Figure 15.4). Fathers pass sex-linked alleles to all of their daughters but to none of their sons. In contrast, mothers can pass sex-linked alleles to both sons and daughters (Figure 15.10).

If a sex-linked trait is due to a recessive allele, a female will express the phenotype only if she is a homozygote. Because males have only one locus, the terms *homozygous* and *heterozygous* lack meaning for describing their sex-linked genes (the term *hemizygous* is used in such cases). Any male receiving the recessive allele from his mother will express the trait. For this reason, far more males than females have sex-linked recessive disorders. However, even though the chance of a female inheriting a double dose of the mutant allele is much less than the probability of a male inheriting a single dose, there are females with sex-linked disorders. For instance, color blindness is a mild disorder inherited as a sex-linked trait. A color-blind daughter may be born to a color-blind father whose mate is a carrier (see Figure 15.10c). However, because the sex-linked allele for color blindness is relatively rare, the probability that such a man and woman will mate is low.

A number of human sex-linked disorders are much more serious than color blindness. An example is **Duchenne muscular dystrophy**, which affects about one out of every 3,500 males

& Figure 15.10 The transmission of sex-linked recessive traits. In this diagram, the superscript A represents a dominant allele carried on the X chromosome, and the superscript a represents a recessive allele. Imagine that this recessive allele is a mutation that causes a sex-linked disorder, such as color blindness. White boxes indicate unaffected individuals, light-colored boxes indicate carriers, and dark-colored boxes indicate individuals with the sex-linked disorder.

born in the United States. The disease is characterized by a progressive weakening of the muscles and loss of coordination. Affected individuals rarely live past their early 20s. Researchers have traced the disorder to the absence of a key muscle protein called dystrophin and have mapped the gene for this protein to a specific locus on the X chromosome.

Hemophilia is a sex-linked recessive disorder defined by the absence of one or more of the proteins required for blood clotting. When a person with hemophilia is injured, bleeding is prolonged because a firm clot is slow to form. Small cuts in the skin are usually not a problem, but bleeding in the muscles or joints can be painful and can lead to serious damage. Today, people with hemophilia are treated as needed with intravenous injections of the missing protein.

X Inactivation in Female Mammals

Although female mammals, including humans, inherit two X chromosomes, one X chromosome in each cell becomes almost completely inactivated during embryonic development. As a result, the cells of females and males have the same effective dose (one copy) of genes with loci on the X chromosome. The inactive X in each cell of a female condenses into a compact object called a Barr body, which lies along the inside of the nuclear envelope. Most of the genes on the X chromosome that forms the Barr body are not expressed. In the ovaries, Barr-body chromosomes are reactivated in the cells that give rise to ova, so every female gamete has an active X.

British geneticist Mary Lyon demonstrated that selection of which X chromosome will form the Barr body occurs randomly and independently in each embryonic cell present at the time of X inactivation. As a consequence, females consist of a mosaic of two types of cells: those with the active X derived from the father and those with the active X derived from the mother. After an X chromosome is inactivated in a

particular cell, all mitotic descendants of that cell have the same inactive X. Thus, if a female is heterozygous for a sex-linked trait, about half her cells will express one allele, while the others will express the alternate allele. **Figure 15.11** shows how this mosaicism results in the mottled coloration of a tortoiseshell cat. In humans, mosaicism can be observed in a recessive X-linked mutation that prevents the development of sweat glands. A woman who is heterozygous for this trait has patches of normal skin and patches of skin lacking sweat glands.

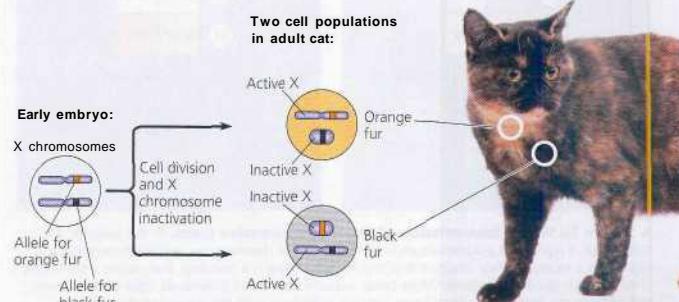

Inactivation of an X chromosome involves modification of the DNA, such as attachment of methyl groups ($-\text{CH}_3$) to one of the nitrogenous bases of DNA nucleotides. (The regulatory role of DNA methylation is discussed further in Chapter 19.) Researchers also have discovered a gene called *XIST* (for X-inactive specific transcript) that is active *only* on the Barr-body chromosome. Multiple copies of the RNA molecule produced from this gene apparently attach to the X chromosome on which they are made, eventually almost covering it. Interaction of this RNA with the chromosome seems to initiate X inactivation. Our understanding of X inactivation is still rudimentary; however.

Concept Check 15.3

1. A white-eyed female *Drosophila* is mated with a red-eyed (wild-type) male, the reciprocal cross of that shown in Figure 15.4. What phenotypes and genotypes do you predict for the offspring?
2. Neither Tim nor Rhoda has Duchenne muscular dystrophy, but their firstborn son does have it. What is the probability that a second child of this couple will have the disease?

For suggested answers, see Appendix A.

• Figure 15.11 X inactivation and the tortoiseshell cat. The tortoiseshell gene is on the X chromosome, and the tortoiseshell phenotype requires the presence of two different alleles, one for orange fur and one for black fur. Normally, only females can have both alleles, because only females have two X chromosomes. If a female is heterozygous for the tortoiseshell gene, she is tortoiseshell. Orange patches are formed by populations of cells in which the X chromosome with the orange allele is active; black patches have cells in which the X chromosome with the black allele is active. ("Calico" cats also have white areas, which are determined by yet another gene.)

Concept 15.4

Alterations of chromosome number or structure cause some genetic disorders

Sex-linked traits are not the only notable deviation from the inheritance patterns observed by Mendel, and the gene mutations that generate new alleles are not the only kind of changes to the genome that can affect phenotype. Physical and chemical disturbances, as well as errors during meiosis, can damage chromosomes in major ways or alter their number in a cell. Large-scale chromosomal alterations often lead to spontaneous abortion (miscarriage) of a fetus, and individuals born with these types of genetic defects commonly exhibit various developmental disorders. In plants, such genetic defects may be tolerated to a greater extent than in animals.

Abnormal Chromosome Number

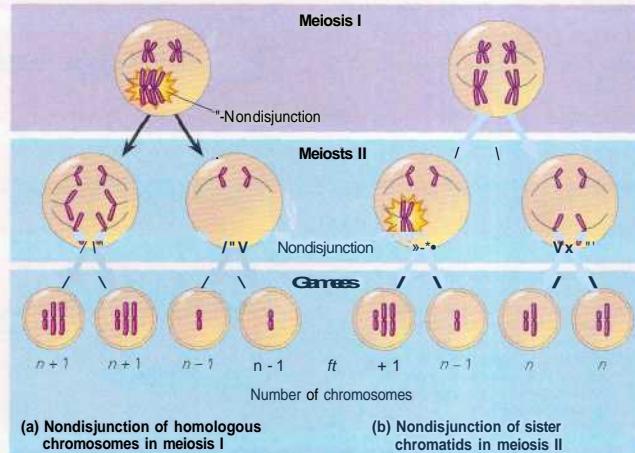

Ideally, the meiotic spindle distributes chromosomes to daughter cells without error. But there is an occasional mishap, called a **nondisjunction**, in which the members of a pair of homologous chromosomes do not move apart properly during meiosis I or sister chromatids fail to separate during meiosis II. In these cases, one gamete receives two of the same type of chromosome and another gamete receives no copy (Figure 15.12). The other chromosomes are usually distributed normally. If either of the aberrant gametes unites with a normal one at fertilization, the

offspring will have an abnormal number of a particular chromosome, a condition known as **aneuploidy**.

If a chromosome is present in triplicate in the fertilized egg (so that the cell has a total of $ln\ 4 - 1$ chromosomes), the aneuploid cell is said to be **trisomic** for that chromosome. If a chromosome is missing (so that the cell has $ln - 1$ chromosomes), the aneuploid cell is **monosomic** for that chromosome. Mitosis will subsequently transmit the anomaly to all embryonic cells. If the organism survives, it usually has a set of symptoms caused by the abnormal dose of the genes associated with the extra or missing chromosome. Nondisjunction can also occur during mitosis. If such an error takes place early in embryonic development, then the aneuploid condition is passed along by mitosis to a large number of cells and is likely to have a substantial effect on the organism.

Some organisms have more than two complete chromosome sets. The general term for this chromosomal alteration is **polyploidy**, with the specific terms **triploidy** ($3n$) and **tetraploidy** ($4n$) indicating three or four chromosomal sets, respectively. One way a triploid cell may be produced is by the fertilization of an abnormal diploid egg produced by nondisjunction of all its chromosomes. An example of an accident that would result in tetraploidy is the failure of a ln zygote to divide after replicating its chromosomes. Subsequent normal mitotic divisions would then produce a $4n$ embryo.

Polyploidy is fairly common in the plant kingdom. As we will see in Chapter 24, the spontaneous origin of polyploid individuals plays an important role in the evolution of plants. In the animal kingdom, polyploid species are much less common, although they are known to occur among the fishes and amphibians. Researchers in Chile were the first to identify a

• **Figure 15.12 Meiotic nondisjunction.** Gametes with an abnormal chromosome number can arise by nondisjunction in either meiosis I or meiosis II.

A Figure 15.13 A tetraploid mammal. The somatic cells of this burrowing rodent, *Tympanoctomys barrerae*, have about twice as many chromosomes as those of closely related species. Interestingly, its sperm's head is unusually large, presumably a necessity for holding all that genetic material. Scientists think that this tetraploid species may have arisen when an ancestor doubled its chromosome number, presumably by errors in mitosis or meiosis within the animal's reproductive organs.

polyploid mammal, a rodent whose cells are tetraploid (**Figure 15.13**). Additional research has found that a closely related species also appears to be tetraploid. In general, polyploids are more nearly normal in appearance than aneuploids. One extra (or missing) chromosome apparently disrupts genetic balance more than does an entire extra set of chromosomes.

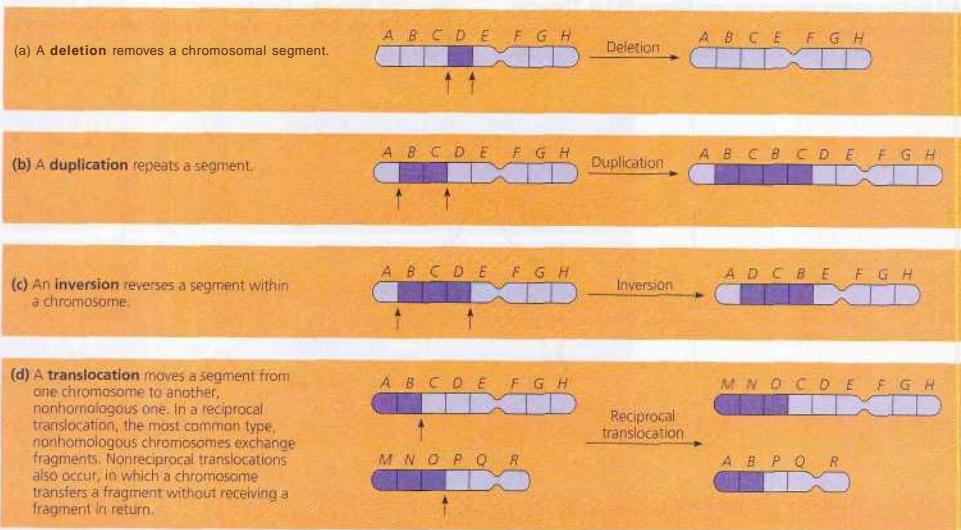

Alterations of Chromosome Structure

Breakage of a chromosome can lead to four types of changes in chromosome structure, depicted in **Figure 15.14**. A **deletion** occurs when a chromosomal fragment lacking a centromere is

lost. The affected chromosome is then missing certain genes. In some cases, if meiosis is in progress, such a "deleted" fragment may become attached as an extra segment to a sister chromatid, producing a **duplication**. Alternatively, a detached fragment could attach to a nonsister chromatid of a **homologous** chromosome. In that case, though, the "duplicated" segments might not be identical because the homologues coi Id **carry** different alleles of certain genes. A chromosomal **fragment** may also reattach to the original chromosome but in tie reverse orientation, producing an **inversion**. A fourth **possible** result of chromosomal breakage is for the fragment to join a nonhomologous **chromosome**, a rearrangement called a **translocation**.

Deletions and duplications are especially likely to occur during meiosis. In crossing over, nonsister chromatids sometimes break and rejoin at "incorrect" places, so that one partner gives up more genes than it receives. The products of such a **nonreciprocal** crossover are one chromosome with a deletion and one chromosome with a duplication.

A diploid embryo that is homozygous for a large deletion (or has a single X chromosome with a large deletion, in a male) is usually missing a number of essential genes, a condition that is ordinarily lethal. Duplications and translocations also tend to have harmful effects. In reciprocal translocations, in which segments are exchanged between nonhomologous chromosomes, and in inversions, the balance of genes is not abnormal—all genes are present in their normal doses. Never-

A Figure 15.14 Alterations of chromosome structure. Vertical arrows indicate breakage points. Dark purple highlights the chromosomal parts affected by the rearrangements.

theless, translocations and inversions can alter phenotype because a gene's expression can be influenced by its location among neighboring genes.

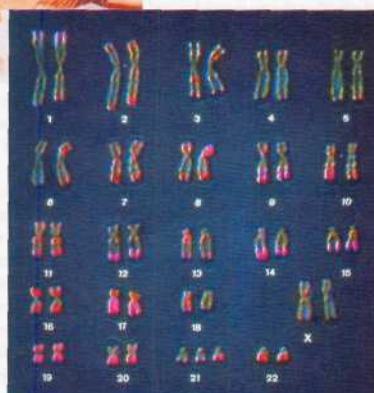

Human Disorders Due to Chromosomal Alterations

Alterations of chromosome number and structure are associated with a number of serious human disorders. Nondisjunction in meiosis results in aneuploid gametes. If an aneuploid gamete combines with a normal haploid gamete during fertilization, the result is an aneuploid zygote. Although the frequency of aneuploid zygotes may be quite high in humans, most of these chromosomal alterations are so disastrous to development that the embryos are spontaneously aborted long before birth. However, some types of aneuploidy appear to upset the genetic balance less than others, with the result that individuals with certain aneuploid conditions can survive to birth and beyond. These individuals have a set of symptoms—a *syndrome*—characteristic of the type of aneuploidy. Genetic disorders caused by aneuploidy can be diagnosed before birth by fetal testing (see Figure 14.17).

Down Syndrome (Trisomy 21)

One aneuploid condition, Down syndrome, affects approximately one out of every 700 children born in the United States (Figure 15.15). Down syndrome is usually the result of an extra chro-

▲ Figure 15.15 Down syndrome. The child exhibits the facial features characteristic of Down syndrome. The karyotype shows trisomy 21, the most common cause of this disorder.

mosome 21, so that each body cell has a total of 47 chromosomes. Because the cells are trisomic for chromosome 21, Down syndrome is often called *trisomy 21*. Down syndrome includes characteristic facial features, short stature, heart defects, susceptibility to respiratory infection, and mental retardation. Furthermore, individuals with Down syndrome are prone to developing leukemia and Alzheimer's disease. Although people with Down syndrome, on average, have a life span shorter than normal, some live to middle age or beyond. Most are sexually underdeveloped and sterile.

The frequency of Down syndrome increases with the age of the mother. While the disorder occurs in just 0.04% of children born to women under age 30, the risk climbs to 1.25% for mothers in their early 30s and is even higher for older mothers. Because of this relatively high risk, pregnant women over 35 are candidates for fetal testing to check for trisomy 21 in the embryo. The correlation of Down syndrome with maternal age has not yet been explained. Most cases result from nondisjunction during meiosis I, and some research points to an age-dependent abnormality in a meiosis checkpoint that normally delays anaphase until all the kinetochores are attached to the spindle (like the M phase checkpoint of the mitotic cell cycle; see Chapter 12). Trisomies of some other chromosomes also increase in incidence with maternal age, although infants with these autosomal trisomies rarely survive for long.

Aneuploidy of Sex Chromosomes

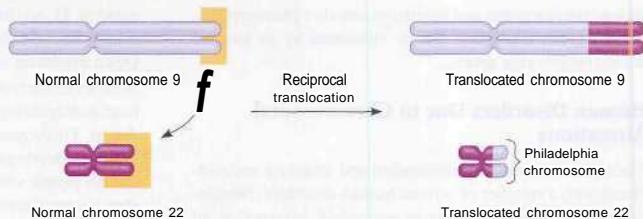

Nondisjunction of sex chromosomes produces a variety of aneuploid conditions. Most of these conditions appear to upset genetic balance less than aneuploid conditions involving autosomes. This may be because the Y chromosome carries relatively few genes and because extra copies of the X chromosome become inactivated as Barr bodies in somatic cells.

An extra X chromosome in a male, producing XYY, occurs approximately once in every 2,000 live births. People with this disorder, called *Klinefelter syndrome*, have male sex organs, but the testes are abnormally small and the man is sterile. "Even though the extra X is inactivated, some breast enlargement and other female body characteristics are common. The affected individual is usually of normal intelligence. Males with an extra Y chromosome (XYY) do not exhibit any well-defined syndrome, but they tend to be somewhat taller than average."

Females with trisomy X (XXX), which occurs once in approximately 1,000 live births, are healthy and cannot be distinguished from XX females except by karyotype. Monosomy X, called *Turner syndrome*, occurs about once in every 5,000 births and is the only known viable monosomy in humans. Although these X0 individuals are phenotypically female, they are sterile because their sex organs do not mature. When provided with estrogen replacement therapy, girls with Turner syndrome do develop secondary sex characteristics. Most have normal intelligence.

• Figure 15.16 Translocation associated with chronic myelogenous leukemia (CML).

The cancerous cells in nearly all CML patients contain an abnormally short chromosome 22, the so-called Philadelphia chromosome, and an abnormally long chromosome 9. These altered chromosomes result from the translocation shown here.

Disorders Caused by Structurally Altered Chromosomes

Many deletions in human chromosomes, even in a heterozygous state, cause severe problems. One such syndrome, known as *cri du chat* ("cry of the cat"), results from a specific deletion in chromosome 5. A child born with this deletion is mentally retarded, has a small head with unusual facial features, and has a cry that sounds like the mewing of a distressed cat. Such individuals usually die in infancy or early childhood.

Another type of chromosomal structural alteration associated with human disorders is translocation, the attachment of a fragment from one chromosome to another, nonhomologous chromosome. Chromosomal translocations have been implicated in certain cancers, including *chronic myelogenous leukemia (CML)*. Leukemia is a cancer affecting the cells that give rise to white blood cells, and in the cancerous cells of CML patients, a reciprocal translocation has occurred. In these cells, the exchange of a large portion of chromosome 22 with a small fragment from a tip of chromosome 9 produces a much shortened, easily recognized chromosome 22, called the *Philadelphia chromosome* (Figure 15.16). We will discuss how such an exchange might cause cancer in Chapter 19.

Concept 15.5

Some inheritance patterns are exceptions to the standard chromosome theory

In the previous section, you learned about abnormal deviations from the usual patterns of chromosomal inheritance. We conclude this chapter by describing two *normal* exceptions to Mendelian genetics, one involving genes located in the nucleus and the other involving genes located outside of the nucleus.

Genomic Imprinting

Throughout our discussions of Mendelian genetics and the chromosomal basis of inheritance, we have assumed that a specific allele will have the same effect regardless of whether it was inherited from the mother or the father. This is probably a safe assumption most of the time. For example, when Mendel crossed purple-flowered pea plants with white-flowered pea plants, he observed the same results regardless of whether the purple-flowered parent supplied the ova or the pollen. In recent years, however, geneticists have identified two to three dozen traits in mammals that depend on which parent passed along the alleles for those traits. Such variation in phenotype depending on whether an allele is inherited from the male or female parent is called genomic imprinting. (Note that the issue here is not sex linkage; most imprinted genes are on autosomes.)

Genomic imprinting occurs during the formation of gametes and results in the silencing of one allele of certain genes. Because these genes are imprinted differently in sperm and ova, a zygote expresses only one allele of an imprinted gene, either the allele inherited from the female parent or the allele inherited from the male parent. The imprints are transmitted to all the body cells during development, so the same allele of a given gene—either the maternally inherited allele or the paternally inherited allele—is expressed in all cells of that organism. In each generation, the old imprints are "erased" in gamete-producing cells, and the chromosomes of the

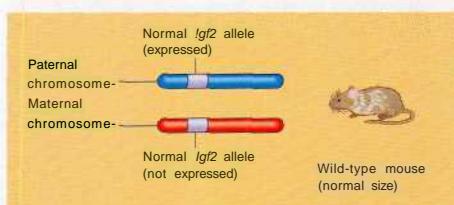

Concept Check 15.4

- More common than completely polyploid animals are mosaic polyploids, animals that are diploid except for patches of polyploid cells. How might a mosaic tetraploid—an animal with some cells containing four sets of chromosomes—arise?
- About 5% of individuals with Down syndrome have a chromosomal translocation in which one copy of chromosome 21 is attached to chromosome 14. How could this translocation in a parent's gonad lead to Down syndrome in a child?
- Explain how a male cat could have the tortoiseshell phenotype.

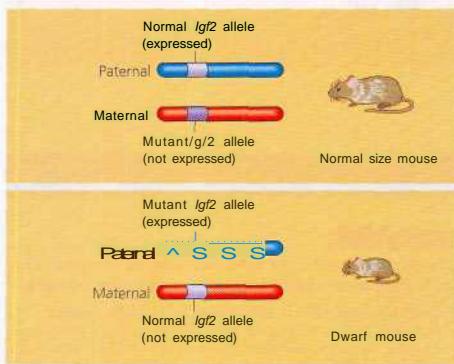

For suggested answers, see Appendix A.

developing gametes are newly imprinted according to the sex of the individual. In a given species, the imprinted genes are always imprinted in the same way. For instance, a gene imprinted for maternal allele expression is always imprinted for maternal allele expression, generation after generation.

Consider, for example, the gene for insulin-like growth factor 2 (*Igf2*), one of the first imprinted genes to be identified. Although this growth factor is required for normal prenatal growth, only the paternal allele is expressed (Figure 15.17a). Evidence that the *Igf2* gene is imprinted initially came from crosses between wild-type mice and dwarf mice homozygous for a recessive mutation in the *Igf2* gene. The phenotypes of heterozygous offspring (one normal allele and one mutant) differed, depending on whether the mutant allele came from the mother or the father (Figure 15.17b).

(a) A wild-type mouse is homozygous for the normal *Igf2* allele.

(b) When a normal *Igf2* allele is inherited from the father, heterozygous mice grow to normal size. But when a mutant allele is inherited from the father, heterozygous mice have the dwarf phenotype.

L Figure 15.17 Genomic imprinting of the mouse *Igf2* gene. (a) In mice, the paternal *Igf2* allele is expressed and the maternal allele is not. (b) Matings between wild-type mice and those homozygous for the recessive mutant *Igf2* allele produce heterozygous offspring that can be either normal size or dwarf, depending on which parent passes on the mutant allele.

What exactly is a genomic imprint? In many cases, it seems to consist of methyl ($-CH_3$) groups that are added to cytosine nucleotides of one of the alleles. Such methylation may directly silence the allele, an effect consistent with evidence that heavily methylated genes are usually inactive (see Chapter 19). However, for a few genes, methylation has been shown to *activate* expression of the allele. This is the case for the *Igf2* gene: Methylation of a certain DNA sequence on the paternal chromosome leads to expression of the paternal *Igf2* allele.

Genomic imprinting is thought to affect only a small fraction of the genes in mammalian genomes, but most of the known imprinted genes are critical for embryonic development. In experiments with mice, for example, embryos engineered to inherit both copies of certain chromosomes from the same parent inevitably die before birth, whether that parent is male or female. Normal development apparently requires that embryonic cells have exactly one active copy—not zero, not two—of certain genes. The association of aberrant imprinting with abnormal development and certain cancers is stimulating numerous studies on how different genes are imprinted.

Inheritance of Organelle Genes

Although our focus in this chapter has been on the chromosomal basis of inheritance, we end with an important amendment: Not all of a eukaryotic cell's genes are located on nuclear chromosomes, or even in the nucleus. Some genes are located in organelles in the cytoplasm; these genes are sometimes called *extranuclear genes*. Mitochondria, as well as chloroplasts and other plant plastids, contain small circular DNA molecules that carry genes coding for proteins and RNA. These organelles reproduce themselves and transmit their genes to daughter organelles. Because organelle genes are not distributed to offspring according to the same rules that direct the distribution of nuclear chromosomes during meiosis, they do not display Mendelian inheritance.

The first hint that extranuclear genes exist came from studies by Karl Correns on the inheritance of yellow or white patches on the leaves of an otherwise green plant. In 1909, he observed that the coloration of the offspring was determined only by the maternal parent (the source of seeds that germinate to give rise to the offspring) and not by the paternal parent (the pollen source). Subsequent research showed that such coloration patterns, or variegation, are due to mutations in plastid genes that control pigmentation. In most plants, a zygote receives all its plastids from the cytoplasm of the egg and none from pollen, which contributes little more than a haploid set of chromosomes. As the zygote develops, plastids containing wild-type or mutant pigment genes are distributed randomly to daughter cells. The pattern of leaf coloration exhibited by a

- **Figure 15.18 Variegated leaves from *Croton dioicus*.** Variegated (striped or spotted) leaves result from mutations in pigment genes located in plastids, which generally are inherited from the maternal parent.

plant depends on the ratio of wild-type to mutant plastids in its various tissues (**Figure 15.18**).

Similar maternal inheritance is also the rule for mitochondrial genes in most animals and plants, because almost all the mitochondria passed on to a zygote come from the cytoplasm of the egg. The products of most mitochondrial genes help make up the protein complexes of the electron transport chain and ATP synthase (see Chapter 9). Defects in one or more of these proteins, therefore, reduce the amount of ATP the cell can make and have been shown to cause a number of rare human disorders. Because the parts of the body most susceptible to energy deprivation are the nervous system and the muscles, most mitochondrial diseases primarily affect these systems. For example, a person with the disease called *mitochondrial myopathy* suffers weakness, intolerance of exercise, and muscle deterioration.

In addition to the rare diseases clearly caused by defects in mitochondrial DNA, mitochondrial mutations inherited

from a person's mother may contribute to at least some cases of diabetes and heart disease, as well as to other disorders that commonly debilitate the elderly, such as Alzheimer's disease, hi the course of a lifetime, new mutations gradually accumulate in our mitochondrial DNA, and some researchers think that these mutations play a role in the normal aging process.

Wherever genes are located in the cell—in the nucleus *DY* in cytoplasmic organelles—their inheritance depends on the precise replication of DNA, the genetic material, in the next chapter, you will learn how this molecular reproduction occurs.

Concept Check 15.5

1. Gene dosage, the number of active copies of a gene, is important to proper development. Identify and describe two processes that help establish the proper dosage of certain genes.
2. Reciprocal crosses between two primrose varieties, A and B, produced the following results: A female X B male → offspring with all green (nonvariegated) leaves. B female X A male → offspring with spotted (variegated) leaves. "Explain these results.
3. Mitochondrial genes are critical to the energy metabolism of cells, but mitochondrial disorders caused by mutations in these genes are generally not lethal. Why not?

For suggested answers, see Appendix A.

Chapter 15 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 15.1

Mendelian inheritance has its physical basis in the behavior of chromosomes

- In the early 1900s, several researchers proposed that genes are located on chromosomes and that the behavior of chromosomes during meiosis accounts for Mendel's laws of segregation and independent assortment (pp. 274–275).
- **Morgan's Experimental Evidence:** *Scientific Inquiry* (pp. 276–277) Morgan's discovery that transmission of the X chromosome in *Drosophila* correlates with inheritance of the eye-color trait was the first solid evidence indicating that a specific gene is associated with a specific chromosome.

Concept 15.2

Linked genes tend to be inherited together because they are located near each other on the same chromosome

- **How Linkage Affects Inheritance:** *Scientific Inquiry* (pp. 277–278) Each chromosome has hundreds or thousands of genes. Genes on the same chromosome whose alleles are so close together that they do not assort independently are said to be linked. The alleles of unlinked genes are either on separate chromosomes or so far apart on the same chromosome that they assort independently.
- **Genetic Recombination and Linkage** (pp. 278–280) Recombinant offspring exhibit new combinations of traits inherited from two parents. Because of the independent assortment of chromosomes and random fertilization, unlinked genes exhibit a 50% frequency of recombination. Even with crossing over between nonsister chromatids during the first meiotic division, linked genes exhibit recombination frequencies less than 50%.

- Linkage Mapping Using Recombination Data: Scientific Inquiry** (pp. 279–281) Geneticists can deduce the order of genes on a chromosome and the relative distances between them from recombination frequencies observed in genetic crosses. In general, the farther apart genes are on a chromosome, the more likely they are to be separated during crossing over.

Activity *Linked Genes and Crossing Over*

Concept 15.3

Sex-linked genes exhibit unique patterns of inheritance

- The Chromosomal Basis of Sex** (pp. 282–283) An organism's sex is an inherited phenotypic character usually determined by the presence or absence of certain chromosomes. Humans and other mammals have an X-Y system in which sex normally is determined by the presence or absence of a Y chromosome. Different systems of sex determination are found in birds, fishes, and insects.
- Inheritance of Sex-Linked Genes** (pp. 283–284) The sex chromosomes carry certain genes for traits that are unrelated to maleness or femaleness. For instance, recessive alleles causing color blindness, hemophilia, and Duchenne muscular dystrophy are carried on the X chromosome. Fathers transmit such sex-linked alleles to all daughters but to no sons. Any male who inherits a single sex-linked recessive allele from his mother will express the trait.

Activity *Sex-Linked Genes*

Investigation *What Can Fruit Flies Reveal About Inheritance?*

Biology Labs *On-Line FlyLab*

Biology Labs *On-Line PedigreeLab*

- X Inactivation in Female Mammals** (p. 284) In mammalian females, one of the two X chromosomes in each cell is randomly inactivated during early embryonic development. If a female is heterozygous for a particular gene located on the X chromosome, she will be mosaic for that character, with about half her cells expressing the maternal allele and about half expressing the paternal allele.

Concept 15.4

Abnormalities of chromosome number or structure cause some genetic disorders

I* Abnormal Chromosome Number (pp. 285–286)

Aneuploidy can arise when a normal gamete unites with one containing two copies or no copies of a particular chromosome as a result of nondisjunction during meiosis. The cells of the resulting zygote have either one extra copy of that chromosome (trisomy) or are missing a copy (monosomy). Polyploidy in which there are more than two complete sets of chromosomes, can result from complete nondisjunction during gamete formation.

Activity *Polyplloid Plants*

I* Alterations of Chromosome Structure (pp. 286–287)

Chromosome breakage can result in various rearrangements. A lost fragment leaves one chromosome with a deletion; the deleted fragment may reattach to the same chromosome in a different orientation, producing an inversion. Or the fragment may attach to a homologous chromosome, producing a duplication, or to a nonhomologous chromosome, producing a translocation.

II Human Disorders Due to Chromosomal Alterations

(pp. 287–288) Changes in the number of chromosomes per cell or in the structure of individual chromosomes can affect phenotype. Such alterations cause Down syndrome (usually due to trisomy of chromosome 21), certain cancers associated with chromosomal translations, and various other human disorders.

Concept 15.5

Some inheritance patterns are exceptions to the standard chromosome theory

- Genomic Imprinting** (pp. 288–289) In mammals, the phenotypic effects of certain genes depend on which allele is inherited from the mother and which is inherited from the father. Imprints are formed during gamete production, with the result that one allele (either maternal or paternal) is not expressed in offspring. Most imprinted genes now known play a role in embryonic development.
- Inheritance of Organelle Genes** (pp. 289–290) The inheritance of traits controlled by the genes present in mitochondria and chloroplasts depends solely on the maternal parent because the zygote's cytoplasm comes from the egg. Some diseases affecting the nervous and muscular systems are caused by defects in mitochondrial genes that prevent cells from making enough ATP.

TESTING YOUR KNOWLEDGE

Genetics Problems

1. A man with hemophilia (a recessive, sex-linked condition) has a daughter of normal phenotype. She marries a man who is normal for the trait. What is the probability that a daughter of this mating will be a hemophiliac? That a son will be a hemophiliac? If the couple has four sons, what is the probability that all four will be born with hemophilia?
2. Pseudohypertrophic muscular dystrophy is an inherited disorder that causes gradual deterioration of the muscles. It is seen almost exclusively in boys born to apparently normal parents and usually results in death in the early teens. Is this disorder caused by a dominant or a recessive allele? Is its inheritance sex-linked or autosomal? How do you know? Explain why this disorder is almost never seen in girls.
3. Red-green color blindness is caused by a sex-linked recessive allele. A color-blind man marries a woman with normal vision whose father was color-blind. What is the probability that they will have a color-blind daughter? What is the probability that their first son will be color-blind? (Note: The two questions are worded a bit differently)
4. A wild-type fruit fly (heterozygous for gray body color and normal wings) is mated with a black fly with vestigial wings. The offspring have the following phenotypic distribution: wild type, 778; black-vestigial, 785; black-normal, 158; gray-vestigial, 162. What is the recombination frequency between these genes for body color and wing size?
5. In another cross, a wild-type fruit fly (heterozygous for gray body color and red eyes) is mated with a black fruit fly with purple eyes. The offspring are as follows: wild type, 721; black-purple, 751; gray-purple, 49; black-red, 45. What is the recombination frequency between these genes for body color and eye color? Using information from problem 4, what fruit flies (genotypes and phenotypes) would you mate to determine the sequence of the body-color, wing-size, and eye-color genes on the chromosome?

6. What pattern of inheritance would lead a geneticist to suspect that an inherited disorder of cell metabolism is due to a defective mitochondrial gene?
7. Women born with an extra X chromosome (XXX) are healthy and phenotypically indistinguishable from normal XX women. What is a likely explanation for this finding? How could you test this explanation?
8. Determine the sequence of genes along a chromosome based on the following recombination frequencies: *A-B*, 8 map units; *A-C*, 28 map units; *A-D*, 25 map units; *B-C*, 20 map units; *B-D*, 33 map units.
9. Assume that genes *A* and *B* are linked and are 50 map units apart. An animal heterozygous at both loci is crossed with one that is homozygous recessive at both loci. What percentage of the offspring will show phenotypes resulting from crossovers? If you did not know that genes *A* and *B* were linked, how would you interpret the results of this cross?
10. A space probe discovers a planet inhabited by creatures who reproduce with the same hereditary patterns seen in humans. Three phenotypic characters are height (*T* = tall, *t* = dwarf), head appendages (*A* = antennae, *a* = no antennae), and nose morphology (*s* = upturned snout, *s'* = downturned snout). Since the creatures are not "intelligent," Earth scientists are able to do some controlled breeding experiments, using various heterozygotes in testcrosses. For tall heterozygotes with antennae, the offspring are: tall-antennae, 46; dwarf-antennae, 7; dwarf-no antennae, 42; tall-no antennae, 5. For heterozygotes with antennae and an upturned snout, the offspring are: antennae-upturned snout, 47; antennae-downturned snout, 2; no antennae-downturned snout, 48; no antennae-upturned snout, 3. Calculate the recombination frequencies for both experiments.
11. Using the information from problem 10, a further testcross is done using a heterozygote for height and nose morphology. The offspring are: tall-upturned snout, 40; dwarf-upturned snout, 9; dwarf-downturned snout, 42; tall-downturned snout, 9. Calculate the recombination frequency from these data; then use your answer from problem 10 to determine the correct sequence of the three linked genes.
12. The ABO blood type locus has been mapped on chromosome 9. A father who has blood type AB and a mother who has blood type O have a child with trisomy 9 and blood type A. Using this information, can you tell in which parent the nondisjunction occurred? Explain your answer.
13. Two genes of a flower, one controlling blue (*B*) versus white (*b*) petals and the other controlling round (*R*) versus oval (*r*) stamens, are linked and are 10 map units apart. You cross a homozygous blue-oval plant with a homozygous white-round plant. The resulting *F₁* progeny are crossed with homozygous white-oval plants, and 1,000 progeny are obtained. How many plants of each of the four phenotypes do you expect?
14. You design *Drosophila* crosses to provide recombination data for gene *a*, which is located on the same chromosome shown in Figure 15.8. Gene *a* has recombination frequencies of 14% with the vestigial-wing locus and 26% with the brown-eye locus. Where is *a* located on the chromosome?

For Genetics Problems answers, see Appendix A.

Go to the website or CD-ROM for more quiz questions.

Evolution Connection

You have seen that crossing over, or recombination, is thought to be evolutionarily advantageous because this process continually shuffles genetic alleles into novel combinations. Some organisms, however, have apparently lost the recombination mechanism, while in others, certain chromosomes do not recombine. What factors do you think may favor reduced levels of recombination?

Scientific Inquiry

Consider Figure 15.5, in which the *F₁* dihybrid females resulted from a cross between parental (*P*) flies with genotypes *b⁺ b⁺ vg⁻ vg⁻* and *b b vg vg*. Now, imagine you make *F_L* females by crossing two different *P* generation flies: *b⁺ b⁺ vg vg X b b vg⁻ vg⁻*.

- What will be the genotype of your *F₁* females? Is this the same as that for the *F₁* females in Figure 15.5?
- Draw the chromosomes for the *F_L* females, indicating the position of each allele. Are these the same as for the *F₂* females in Figure 15.5?
- Knowing that the distance between these two genes is 17 map units, predict the phenotypic ratios you will get from a cross. Will they be the same as in Figure 15.5?
- Draw the chromosomes of the *P*, *F_A*, and *F₂* generations (as is done in Figure 15.6 for the cross in Figure 15.5), showing how this arrangement of alleles in the *P* generation leads, via *F₁* gametes, to the phenotypic ratios seen in the *F₂* flies.

[Biology Labs On-Line PedigreeLab](#)

Science, Technology, and Society

About one in every 1,500 boys and one in every 2,500 girls are born with a fragile X chromosome, the tip of which hangs on to the rest of the chromosome by a thin thread of DNA. This abnormality causes mental retardation. Opinions differ about whether children with learning disorders should be tested by karyotyping for the presence of a fragile X chromosome. Some argue that it's always better to know the cause of the problem so that education specialized for that disorder can be prescribed. Others counter that attaching a specific biological cause to a learning disability stigmatizes a child and limits his or her opportunities. What is your evaluation of these arguments?

16 The Molecular Basis of Inheritance

A Figure 16.1 Watson and Crick with their DNA model.

Key Concepts

- 16.1 DNA is the genetic material
- 16.2 Many proteins work together in DNA replication and repair

Overview

life Operating Instructions

In April 1953, James Watson and Francis Crick shook the scientific world with an elegant double-helical model for the structure of deoxyribonucleic acid, or DNA. **Figure 16.1** shows Watson and Crick admiring their DNA model, which they built from tin and wire. Over the past 50 years, their model has evolved from a novel proposition to an icon of modern biology. DNA, the substance of inheritance, is the most celebrated molecule of our time. Mendel's heritable factors and Morgan's genes on chromosomes are, in fact, composed of DNA. Chemically speaking, your genetic endowment is the DNA contained in the 46 chromosomes you inherited from your parents.

Of all nature's molecules, nucleic acids are unique in their ability to direct their own replication from monomers. Indeed, the resemblance of offspring to their parents has its basis in the precise replication of DNA and its transmission from one generation to the next. Hereditary information is encoded in the chemical language of DNA and reproduced in all the cells of your body. It is this DNA program that directs the development of your biochemical, anatomical, physiological, and, to some extent, behavioral traits. In this chapter, you will learn how biologists deduced that DNA is the genetic material, how Watson and Crick discovered its structure, and how cells replicate and repair their DNA—the molecular basis of inheritance.

Concept 16.1

DNA is the genetic material

Today even schoolchildren have heard of DNA, and scientists routinely manipulate DNA in the laboratory and use it to change the heritable characteristics of cells. Early in the 20th century, however, the identification of the molecules of inheritance loomed as a major challenge to biologists.

The Search for the Genetic Material: Scientific Inquiry

Once T. H. Morgan's group showed that genes are located on chromosomes (described in Chapter 15), the two chemical components of chromosomes—DNA and protein—became the candidates for the genetic material. Until the 1940s, the case for proteins seemed stronger, especially since biochemists had identified them as a class of macromolecules with great heterogeneity and specificity of function, essential requirements for the hereditary material. Moreover, little was known about nucleic acids, whose physical and chemical properties seemed far too uniform to account for the multitude of specific inherited traits exhibited by every organism. This view gradually changed as experiments with microorganisms yielded unexpected results. As with the work of Mendel and Morgan, a key factor in determining the identity of the genetic material was the choice of appropriate experimental organisms. The role of DNA in heredity was first worked out by studying bacteria and the viruses that infect them, which are far simpler than pea plants, fruit flies, or humans. In this section, we will trace the search for the genetic material in some detail as a case study in scientific inquiry.

Evidence That DNA Can Transform Bacteria

We can trace the discovery of the genetic role of DNA back to 1928. Frederick Griffith, a British medical officer, was studying *Streptococcus pneumoniae*, a bacterium that causes pneumonia in mammals. Griffith had two strains (varieties) of the bacterium, a pathogenic (disease-causing) one and a nonpathogenic (harmless) strain. He was surprised to find that when he killed the pathogenic bacteria with heat and then mixed the cell remains with living bacteria of the nonpathogenic strain, some of the living cells became pathogenic (Figure 16.2). Furthermore, this new trait of pathogenicity was inherited by all the descendants of the transformed bacteria. Clearly some chemical component of the dead pathogenic cells caused this heritable change, although the identity of the substance was not known. Griffith called the phenomenon transformation, now defined as a change in genotype and phenotype due to the assimilation of external DNA by a cell. (This use of the word *transformation* should not be confused with the conversion of a normal animal cell to a cancerous one, discussed in Chapter 12.)

Griffith's work set the stage for a 14-year search for the identity of the transforming substance by American bacteriologist Oswald Avery. Avery purified various types of molecules from the heat-killed pathogenic bacteria, then tried to transform live nonpathogenic bacteria with each type. Only DNA worked. Finally, in 1944, Avery and his colleagues Maclyn McCarty and Colin MacLeod announced that the transforming agent was DNA. Their discovery was greeted with interest but considerable skepticism, in part because of the lingering belief that proteins were better candidates for the genetic material. Moreover, many biologists were not convinced that the genes of bacteria would be similar in composition and function to those of more complex organisms. But the major reason for the continued doubt was that so little was known about DNA.

Evidence That Viral DNA Can Program Cells

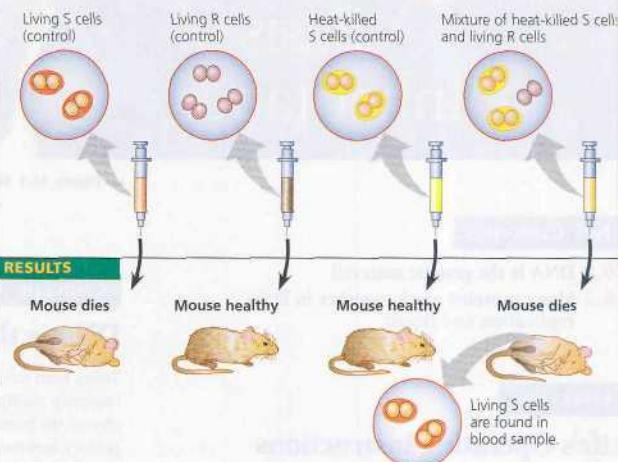

Additional evidence for DNA as the genetic material came from studies of a virus that infects bacteria. Viruses are much simpler than cells. A virus is little more than DNA (or sometimes RNA) enclosed by a protective coat, which is often simply protein. To reproduce, a virus must infect a cell and take over the cell's metabolic machinery.

Figure 16.2

Inquiry Can the genetic trait of pathogenicity be transferred between bacteria?

EXPERIMENT

Bacteria of the "S" (smooth) strain of *Streptococcus pneumoniae* are pathogenic because they have a capsule that protects them from an animal's defense system. Bacteria of the "R" (rough) strain lack a capsule and are nonpathogenic. Frederick Griffith injected mice with the two strains as shown below:

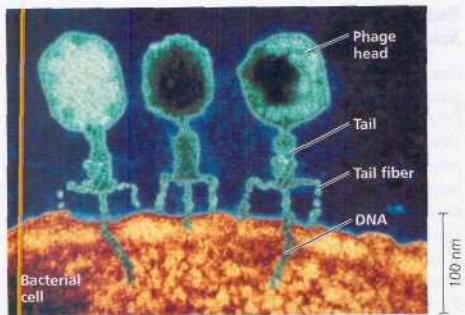

RESULTS

Griffith concluded that the living R bacteria had been transformed into pathogenic S bacteria by an unknown, heritable substance from the dead S cells.

Viruses that infect bacteria are widely used as tools by researchers in molecular genetics. These viruses are called bacteriophages (meaning "bacteria-eaters"), or just phages (Figure 16.3). In 1952, Alfred Hershey and Martha Chase performed experiments showing that DNA is the genetic material of a phage known as T2. This is one of many phages that infect *Escherichia coli* (*E. coli*), a bacterium that normally lives in the intestines of mammals. At that time, biologists already knew that T2, like many other viruses, was composed almost entirely of DNA and protein. They also knew that the T2 phage could quickly turn an *E. coli* cell into a T2-producing factory that released many copies when the cell ruptured. Somehow, T2 could reprogram its host cell to produce viruses. But which viral component—protein or DNA—was responsible?

Hershey and Chase answered this question by devising an experiment showing that only one of the two components of T2 actually enters the *E. coli* cell during infection (Figure 16.4). In preparation for their experiment, they used different radioactive isotopes to tag phage DNA and protein. First, they grew T2 with *E. coli* in the presence of radioactive sulfur.

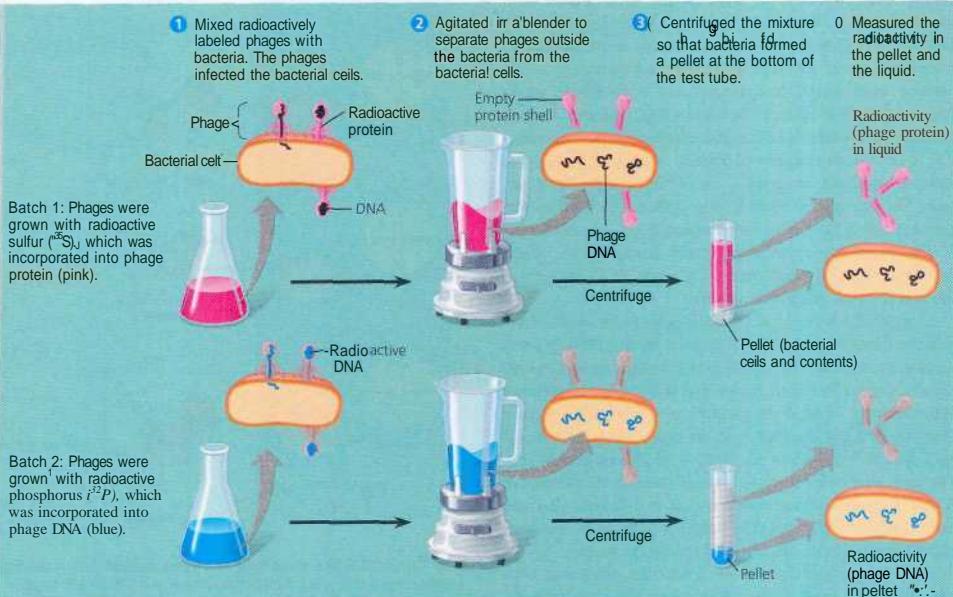

A Figure 16.3 Viruses infecting a bacterial cell. T2 and related phages attach to the host cell and inject their genetic material (colorized TEM).

Because protein, but not DNA, contains sulfur, the radioactive atoms were incorporated only into the protein of the phage. Next, in a similar way, the DNA of a separate batch of T2 was labeled with atoms of radioactive phosphorus; because nearly all the phage's phosphorus is in its DNA, this procedure left the phage protein unlabeled. In the experiment, the protein-labeled and DNA-labeled batches of T2 were each allowed to infect separate samples of nonradioactive *E. coli* cells. Shortly after the onset of infection, the cultures were whirled in a blender to shake loose any parts of the phages that remained outside the bacterial cells. The mixtures were then spun in a centrifuge, forcing the bacterial cells to form a pellet at the bottom of the centrifuge tubes, but allowing free phages and parts of phages, which are lighter, to remain suspended in the liquid, or supernatant. The scientists then measured the radioactivity in the pellet and in the supernatant.

Figure 16.4 Inquiry Is DNA or protein the genetic material of phage T2?

EXPERIMENT

In their famous 1952 experiment, Alfred Hershey and Martha Chase used radioactive sulfur and phosphorus to trace the fates of the protein and DNA, respectively, of T2 phages that infected bacterial cells.

RESULTS

Phage proteins remained outside the bacterial cells during infection, while phage DNA entered the cells. When cultured, bacterial cells with radioactive phage DNA released new phages with some radioactive phosphorus.

CONCLUSION

Hershey and Chase concluded that DNA, not protein, functions as the T2 phage's genetic material.

Hershey and Chase found that when the bacteria had been infected with the T2 phage containing radioactively labeled proteins, most of the radioactivity was found in the supernatant, which contained phage particles (but not bacteria). This result suggested that the protein of the phage did not enter the host cells. But when the bacteria had been infected with the T2 phage containing radioactively labeled DNA, most of the radioactivity was found in the pellet, which contained the host bacteria. This result suggested that the phage DNA entered the host cells. Moreover, when these bacteria were returned to a culture medium, the infection ran its course, and the *E. coli* released phages that contained some radioactive phosphorus.

Hershey and Chase concluded that the DNA of the virus is injected into the host cell during infection, leaving the protein outside. The injected DNA provides genetic information that makes the cells produce new viral DNA and proteins, which assemble into new viruses. Thus, the Hershey-Chase experiment provided powerful evidence that nucleic acids, rather than proteins, are the hereditary material, at least for viruses.

Additional Evidence That DNA Is the Genetic Material

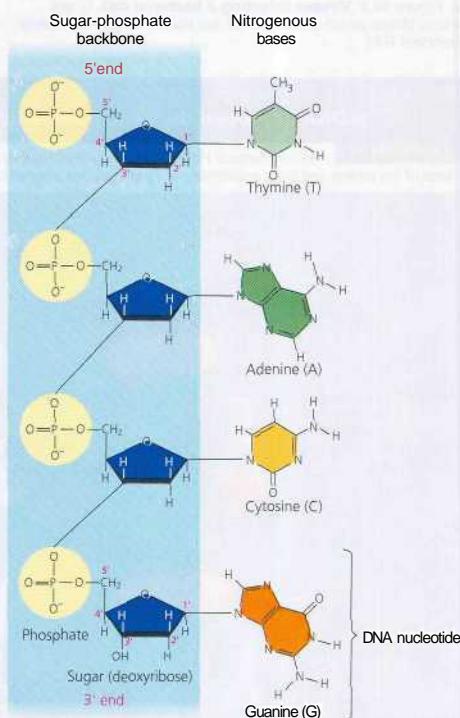

Further evidence that DNA is the genetic material came from the laboratory of biochemist Erwin Chargaff. It was already known that DNA is a polymer of nucleotides, each consisting of three components: a nitrogenous (nitrogen-containing) base, a pentose sugar called deoxyribose, and a phosphate group (**Figure 16.5**). The base can be adenine (A), thymine (T), guanine (G), or cytosine (C). Chargaff analyzed the base composition of DNA from a number of different organisms. In 1947, he reported that DNA composition varies from one species to another. For example, 30.3% of human DNA nucleotides have the base A, whereas DNA from the bacterium *E. coli* has only 26.0% A. This evidence of molecular diversity among species, which had been presumed absent from DNA, made DNA a more credible candidate for the genetic material.

Chargaff also found a peculiar regularity in the ratios of nucleotide bases within a single species. In the DNA of each species he studied, the number of adenines approximately equaled the number of thymines, and the number of guanines approximately equaled the number of cytosines. In human DNA, for example, the four bases are present in these percentages: A = 30.3% and T = 30.3%; G = 19.5% and C = 19.9%. The equivalences for any given species between the number of A and T bases and the number of G and C bases became known as *Chargaff's rules*. The basis for these rules remained unexplained until the discovery of the double helix.

Additional circumstantial evidence was consistent with DNA being the genetic material in eukaryotes. Prior to mitosis, a eukaryotic cell exactly doubles its DNA content, and during mitosis, this DNA is distributed equally to the two daughter cells. Also, in a given species, a diploid set of chromosomes has twice as much DNA as the haploid set.

Building a Structural Model of DNA: Scientific Inquiry

Once most biologists were convinced that DNA was the genetic material, the challenge was to determine how the structure of DNA could account for its role in inheritance. By the early 1950s, the arrangement of covalent bonds in a nucleic acid polymer was well established (see Figure 16.5), and researchers focused on discovering the three-dimensional structure of DNA. Among the scientists working on the problem were Linus Pauling, in California, and Maurice Wilkins and Rosalind Franklin, in London. First to come up with the correct answer, however, were two scientists who were relatively unknown at the time—the American James Watson and the Englishman Francis Crick.

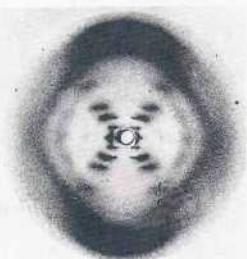

A Figure 16.5 The structure of a DNA strand. Each nucleotide (monomer) consists of a nitrogenous base (T, A, C, or G), the sugar deoxyribose (blue), and a phosphate group (yellow). The phosphate of one nucleotide is attached to the sugar of the next, resulting in a "backbone" of alternating phosphates and sugars from which the bases project. The polynucleotide strand has directionality, from the 5' end (with the phosphate group) to the 3' end (with the —OH group). 5' and 3' refer to the numbers assigned to the carbons in the sugar ring.

The brief but celebrated partnership that solved the puzzle of DNA structure began soon after Watson journeyed to Cambridge University, where Crick was studying protein structure with a technique called X-ray crystallography (see Figure 5.24). While visiting the laboratory of Maurice Wilkins at King's College in London, Watson saw an X-ray diffraction image of DNA

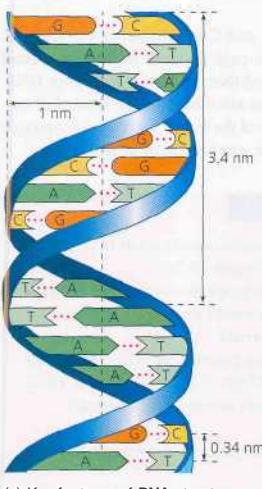

(a) Rosalind Franklin

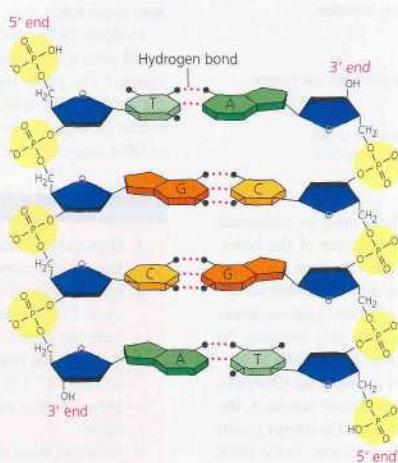

(b) Franklin's X-ray diffraction photograph of DNA

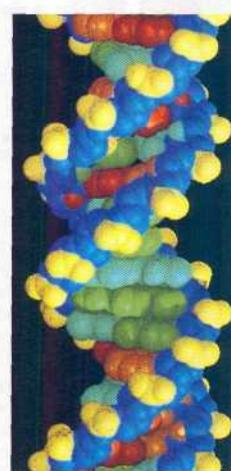

A Figure 16.6 Rosalind Franklin and her X-ray diffraction photo of DNA. Franklin, an X-ray crystallographer, made the photo that Watson and Crick used in deducing the double-helical structure of DNA. Franklin died of cancer in 1958, when she was only 38. Her colleague Maurice Wilkins received the Nobel Prize in 1962 along with Watson and Crick.

(a) Key features of DNA structure

(c) Space-filling model

A Figure 16.7 The double helix. (a) The "ribbons" in this diagram represent the sugar-phosphate backbones of the two DNA strands. The helix is "right-handed," curving up to the right. The two strands are held together by

hydrogen bonds (dotted lines) between the nitrogenous bases, which are paired in the interior of the double helix. (b) For clarity, the two DNA strands are shown untwisted in this partial chemical structure. Notice that the strands are

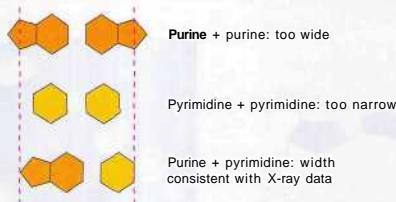

antiparallel, meaning that they are oriented in opposite directions. (c) The tight stacking of the base pairs is clear in this computer model. Van der Waals attractions between the stacked pairs play a major role in holding the molecule together.

produced by Wilkins¹ colleague, Rosalind Franklin (**Figure 16.6a**). Images produced by X-ray crystallography are not actually pictures of molecules. The spots and smudges in **Figure 16.6b** were produced by X-rays that were diffracted (deflected) as they passed through aligned fibers of purified DNA. Crystallographers use mathematical equations to translate such patterns into information about the three-dimensional shapes of molecules, and Watson was familiar with the types of patterns that helical molecules produce, just a glance at Franklin's X-ray diffraction photo of DNA not only told him that DNA was helical in shape, but also enabled him to deduce the width of the helix and the spacing of the nitrogenous bases along it. The width of the helix suggested that it was made up of two strands, contrary to a three-stranded model that Linus Pauling had recently proposed. The presence of two strands accounts for the now-familiar term double helix (**Figure 16.7**).

Watson and Crick began building models of a double helix that would conform to the X-ray measurements and what was then known about the chemistry of DNA. Having read an annual report summarizing Franklin's work, they knew she had concluded that the sugar-phosphate backbones were on the outside of the double helix. This arrangement was appealing because it put the relatively hydrophobic nitrogenous bases in the molecule's interior and thus away from the surrounding aqueous solution. Watson constructed a model with the nitrogenous bases facing the interior of the double helix (see

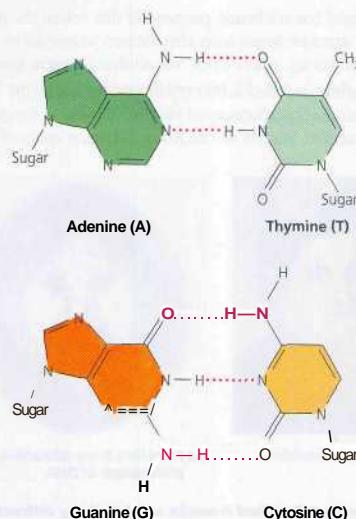

Figure 16.7). You can imagine this arrangement as a rope ladder with rigid rungs. The side ropes are the equivalent of the sugar-phosphate backbones, and the rungs represent pairs of nitrogenous bases. Now imagine the ladder twisted into a spiral. Franklin's X-ray data indicated that the helix makes one full turn every 3.4 nm along its length. With the bases stacked just 0.34 nm apart, there are ten layers of base pairs, or rungs of the ladder, in each turn of the helix.

The nitrogenous bases of the double helix are paired in specific combinations: adenine (A) with thymine (T), and guanine (G) with cytosine (C). It was mainly by trial and error that Watson and Crick arrived at this key feature of DNA. At first, Watson imagined that the bases paired like with like—for example, A with A and C with C. But this model did not fit the X-ray data, which suggested that the double helix had a uniform diameter. Why is this requirement inconsistent with like-with-like pairing of bases? Adenine and guanine are purines, nitrogenous bases with two organic rings. In contrast, cytosine and thymine belong to the family of nitrogenous bases known as pyrimidines, which have a single ring. Thus, purines (A and C) are about twice as wide as pyrimidines (C and T). A purine-purine pair is too wide and a pyrimidine-pyrimidine pair too narrow to account for the 2-nm diameter of the double helix. Always pairing a purine with a pyrimidine, however, results in a uniform diameter:

Watson and Crick reasoned that there must be additional specificity of pairing dictated by the structure of the bases. Each base has chemical side groups that can form hydrogen bonds with its appropriate partner: Adenine can form two hydrogen bonds with thymine and only thymine; guanine forms three hydrogen bonds with cytosine and only cytosine. In shorthand, A pairs with T, and G pairs with C (**Figure 16.8**).

The Watson-Crick model explained the basis for Chargaff's rules. Wherever one strand of a DNA molecule has an A, the partner strand has a T. And a G in one strand is always paired with a C in the complementary strand. Therefore, in the DNA of any organism, the amount of adenine equals the amount of thymine, and the amount of guanine equals the amount of cytosine. Although the base-pairing rules dictate the combinations of nitrogenous bases that form the "rungs" of the double helix, they do not restrict the sequence of nucleotides *along* each DNA strand. The linear sequence of the four bases can be

A Figure 16.8 Base pairing in DNA. The pairs of nitrogenous bases in a DNA double helix are held together by hydrogen bonds, as shown here.

varied in countless ways, and each gene has a unique order, or **base sequence**.

In April 1953, Watson and Crick surprised the scientific world with a succinct, one-page paper in the British journal *Nature*.^{*} The paper reported their molecular model for DNA: the double helix, which has since become the symbol of molecular biology. The beauty of the model was that the structure of DNA suggested the basic mechanism of its replication.

Concept Check 16.1

- How did bacterial transformation occur in Griffith's famous experiment (Figure 16.2)?
- In Hershey and Chases experiment with the bacterial virus T2, what result would you expect if protein were the genetic material?
- A fly has the following percentages of nucleotides in its DNA: 27.3% A, 27.6% T, 22.5% G, and 22.5% C. How do these numbers demonstrate Chargaff's rules?
- How did Watson and Cricks model explain the basis for Clivj.arf? rules?

For suggested answers, see Appendix A.

*J. D. Watson and F. H. C. Crick, "Molecular Structure of Nucleic Acids: A Structure for Deoxyribonucleic Acid," *Nature* 171 (1953): 738.

Many proteins work together in DNA replication and repair

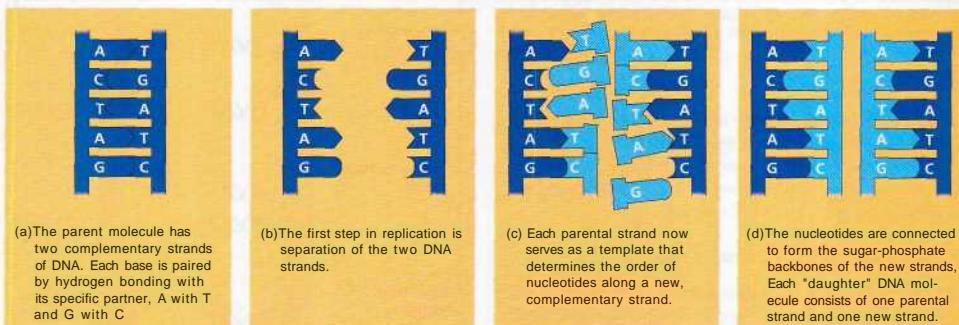

The relationship between structure and function is manifest in the double helix. The idea that there is specific pairing of nitrogenous bases in DNA was the flash of inspiration that led Watson and Crick to the correct double helix. At the same time, they saw the functional significance of the base-pairing rules. They ended their classic paper with this wry statement: "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material." In this section, you will learn about the basic principle of DNA replication, as well as some important details of the process.

The Basic Principle: Base Pairing to a Template Strand

In a second paper, Watson and Crick stated their hypothesis for how DNA replicates:

Now our model for deoxyribonucleic acid is, in effect, a pair of templates, each of which is complementary to the other. We imagine that prior to duplication the hydrogen bonds are broken, and the two chains unwind and separate. Each chain then acts as a template for the formation onto itself of a new companion chain, so that eventually we shall have two pairs of chains, where we only had one before. Moreover, the sequence of the pairs of bases will have been duplicated exactly.*

*] H. C. Crick and J. D. Watson, "The Complementary Structure of Deoxyribonucleic Acid," *Proc. Roy. Soc. (A)* 223 (1954): 80.

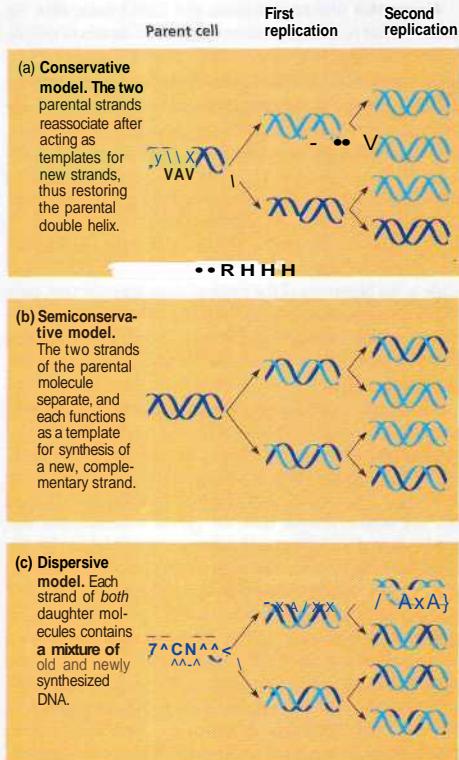

A Figure 16.9 A model for DNA replication: the basic concept. In this simplification, a short segment of DNA has been untwisted into a structure that

resembles a ladder. The rails of the ladder are the sugar-phosphate backbones of the two DNA strands; the rungs are the pairs of nitrogenous bases. Simple shapes symbolize

the four kinds of bases. Dark blue represents DNA strands present in the parent molecule; light blue represents free nucleotides and newly synthesized DNA.

Figure 16.9 illustrates Watson and Crick's basic idea. To make it easier to follow, we show only a short segment of double helix in untwisted form. Notice that if you cover one of the two DNA strands of Figure 16.9a, you can still determine its linear sequence of bases by referring to the uncovered strand and applying the base-pairing rules. The two strands are complementary; each stores the information necessary to reconstruct the other. When a cell copies a DNA molecule, each strand serves as a template for ordering nucleotides into a new, complementary strand. As nucleotides line up along the template strand according to the base-pairing rules, they are linked to form the new strands. Where there was one double-stranded DNA molecule at the beginning of the process, there are soon two, each an exact replica of the "parent" molecule. The copying mechanism is analogous to using a photographic negative to make a positive image, which can in turn be used to make another negative, and so on.

This model of DNA replication remained untested for several years following publication of the DNA structure. The requisite experiments were simple in concept but difficult to perform. Watson and Crick's model predicts that when a double helix replicates, each of the two daughter molecules will have one old strand, derived from the parent molecule, and one newly made strand. This semiconservative model can be distinguished from a conservative model of replication, in which the parent molecule somehow re-forms after the process (that is, it is conserved). In yet a third model, called the dispersive model, all four strands of DNA following replication have a mixture of old and new DNA (Figure 16.10, on the next page). Although mechanisms for conservative or dispersive DNA replication are not easy to devise, these models remained possibilities until they could be ruled out. Finally, in the late 1950s, Matthew Meselson and Franklin Stahl devised experiments that tested the three hypotheses. Their experiments

A Figure 16.10 Three alternative models of DNA replication.

replication. The short segments of double helix here symbolize the DNA within a cell. Beginning with a parent cell, we follow the DNA for two generations of cells—two rounds of DNA replication. Newly made DNA is light blue.

supported the semiconservative model of DNA replication, as predicted by Watson and Crick (**Figure 16.11**).

The basic principle of DNA replication is elegantly simple. However, the actual process involves some complicated biochemical gymnastics, as we will now see.

DNA Replication: A Closer Look

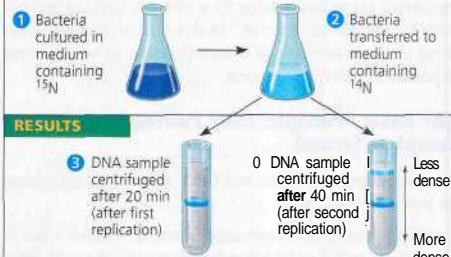

The bacterium *E. coli* has a single chromosome of about 4.6 million nucleotide pairs. In a favorable environment, an *E. coli* cell can copy all this DNA and divide to form two genetically identical daughter cells in less than an hour. Each of your cells has 46 DNA molecules in its nucleus, one long double helical molecule per chromosome. In all, that represents about

Figure 16.11

Inquiry Does DNA replication follow the conservative, semiconservative, or dispersive model?

EXPERIMENT

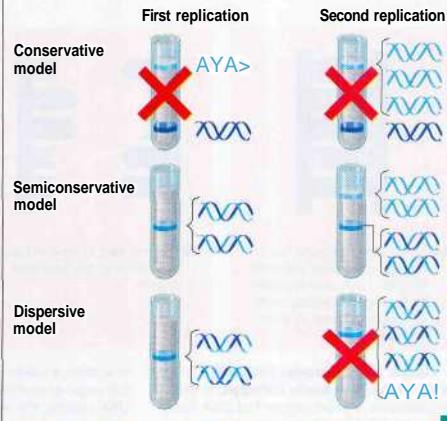

Matthew Meselson and Franklin Stahl cultured *E. coli* bacteria for several generations on a medium containing nucleotide precursors labeled with a heavy isotope of nitrogen, ^{15}N . The bacteria incorporated the heavy nitrogen into their DNA. Then they transferred the bacteria to a medium with only ^{14}N , the lighter, more common isotope of nitrogen. Any new DNA that the bacteria synthesized would be lighter than the parental DNA made in the ^{15}N medium. Meselson and Stahl could distinguish DNA of different densities by centrifuging DNA extracted from the bacteria.

The bands in these two centrifuge tubes represent the results of centrifuging two DNA samples from the flask in step 2, one sample taken after 20 minutes and one after 40 minutes.

CONCLUSION

Meselson and Stahl concluded that DNA replication follows the semiconservative model by comparing their result to the results predicted by each of the three models in Figure 16.10. The first replication in the ^{15}N - ^{14}N DNA produced a band of hybrid (^{15}N - ^{14}N) DNA. This result eliminated the conservative model. A second replication produced both light and hybrid DNA, a result that eliminated the dispersive model and supported the semiconservative model.

6 billion base pairs, or over a thousand times more DNA than is found in a bacterial cell. If we were to print the one-letter symbols for these bases (A, G, C, and T) the size of the letters you are now reading, the 6 billion bases of information in a diploid human cell would fill about 1,200 books as thick as this text. Yet it takes a cell just a few hours to copy all this DNA. This replication of an enormous amount of genetic information is achieved with very few errors—only about one per 10 billion nucleotides. The copying of DNA is remarkable in its speed and accuracy.

More than a dozen enzymes and other proteins participate in DNA replication. Much more is known about how this “replication machine” works in bacteria than in eukaryotes, and we will describe the basic steps of the process for *E. coli*, except where otherwise noted. What scientists have learned about eukaryotic DNA replication suggests, however, that most of the process is fundamentally similar for prokaryotes and eukaryotes.

Getting Started: Origins of Replication

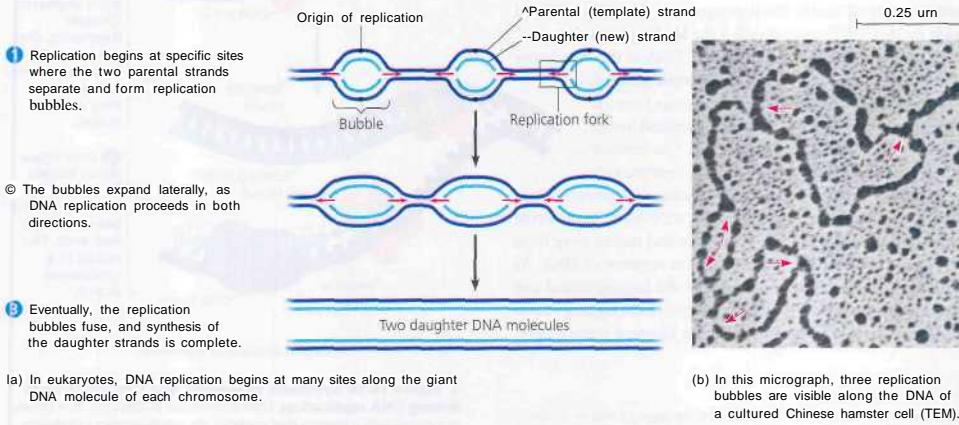

The replication of a DNA molecule begins at special sites called origins of replication. The bacterial chromosome, which is circular, has a single origin, a stretch of DNA having a specific sequence of nucleotides. Proteins that initiate DNA replication recognize this sequence and attach to the DNA, separating the two strands and opening up a replication “bubble.” Replication of DNA then proceeds in both directions “until the entire molecule is copied (see Figure 18.14). In contrast to a bacterial chromosome, a eukaryotic chromosome may have hundreds or even thousands of replication origins. Multiple replication bubbles form and eventually fuse, thus speeding up the copying of the very long DNA molecules (**Figure 16.12**). As in bacteria, eu-

karyotic DNA replication proceeds in both directions from each origin. At each end of a replication bubble is a replication fork, a Y-shaped region where the new strands of DNA are elongating.

Elongating a New DNA Strand

Elongation of new DNA at a replication fork is catalyzed by enzymes called DNA polymerases. As individual nucleotides align with complementary nucleotides along a template strand of DNA, DNA polymerase adds them, one by one, to the growing end of the new DNA strand. The rate of elongation is about 500 nucleotides per second in bacteria and 50 per second in human cells. In *E. coli*, two different DNA polymerases are involved in replication: DNA polymerase III and DNA polymerase I. The situation in eukaryotes is more complicated, with at least 11 different DNA polymerases discovered so far; however, the general principles are the same.

Each nucleotide that is added to a growing DNA strand is actually a nucleoside triphosphate, which is a nucleoside (a sugar and a base) with three phosphate groups. You have already encountered such a molecule—ATP (adenosine triphosphate; see Figure 8.8). The only difference between the ATP of energy metabolism and the nucleoside triphosphate that supplies adenine to DNA is the sugar component, which is deoxyribose in the building block of DNA, but ribose in ATP. Like ATP, the triphosphate monomers used for DNA synthesis are chemically reactive, partly because their triphosphate tails have an unstable cluster of negative charge. As each monomer joins the growing end of a DNA strand, it loses two phosphate groups as a molecule of pyrophosphate PO_4^{2-} . Subsequent hydrolysis of the pyrophosphate to two molecules of inorganic

A Figure 16.12 Origins of replication in eukaryotes. The red arrows indicate the movement of the replication forks and thus the overall directions of DNA replication within each bubble.

8* Figure 16.13 Incorporation of a nucleotide into a DNA strand. DNA polymerase catalyzes the addition of a nucleoside triphosphate to the 3' end of a growing DNA strand.

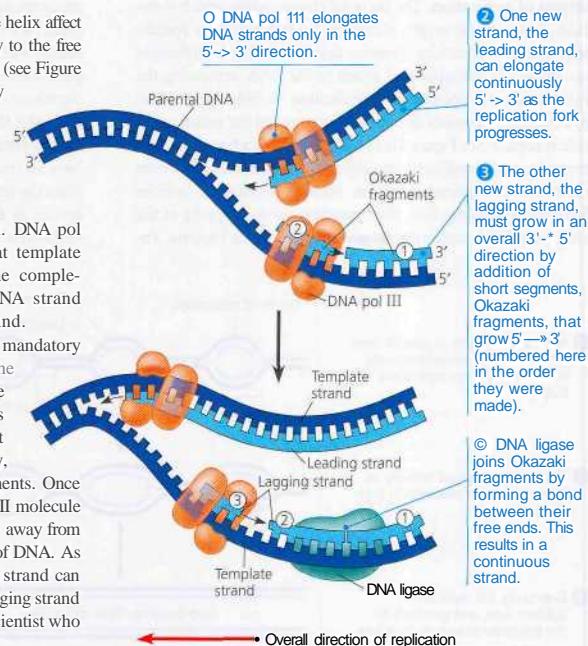

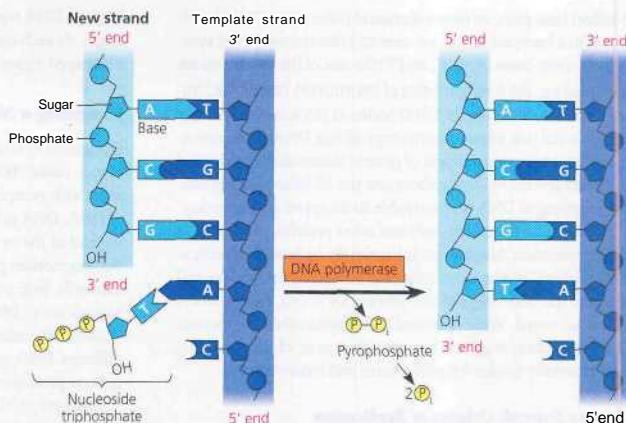

phosphate (\wedge) is the exergonic reaction that drives the polymerization reaction (Figure 16.13).

Antiparallel Elongation

As we have noted throughout this chapter, the two ends of a DNA strand are different (see Figure 16.5). In addition, the two strands of DNA in a double helix are antiparallel, meaning that they are oriented in opposite directions to each other (see Figure 16.13). Clearly, the two new strands formed during DNA replication must also be antiparallel to their template strands.

How does the antiparallel structure of the double helix affect replication? DNA polymerases add nucleotides only to the free 3' end of a growing DNA strand, never to the 5' end (see Figure 16.13). Thus, a new DNA strand can elongate only in the 5' → 3' direction. With this in mind, let's examine a replication fork (Figure 16.14). Along one template strand, DNA polymerase III (abbreviated DNA pol III) can synthesize a complementary strand continuously by elongating the new DNA in the mandatory 5' → 3' direction. DNA pol III simply nestles in the replication fork on that template strand and continuously adds nucleotides to the complementary strand as the fork progresses. The DNA strand made by this mechanism is called the leading strand.

To elongate the other new strand of DNA in the mandatory 5' → 3' direction, DNA pol III must work along the other template strand in the direction away from the replication fork. The DNA strand synthesized in this direction is called the lagging strand.* In contrast to the leading strand, which elongates continuously, the lagging strand is synthesized as a series of segments. Once a replication bubble opens far enough, a DNA pol III molecule attaches to the lagging strand's template and moves away from the replication fork, synthesizing a short segment of DNA. As the bubble grows, another segment of the lagging strand can be made in a similar way. These segments of the lagging strand are called Okazaki fragments, after the Japanese scientist who

*Synthesis of the leading strand and synthesis of the lagging strand occur concurrently and at the same rate. The lagging strand is so named because its synthesis is slightly delayed relative to synthesis of the leading strand; each new fragment cannot be started until enough template has been exposed at the replication fork.

A Figure 16.14 Synthesis of leading and lagging strands during DNA replication. DNA polymerase III (DNA pol 111) is closely associated with a protein that encircles the newly synthesized double helix like a doughnut. Note that Okazaki fragments are actually much longer than the ones shown here. In this figure, we depict only five bases per fragment for simplicity.

discovered them. The fragments are about 1,000 to 2,000 nucleotides long in *E. coli* and 100 to 200 nucleotides long in eukaryotes. Another enzyme, DNA ligase, eventually joins (ligates) the sugar-phosphate backbones of the Okazaki fragments, forming a single new DNA strand.

Piiming DNA Synthesis

DNA polymerases cannot *initiate* the synthesis of a polynucleotide; they can only add nucleotides to the 3' end of an already existing chain that is base-paired with the template strand (see Figure 16.13). The initial nucleotide chain is a short one called a **primer**. Primers may consist of either DNA or RNA (the other class of nucleic acid), and in initiating the replication of cellular DNA, the primer is a short stretch of RNA with an available 3' end. An enzyme called primase can start an RNA chain from scratch. Primase joins RNA nucleotides together one at a time, making a primer complementary to the template strand at the location where initiation of the new DNA strand will occur. (Primers are generally 5 to 10 nucleotides long.) DNA pol III then adds a DNA nucleotide to the 3' end of the RNA primer and continues adding DNA nucleotides to the growing DNA strand according to the base-pairing rules.

Only one primer is required for DNA pol III to begin synthesizing the leading strand. For synthesis of the lagging strand, however, each Okazaki fragment must be primed separately (figure 16.15). Another DNA polymerase, DNA polymerase I (DNA pol I), replaces the RNA nucleotides of the primers with DNA versions, adding them one by one onto the 3' end of the adjacent Okazaki fragment (fragment 2 in Figure 16.15). But DNA pol I cannot join the final nucleotide of this replacement DNA segment to the first DNA nucleotide of the Okazaki fragment whose primer was just replaced (fragment 1 in Figure 16.15). DNA ligase accomplishes this task, joining the sugar-phosphate backbones of all the Okazaki fragments into a continuous DNA strand.

Other ProteiiK That Assist DNA Replication

You have learned about three kinds of proteins that function in DNA synthesis: DNA polymerases, ligase, and primase. Other kinds of proteins also participate, including helicase, topoisomerase, and single-strand binding proteins. Helicase is an enzyme that untwists the double helix at the replication fork, separating the two parental strands and making them available as template strands. This untwisting causes tighter twisting and strain ahead of the replication fork, and topoisomerase helps relieve this strain. After helicase separates the two parental strands, molecules of single-strand binding protein then bind to the unpaired DNA strands, stabilizing them until they serve as templates for the synthesis of new complementary strands.

Table 16.1 and **Figure 16.16**, on the next page, summarize DNA replication. Study them carefully before proceeding.

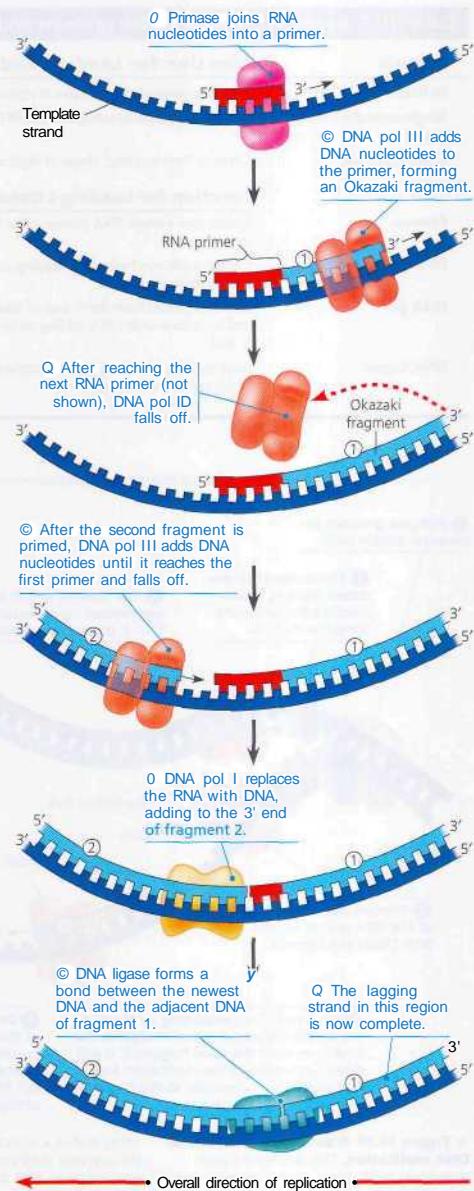

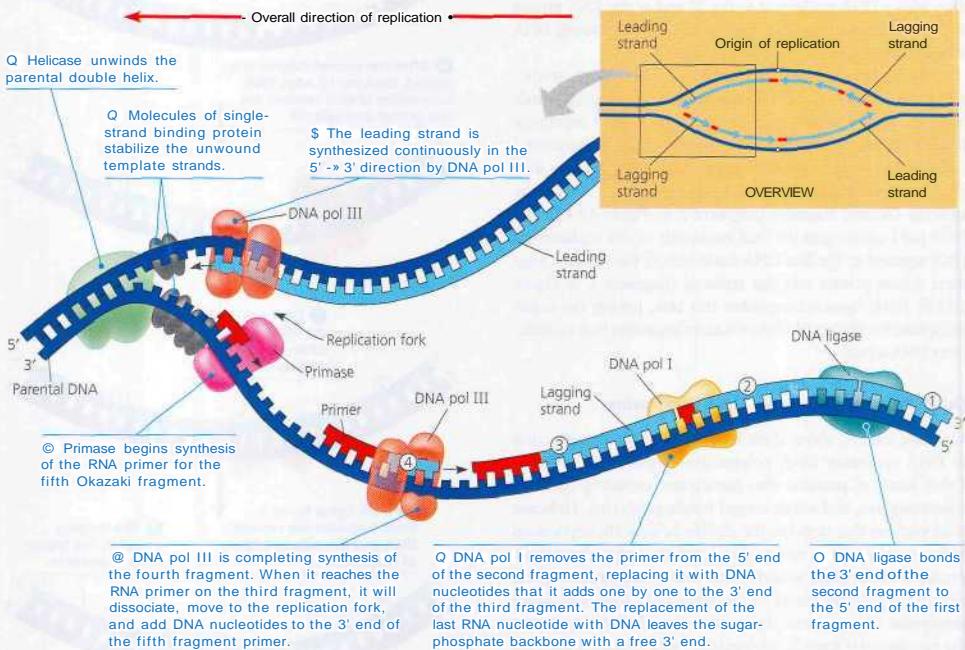

Figure 16.15 Synthesis of the lagging strand.

Table 16.1 Bacterial DNA replication proteins and their functions

| Protein | Function for Leading and Lagging Strands | |
|--------------------------------------|---|--|
| Helicase | Unwinds parental double helix at replication forks | |
| Single-strand binding protein | Binds to and stabilizes single-stranded DNA until it can be used as a template | |
| Topoisomerase | Corrects "overwinding" ahead of replication forks by breaking, swiveling, and rejoining DNA strands | |
| Function for Leading Strand | | Function for Lagging Strand |
| Primase | Synthesizes a single RNA primer at the 5' end of the leading strand | Synthesizes an RNA primer at the 5' end of each Okazaki fragment |
| DNA pol III | Continuously synthesizes the leading strand, adding on to the primer | Elongates each Okazaki fragment, adding on to its primer |
| DNA pol I | Removes primer from the 5' end of leading strand and replaces it with DNA, adding on to the adjacent 3' end | Removes the primer from the 5' end of each fragment and replaces it with DNA, adding on to the 3' end of the adjacent fragment |
| DNA Ligase | joins the 3' end of the DNA that replaces the primer to the rest of the leading strand | Joins the Okazaki fragments |

A Figure 16.16 A summary of bacterial DNA replication. The detailed diagram shows one replication fork, but as indicated in the overview diagram, replication usually occurs simultaneously at two forks, one at

either end of a replication bubble. Notice in the overview diagram that a leading strand is initiated by an RNA primer (red), as is each Okazaki fragment in a lagging strand. Viewing each daughter strand in its entirety

in the overview, you can see that half of it is made continuously as a leading strand, while the other half (on the other side of the origin) is synthesized in fragments as a lagging strand.

The DNA Replication Machine as a Stationary Complex

It is traditional—and convenient—to represent DNA polymerase molecules as locomotives moving along a DNA "railroad track," but such a model is inaccurate in two important ways. First, the various proteins that participate in DNA replication actually form a single large complex, a DNA replication "machine." Many protein-protein interactions facilitate the efficiency of this machine; for example, helicase works much more rapidly when it is in contact with primase. Second, the DNA replication machine is probably stationary during the replication process. In eukaryotic cells, multiple copies of the machine, perhaps grouped into "factories," may anchor to the nuclear matrix, a framework of fibers extending through the interior of the nucleus. Recent studies support a model in which DNA polymerase molecules "reel in" the parental DNA and extrude newly made daughter DNA molecules. Additional evidence suggests that the lagging strand is looped through the complex, so that when a DNA polymerase completes synthesis of an Okazaki fragment and dissociates, it doesn't have far to travel to reach the primer for the next fragment, near the replication fork. This looping of the lagging strand enables more Okazaki fragments to be synthesized in less time.

Proofreading and Repairing DNA

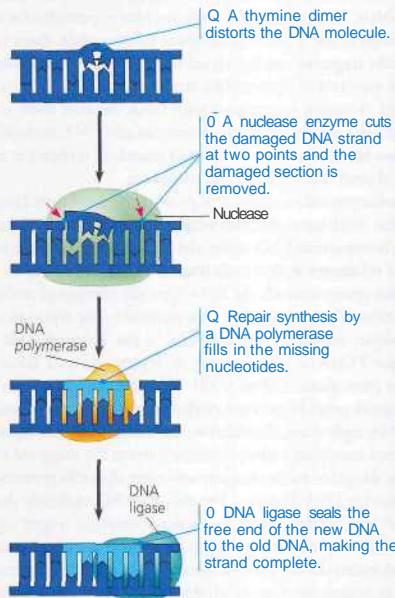

We cannot attribute the accuracy of DNA replication solely to the specificity of base pairing. Although errors in the completed DNA molecule amount to only one in 10 billion nucleotides, initial pairing errors between incoming nucleotides and those in the template strand are 100,000 times more common—an error rate of one in 100,000 base pairs. During DNA replication, DNA polymerases proofread each nucleotide against its template as soon as it is added to the growing strand. Upon finding an incorrectly paired nucleotide, the polymerase removes the nucleotide and then resumes synthesis. (This action is similar to fixing a typing error by using the "delete" key and then entering the correct letter.)

Mismatched nucleotides sometimes evade proofreading by a DNA polymerase or arise after DNA synthesis is completed—by damage to an existing nucleotide base, for instance. In mismatch repair, cells use special enzymes to fix incorrectly paired nucleotides. Researchers spotlighted the importance of such enzymes when they found that a hereditary defect in one of them is associated with a form of colon cancer. Apparently, this defect allows cancer-causing errors to accumulate in the DNA at a faster rate than normal.

Maintenance of the genetic information encoded in DNA requires frequent repair of various kinds of damage to existing DNA. DNA molecules are constantly subjected to potentially harmful chemical and physical agents, as we'll discuss in Chapter 17. Reactive chemicals in the environment and occurring

naturally in cells), radioactive emissions, X-rays, and ultraviolet light can change nucleotides in ways that can affect encoded genetic information, usually adversely. In addition, DNA bases often undergo spontaneous chemical changes under normal cellular conditions. Fortunately changes in DNA are usually corrected before they become self-perpetuating mutations. Each cell continuously monitors and repairs its genetic material. Because repair of damaged DNA is so important to the survival of an organism, it is no surprise that many different DNA repair enzymes have evolved. Almost 100 are known in *E. coli*, and about 130 have been identified so far in humans.

Most mechanisms for repairing DNA damage take advantage of the base-paired structure of DNA. Usually, a segment of the strand containing the damage is cut out (excised) by a DNA-cutting enzyme—a nuclease—and the resulting gap is filled in with nucleotides properly paired with the nucleotides in the undamaged strand. The enzymes involved in filling the gap are a DNA polymerase and ligase. DNA repair of this type is called nucleotide excision repair (**Figure 16.17**).

A. Figure 16.17 Nucleotide excision repair of DNA damage.

A team of enzymes detects and repairs damaged DNA. This figure shows DNA containing a thymine dimer, a type of damage often caused by ultraviolet radiation. A nuclease enzyme cuts out the damaged region of DNA, and a DNA polymerase (in bacteria, DNA pol I) replaces it with a normal DNA segment. Ligase completes the process by closing the remaining break in the sugar-phosphate backbone.

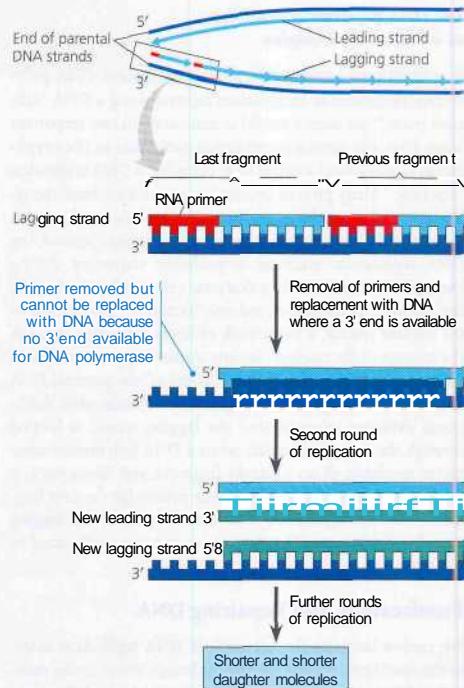

One function of the DNA repair enzymes in our skin cells is to repair genetic damage caused by the ultraviolet rays of sunlight. One type of damage, the type shown in Figure 16.17, is the covalent linking of thymine bases that are adjacent on a DNA strand. Such thymine dimers cause the DNA to buckle and interfere with DNA replication. The importance of repairing this kind of damage is underscored by the disorder xeroderma pigmentosum, which in most cases is caused by an inherited defect in a nucleotide excision repair enzyme; individuals with this disorder are hypersensitive to sunlight; mutations in their skin cells caused by ultraviolet light are left uncorrected and cause skin cancer.

Replicating the Ends of DNA Molecules

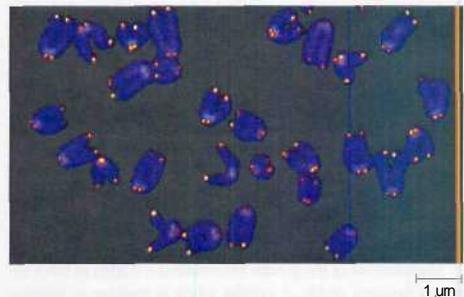

In spite of the major role played by DNA polymerases in DNA replication and repair, it turns out that there is a small portion of the cell's DNA that DNA polymerases cannot replicate or repair. For linear DNA, such as the DNA of eukaryotic chromosomes, the fact that a DNA polymerase can only add nucleotides to the 3' end of a preexisting polynucleotide leads to a problem. The usual replication machinery provides no way to complete the 5' ends of daughter DNA strands. Even if an Okazaki fragment can be started with an RNA primer bound to the very end of the template strand, once that primer is removed, it cannot be replaced with DNA, because there is no 3' end onto which DNA polymerase can add DNA nucleotides (**Figure 16.18**). As a result, repeated rounds of replication produce shorter and shorter DNA molecules.

Prokaryotes do not have this problem because their DNA is circular (with no ends), but what about eukaryotes? Eukaryotic chromosomal DNA molecules have nucleotide sequences called telomeres at their ends (**Figure 16.19**). Telomeres do not contain genes; instead, the DNA typically consists of multiple repetitions of one short nucleotide sequence. The repeated unit in human telomeres, for example, is the six-nucleotide sequence TTAGGG. The number of repetitions in a telomere varies from about 100 to 1,000. Telomeric DNA protects the organism's genes from being eroded through successive rounds of DNA replication. In addition, telomeric DNA and specific proteins associated with it somehow prevent the staggered ends of the daughter molecule from activating the cell's systems for monitoring DNA damage. (The end of a DNA molecule that is "seen" as a double-strand break may otherwise trigger signal transduction pathways leading to cell cycle arrest or cell death.)

Telomeres do not prevent the shortening of DNA molecules due to successive rounds of replication; they just postpone the erosion of genes near the ends of DNA molecules. As shown in Figure 16.18, telomeres become shorter during every round of replication. As we would expect, telomeric DNA does tend to be shorter in dividing somatic cells of older individuals and in cultured cells that have divided many times. It has been proposed that shortening of telomeres is somehow connected

A Figure 16.18 Shortening of the ends of linear DNA molecules. Here we follow the end of one strand of a DNA molecule through two rounds of replication. After the first round, the new lagging strand is shorter than its template. After a second round, both the leading and lagging strands have become shorter than the original parental DNA. Although not shown here, the other ends of these DNA molecules also become shorter.

A Figure 16.19 Telomeres. Eukaryotes have repetitive, noncoding sequences called telomeres at the ends of their DNA, marked in these mouse chromosomes by a bright orange stain (LM).

to the aging process of certain tissues and even to aging of the organism, as a whole.

But what about the cells whose genomes persist unchanged from an organism to its offspring over many generations? If the chromosomes of germ cells (which give rise to gametes) became shorter in every cell cycle, essential genes would eventually be missing from the gametes they produce. Fortunately, this does not occur: An enzyme called telomerase catalyzes the lengthening of telomeres in eukaryotic germ cells, thus restoring their original length and compensating for the shortening that occurs during DNA replication. The lengthening process is made possible by the presence, in telomerase, of a short molecule of RNA that serves as a template for new telomere segments. Telomerase is not active in most somatic cells, but its activity in germ cells results in telomeres of maximum length in the zygote.

Normal shortening of telomeres may protect organisms from cancer by limiting the number of divisions that somatic cells can undergo. Cells from large tumors often have unusually short telomeres, as one would expect for cells that have undergone many cell divisions. Further shortening would presumably lead to self-destruction of the cancer. Intriguingly, researchers have found telomerase activity in cancerous somatic cells, suggesting that its ability to stabilize telomere length may allow these cancer cells to persist. Many cancer

cells do seem capable of unlimited cell division, as do immortal strains of cultured cells (see Chapter 12). If telomerase is indeed an important factor in many cancers, it may provide a useful target for both cancer diagnosis and chemotherapy.

In this chapter, you have learned how DNA replication provides the copies of genes that parents pass to offspring. However, it is not enough that genes be copied and transmitted; they must also be expressed. In the next chapter, we will examine how the cell translates genetic information encoded in DNA.

Concept Check 16.2

- What role does complementary base pairing play in the replication of DNA?
- Identify two major functions of DNA pol III in DNA replication.
- Why is DNA pol I necessary to complete synthesis of a leading strand? Point out in the overview box in Figure 16.16 where DNA pol I would function on the top leading strand.
- How are telomeres important for preserving eukaryotic genes?

For suggested answers, see Appendix A.

Chapter 16 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 16.1

DNA is the genetic material

- The Search for the Genetic Material: Scientific Inquiry** (pp. 293–296) Experiments with bacteria and with phages provided the first strong evidence that the genetic material is DNA.
Activity The Hershey-Chase Experiment
- Building a Structural Model of DNA: Scientific Inquiry** (pp. 296–298) Watson and Crick deduced that DNA is a double helix. Two antiparallel sugar-phosphate chains wind around the outside of the molecule; the nitrogenous bases project into the interior, where they hydrogen-bond in specific pairs, A with T and G with C.

Activity DNA and RNA Structure

Activity DNA Double Helix

Concept 16.2

Many proteins work together in DNA replication and repair

- The Basic Principle: Base Pairing to a Template Strand** (pp. 299–300) DNA replication is semiconservative: The parent molecule unwinds, and each strand then serves as a template

for the synthesis of a new strand according to base-pairing rules.

Activity DNA Replication: An Overview

Investigation What Is the Correct Model for DNA Replication?

- DNA Replication: A Closer Look** (pp. 300–305) DNA replication begins at origins of replication. Y-shaped replication forks form at opposite ends of a replication bubble, where the two DNA strands separate. DNA synthesis starts at the 3' end of an RNA primer, a short polynucleotide complementary to the template strand. DNA polymerases catalyze the synthesis of new DNA strands, working in the 5' → 3' direction. The leading strand is synthesized continuously, and the lagging strand is synthesized in short segments, called Okazaki fragments. The fragments are joined together by DNA ligase.

Activity DNA Replication: A Closer Look

Activity DNA Replication Review

- Proofreading and Repairing DNA** (pp. 305–306) DNA polymerases proofread newly made DNA, replacing any incorrect nucleotides. In mismatch repair of DNA, repair enzymes correct errors in base pairing. In nucleotide excision repair, enzymes cut out and replace damaged stretches of DNA.

- Replicating the Ends of DNA Molecules** (pp. 306–307) The ends of eukaryotic chromosomal DNA get shorter with each round of replication. The presence of telomeres, repetitive sequences at the ends of linear DNA molecules, postpones the erosion of genes. Telomerase catalyzes the lengthening of telomeres in germ cells.

TESTING YOUR KNOWLEDGE

Evolution Connection

Many bacteria may be able to respond to environmental stress by increasing the rate at which mutations occur during cell division. How might this be accomplished, and what might be an evolutionary advantage of this ability?

Scientific Inquiry

Demonstrate your understanding of the Meselson-Stahl experiment by answering the following questions.

- Describe in your own words exactly what each of the centrifugation bands pictured in Figure 16.11 represents.

- Imagine that the experiment is done as follows: Bacteria are first grown for several generations in a medium containing the *lighter* isotope of nitrogen, ^{14}N , then switched into a medium containing ^{15}N . The rest of the experiment is identical. Redraw Figure 16.11 to reflect this experiment, predicting what band positions you would expect after one generation and after two generations if each of the three models shown in Figure 16.10 were true.

Investigation *What Is the Correct Model for DNA Replication?*

Science, Technology, and Society

Cooperation and competition are both common in science. What roles did these two social behaviors play in Watson and Crick's discovery of the double helix? How might competition between scientists accelerate progress? How might it slow progress?

- 17.6 Comparing gene expression in prokaryotes and eukaryotes reveals key differences
- 17.7 Point mutations can affect protein structure and function

Why do dwarf peas fail to make their own gibberellins? They are missing a key protein, an enzyme required for gibberellin synthesis. And they are missing that protein because they do not have a properly functioning gene for that protein.

This example illustrates the main point of this chapter: The DNA inherited by an organism leads to specific traits by dictating the synthesis of proteins. In other words, proteins are the links between genotype and phenotype. The process by which DNA directs protein synthesis, *gene expression*, includes two stages, called transcription and translation. In **Figure 17.1**, you can see a computer model of a ribosome, which is part of the cellular machinery for translation—polypeptide synthesis. This chapter describes the flow of information from gene to protein in detail. By the end, you will understand how genetic mutations, such as the one causing the dwarf trait in pea plants, affect organisms through their proteins.

Concept 17.1

Genes specify proteins via transcription and translation

Before going into the details of how genes direct protein synthesis, let's step back and examine how the fundamental relationship between genes and proteins was discovered.

Evidence from the Study of Metabolic Defects

In 1909, British physician Archibald Garrod was the first to suggest that genes dictate phenotypes through enzymes that catalyze specific chemical reactions in the cell. Garrod postulated that the symptoms of an inherited disease reflect a person's inability to make a particular enzyme. He referred to

Overview

The Flow of Genetic Information

The information content of DNA, the genetic material, is in the form of specific sequences of nucleotides along the DNA strands. But how does this information determine an organism's traits? Put another way, what does a gene actually say? And how is its message translated by cells into a specific trait, such as brown hair or type A blood?

Consider, once again, Mendel's peas. One of the characters Mendel studied was stem length (see Table 14.1). Mendel did not know the physiological basis for the difference between the tall and dwarf varieties of pea plants, but plant scientists have since worked out the explanation: Dwarf peas lack growth hormones called gibberellins, which stimulate the normal elongation of stems. A dwarf plant treated with gibberellins from an external source grows to normal height.

such diseases as "inborn errors of metabolism." Garrod gave as one example the hereditary condition called alkapturia, in which the urine is black because it contains the chemical alkaption, which darkens upon exposure to air. Garrod reasoned that most people have an enzyme that breaks down alkaption, whereas people with alkapturia have inherited an inability to make the enzyme that metabolizes alkaption.

Garrod's idea was ahead of its time, but research conducted several decades later supported his hypothesis that a gene dictates the production of a specific enzyme. Biochemists accumulated much evidence that cells synthesize and degrade most organic molecules via metabolic pathways, in which each chemical reaction in a sequence is catalyzed by a specific enzyme. Such metabolic pathways lead, for instance, to the synthesis of the pigments that give fruit flies (*Drosophila*) their eye color (see Figure 15.3). In the 1930s, George Beadle and Boris Ephrussi speculated that in *Drosophila*, each of the various mutations affecting eye color blocks pigment synthesis at a specific step by preventing production of the enzyme that catalyzes that step. However, neither the chemical reactions nor the enzymes that catalyze them were known at the time.

Nutritional Mutants in *Neurospora*: Scientific Inquiry

A breakthrough in demonstrating the relationship between genes and enzymes came a few years later, when Beadle and Edward Tatum began working with a bread mold, *Neurospora crassa*. They bombarded *Neurospora* with X-rays and then looked among the survivors for mutants that differed in their nutritional needs from the wild-type mold. Wild-type *Neurospora* has modest food requirements. It can survive in the laboratory on agar (a moist support medium) mixed only with inorganic salts, glucose, and the vitamin biotin. From this minimal medium, the mold uses its metabolic pathways to produce all the other molecules it needs. Beadle and Tatum identified mutants that could not survive on minimal medium, apparently because they were unable to synthesize certain essential molecules from the minimal ingredients. However, most such nutritional mutants can survive on a complete growth medium, minimal medium supplemented with all 20 amino acids and a few other nutrients.

To characterize the metabolic defect in each nutritional mutant, Beadle and Tatum took samples from the mutant growing on complete medium and distributed them to a number of different vials. Each vial contained minimal medium plus a single additional nutrient. The particular supplement that allowed growth indicated the metabolic defect. For example, if the only supplemented vial that supported growth of the mutant was the one fortified with the amino acid arginine, the researchers could conclude that the mutant was defective in the biochemical pathway that wild-type cells use to synthesize arginine.

Beadle and Tatum went on to pin down each mutant's defect more specifically. Their work with arginine-requiring mutants was especially instructive. Using genetic crosses, they determined that their mutants fell into three classes, each mutated in a different gene. The researchers then showed that they could distinguish among the classes of mutants nutritionally by additional tests of their growth requirements (Figure 17.2). In the synthetic pathway leading to arginine, they suspected, a precursor nutrient is converted to ornithine, which is converted to citrulline, which is converted to arginine. When they tested their arginine mutants for growth on ornithine and citrulline, they found that one class could grow on either compound (or arginine), the second class only on citrulline (or arginine), and the third on neither—it absolutely required arginine. The three classes of mutants, the researchers reasoned, must be blocked at different steps in the pathway that synthesizes arginine, with each mutant class lacking the enzyme that catalyzes the blocked step.

Because each mutant was defective in a single gene, Beadle and Tatum's results provided strong support for the *one gene-one enzyme hypothesis*, as they dubbed it, which states that the function of a gene is to dictate the production of a specific enzyme. The researchers also showed how a combination of genetics and biochemistry could be used to work out the steps in a metabolic pathway. Further support for the one gene-one enzyme hypothesis came with experiments that identified the specific enzymes lacking in the mutants.

The Products of Gene Expression: A Developing Story

As researchers learned more about proteins, they made minor revisions to the one gene-one enzyme hypothesis. First of all, not all proteins are enzymes. Keratin, the structural protein of animal hair, and the hormone insulin are two examples of nonenzyme proteins. Because proteins that are not enzymes are nevertheless gene products, molecular biologists began to think in terms of one gene-one protein. However, many proteins are constructed from two or more different polypeptide chains, and each polypeptide is specified by its own gene. For example, hemoglobin, the oxygen-transporting protein of vertebrate red blood cells, is built from two kinds of polypeptides, and thus two genes code for this protein (see Figure 5.20). Beadle and Tatum's idea has therefore been restated as the *one gene-one polypeptide hypothesis*. Even this statement is not entirely accurate, though. As you will learn later in this chapter, some genes code for RNA molecules that have important functions in cells even though they are never translated into protein. But for now, we will focus on genes that code for polypeptides. (Note that it is common to refer to proteins, rather than polypeptides, as the gene products, a practice you will encounter in this book.)

Figure 17.2

Inquiry Do individual genes specify different enzymes in arginine biosynthesis?

EXPERIMENT

Working with the mold *Neurospora crassa*, George Beadle and Edward Tatum had isolated mutants requiring arginine in their growth medium and had shown genetically that these mutants fell into three classes, each defective in a different gene. From other considerations, they suspected that the metabolic pathway of arginine biosynthesis included the precursors ornithine and citrulline. Their most famous experiment, shown here, tested both their one gene-one enzyme hypothesis and their postulated arginine pathway. In this experiment, they grew their three classes of mutants under the four different conditions shown in the Results section below.

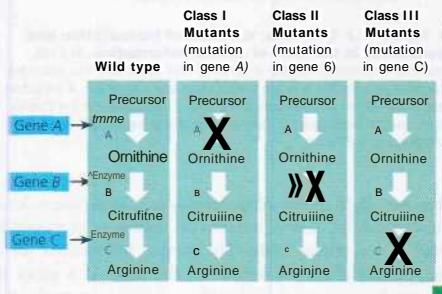

RESULTS

The wild-type strain required only the minimal medium for growth. The three classes of mutants had different growth requirements.

| | Wild type | Class I Mutants | Class II Mutants | Class III Mutants |
|-------------------------------|---------------|-----------------|------------------|-------------------|
| Minimal medium (MM) (control) | Normal growth | Normal growth | Normal growth | Normal growth |
| MM + Ornithine | Normal growth | Normal growth | Normal growth | Normal growth |
| MM + Citrulline | Normal growth | Normal growth | Normal growth | Normal growth |
| MM + Arginine (control) | Normal growth | U | U | P |

CONCLUSION

From the growth patterns of the mutants, Beadle and Tatum deduced that each mutant was unable to carry out one step in the pathway for synthesizing arginine, presumably because it lacked the necessary enzyme. Because each of their mutants was mutated in a single gene, they concluded that each mutated gene must normally dictate the production of one enzyme. Their results supported the one gene-one enzyme hypothesis and also confirmed the arginine pathway. (Notice that a mutant can grow only if supplied with a compound made after the defective step.)

Basic Principles of Transcription and Translation

Genes provide the instructions for making specific proteins. But a gene does not build a protein directly. The bridge between DNA and protein synthesis is the nucleic acid RNA. You learned in Chapter 5 that RNA is chemically similar to DNA, except that it contains ribose instead of deoxyribose as its sugar and has the nitrogenous base uracil rather than thymine (see Figure 5.26). Thus, each nucleotide along a DNA strand has A, G, C, or T as its base, and each nucleotide along an RNA strand has A, G, C, or U as its base. An RNA molecule usually consists of a single strand.

It is customary to describe the flow of information from gene to protein in linguistic terms because both nucleic acids and proteins are polymers with specific sequences of monomers that convey information, much as specific sequences of letters communicate information in a language like English. In DNA or RNA, the monomers are the four types of nucleotides, which differ in their nitrogenous bases. Genes are typically hundreds or thousands of nucleotides long, each gene having a specific sequence of bases. Each polypeptide of a protein also has monomers arranged in a particular linear order (the protein's primary structure), but its monomers are the 20 amino acids. Thus, nucleic acids and proteins contain information written in two different chemical languages. Getting from DNA to protein requires two major stages, transcription and translation.

Transcription is the synthesis of RNA under the direction of DNA. Both nucleic acids use the same language, and the information is simply transcribed, or copied, from one molecule to the other. Just as a DNA strand provides a template for the synthesis of a new complementary strand during DNA replication, it provides a template for assembling a sequence of RNA nucleotides. The resulting RNA molecule is a faithful transcript of the gene's protein-building instructions. In discussing protein-coding genes, this type of RNA molecule is called **messenger RNA (mRNA)**, because it carries a genetic message from the DNA to the protein-synthesizing machinery of the cell. (Transcription is the general term for the synthesis of *any* kind of RNA on a DNA template. Later in this chapter, you will learn about other types of RNA produced by transcription.)

Translation is the actual synthesis of a polypeptide, which occurs under the direction of mRNA. During this stage, there is a change in language: The cell must translate the base sequence of an mRNA molecule into the amino acid sequence of a polypeptide. The sites of translation are ribosomes, complex particles that facilitate the orderly linking of amino acids into polypeptide chains.

You might wonder why proteins couldn't simply be translated directly from DNA. There are evolutionary reasons for using an RNA intermediate. First, it provides protection for the DNA and its genetic information. As an analogy, when an architect designs a house, the original specifications (analogous

to DNA) are not what the construction workers use at the site. Instead they use *copies* of the originals (analogous to mRNA), keeping the originals pristine and undamaged. Second, using an RNA intermediate allows more copies of a protein to be made simultaneously, since many RNA transcripts can be made from one gene. Also, each RNA transcript can be translated repeatedly.

Although the basic mechanics of transcription and translation are similar for prokaryotes and eukaryotes, there is an important difference in the flow of genetic information within the cells. Because bacteria lack nuclei, their DNA is not segregated from ribosomes and the other protein-synthesizing equipment (**Figure 17.3a**). As you will see later, this allows translation of an mRNA to begin while its transcription is still in progress (see Figure 17.22). In a eukaryotic cell, by contrast, the nuclear envelope separates transcription from translation in space and time (**Figure 17.3b**). Transcription occurs in the nucleus, and mRNA is transported to the cytoplasm, where translation occurs. But before they can leave the nucleus, eukaryotic RNA transcripts are modified in various ways to produce the final, functional mRNA. The transcription of a protein-coding eukaryotic gene results in *pre-mRNA*, and RNA processing yields the finished mRNA. The initial RNA transcript from any gene, including those coding for RNA that is not translated into protein, is more generally called a primary transcript.

Lets summarize: Genes program protein synthesis via genetic messages in the form of messenger RNA. Put another way, cells are governed by a molecular chain of command: DNA → RNA → protein. In the next section, we discuss how the instructions for assembling amino acids into a specific order are encoded in nucleic acids.

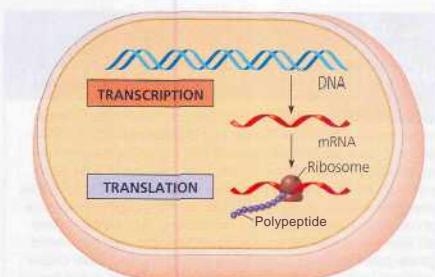

The Genetic Code

When biologists began to suspect that the instructions for protein synthesis were encoded in DNA, they recognized a problem: There are only four nucleotide bases to specify 20 amino acids. Thus, the genetic code cannot be a language like Chinese, where each written symbol corresponds to a single word. How many bases, then, correspond to an amino acid?

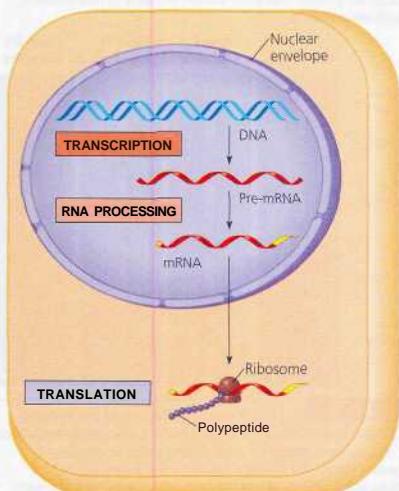

Codons: Triplets of Bases

If each nucleotide base were translated into an amino acid, only 4 of the 20 amino acids could be specified. Would a language of two-letter code words suffice? The base sequence AG, for example, could specify one amino acid, and GT could specify another. Since there are four bases, this would give us 16 (that is, 4^2) possible arrangements—still not enough to code for all 20 amino acids.

Triplets of nucleotide bases are the smallest units of uniform length that can code for all the amino acids. If each arrangement of three consecutive bases specifies an amino acid, there can be 64 (that is, 4^3) possible code words—more

(a) Prokaryotic cell. In a cell lacking a nucleus, mRNA produced by transcription is immediately translated without additional processing.

(b) Eukaryotic cell. The nucleus provides a separate compartment for transcription. The original RNA transcript, called pre-mRNA, is processed in various ways before leaving the nucleus as mRNA.

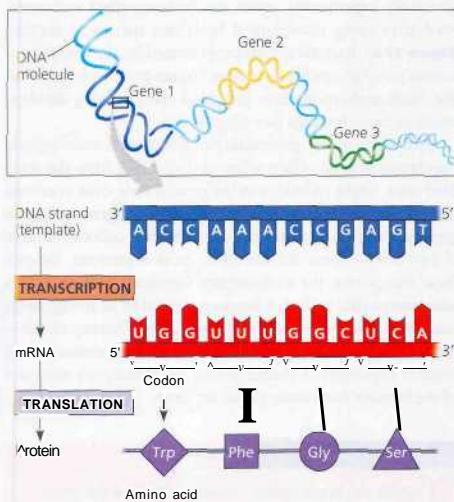

A Figure 17.3 Overview: the roles of transcription and translation in the flow of genetic information. In a cell, inherited information flows from DNA to RNA to protein. The two main stages of information flow are transcription and translation. A miniature version of part (a) or (b) accompanies several figures later in the chapter as an orientation diagram to help you see where a particular figure fits into the overall scheme.

than enough to specify all the amino acids. Experiments have verified that the flow of information from gene to protein is based on a triplet code: The genetic instructions for a polypeptide chain are written in the DNA as a series of non-overlapping, three-nucleotide words. For example, the

base triplet AGT at a particular position along a DNA strand results in the placement of the amino acid serine at the corresponding position of the polypeptide to be produced.

During transcription, the gene determines the sequence of bases along the length of an mRNA molecule (**Figure 17.4**). For each gene, only one of the two DNA strands is transcribed. This strand is called the template strand because it provides the template for ordering the sequence of nucleotides in an RNA transcript. A given DNA strand can be the template strand for some genes along a DNA molecule, while for other genes in other regions, the complementary strand may function as the template. Note, however, that for a given gene, the same strand is used as the template every time it is transcribed.

An mRNA molecule is complementary rather than identical to its DNA template because RNA bases are assembled on the template according to base-pairing rules. The pairs are similar to those that form during DNA replication, except that U, the RNA substitute for T, pairs with A and the mRNA nucleotides contain ribose instead of deoxyribose. Like a new strand of DNA, the RNA molecule is synthesized in an antiparallel direction to the template strand of DNA. (To review what is meant by "antiparallel" and the 5' and 3' ends of a nucleic acid chain, see Figure 16.7.) For example, the base triplet ACC along the DNA (written as 3'-ACC-5') provides a template for 5'-UGG-3' in

A Figure 17.4 The triplet code. For each gene, one DNA strand functions as a template for transcription. The base-pairing rules for DNA synthesis also guide transcription, but uracil (U) takes the place of thymine (T) in RNA. During translation, the mRNA is read as a sequence of base triplets, called codons. Each codon specifies an amino acid to be added to the growing polypeptide chain. The mRNA is read in the 5' → 3' direction.

the mRNA molecule. The mRNA base triplets are called codons, and they are customarily written in the 5' → 3' direction. In our example, UGG is the codon for the amino acid tryptophan (abbreviated Trp). The term *codon* is also sometimes used for the DNA base triplets along the *nontemplate* strand. These codons are complementary to the template strand and thus identical in sequence to the mRNA except that they have T instead of U. (For this reason, the nontemplate DNA strand is sometimes called the "coding strand".)

During translation, the sequence of codons along an mRNA molecule is decoded, or translated, into a sequence of amino acids making up a polypeptide chain. The codons are read by the translation machinery in the 5' → 3' direction along the mRNA. Each codon specifies which one of the 20 amino acids will be incorporated at the corresponding position along a polypeptide. Because codons are base triplets, the number of nucleotides making up a genetic message must be three times the number of amino acids making up the protein product. For example, it takes 300 nucleotides along an mRNA strand to code for a polypeptide that is 100 amino acids long.

Cracking the Code

Molecular biologists cracked the code of life in the early 1960s, when a series of elegant experiments disclosed the amino acid translations of each of the RNA codons. The first codon was deciphered in 1961 by Marshall Nirenberg, of the National Institutes of Health, and his colleagues. Nirenberg synthesized an artificial mRNA by linking identical RNA nucleotides containing uracil as their base. No matter where this message started or stopped, it could contain only one codon in repetition: UUU. Nirenberg added this "poly-U" to a test-tube mixture containing amino acids, ribosomes, and the other components required for protein synthesis. His artificial system translated the poly-U into a polypeptide containing a single amino acid, phenylalanine (Phe), strung together as a long polyphenylalanine chain. Thus, Nirenberg determined that the mRNA codon UUU specifies the amino acid phenylalanine. Soon, the amino acids specified by the codons AAA, GGG, and CCC were also determined.

Although more elaborate techniques were required to decode mixed triplets such as AUA and CGA, all 64 codons were deciphered by the mid-1960s. As **Figure 17.5** on the next page shows, 61 of the 64 triplets code for amino acids. The three codons that do not designate amino acids are "stop" signals, or termination codons, marking the end of translation. Notice that the codon AUG has a dual function: It codes for the amino acid methionine (Met) and also functions as a "start" signal, or initiation codon. Genetic messages begin with the mRNA codon AUG, which signals the protein-synthesizing machinery to begin translating the mRNA at that location. (Because AUG also stands for methionine, polypeptide chains begin with methionine when they are synthesized. However, an enzyme may subsequently remove this starter amino acid from the chain.)

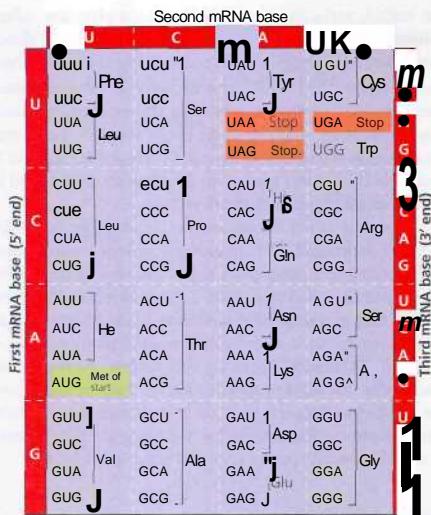

Figure 17.5 The dictionary of the genetic code. The three bases of an mRNA codon are designated here as the first, second, and third bases, reading in the 5' → 3' direction along the mRNA. (Practice using this dictionary by finding the codons in Figure 17.4.) The codon AUG not only stands for the amino acid methionine (Met) but also functions as a "start" signal for ribosomes to begin translating the mRNA at that point. Three of the 64 codons function as "stop" signals, marking the end of a genetic message.

Notice in Figure 17.5 that there is *redundancy* in the genetic code, but no ambiguity. For example, although codons GAA and GAG both specify glutamic acid (redundancy), neither of them ever specifies any other amino acid (no ambiguity). The redundancy in the code is not altogether random. In many cases, codons that are synonyms for a particular amino acid differ only in the third base of the triplet. We will consider a possible benefit for this redundancy later in the chapter.

Our ability to extract the intended message from a written language depends on reading the symbols in the correct groupings—that is, in the correct reading frame. Consider this statement: "The red dog ate the cat." Group the letters incorrectly by starting at the wrong point, and the result will probably be gibberish: for example, "her edd oga tet hec at." The reading frame is also important in the molecular language of cells. The short stretch of polypeptide shown in Figure 17.4, for instance, will only be made correctly if the mRNA nucleotides are read from left to right (5' → 3') in the groups of three shown in the figure: UGG UUU GGC UCA. Although a genetic message is written with no spaces between the codons, the cell's protein-synthesizing machinery reads the message as a series of nonoverlapping three-letter words. The message is *not* read as a series of overlapping

► **Figure 17.6 A tobacco plant expressing a firefly gene.** Because diverse forms of life share a common genetic code, it is possible to program one species to produce proteins characteristic of another species by transplanting DNA. In this experiment, researchers were able to incorporate a gene from a firefly into the DNA of a tobacco plant. The firefly gene codes for an enzyme that catalyzes a chemical reaction that releases light energy.

words—UGGUUU, and so on—which would convey a very different message.

Evolution of the Genetic Code

The genetic code is nearly universal, shared by organisms from the simplest bacteria to the most complex animals. The RNA codon CCG, for instance, is translated as the amino acid proline in all organisms whose genetic code has been examined. In laboratory experiments, genes can be transcribed and translated after being transplanted from one species to another (Figure 17.6). Bacteria can be programmed by the insertion of human genes to synthesize certain human proteins for medical use. Such applications have produced many exciting developments in biotechnology (see Chapter 20).

Exceptions to the universality of the genetic code include translation systems where a few codons differ from the standard ones. Slight variations in the genetic code exist in certain unicellular eukaryotes and in the organelle genes of some species. Some prokaryotes can translate stop codons into one of two amino acids not found in most organisms. Despite these exceptions, the evolutionary significance of the code's *near* universality is clear. A language shared by all living things must have been operating very early in the history of life—early enough to be present in the common ancestors of all modern organisms. A shared genetic vocabulary is a reminder of the kinship that bonds all life on Earth.

Concept Check 17.1

1. Draw the nontemplate strand of DNA for the template shown in Figure 17.4. Compare and contrast its base sequence with the mRNA molecule.
2. What protein product would you expect from a poly-G mRNA that is 30 nucleotides long?

For suggested answers, see Appendix A.

Concept 17.2

Transcription is the DNA-directed synthesis of RNA: *a closer look*

Now that we have considered the linguistic logic and evolutionary significance of the genetic code, we are ready to reexamine transcription, the first stage of gene expression, in more detail.

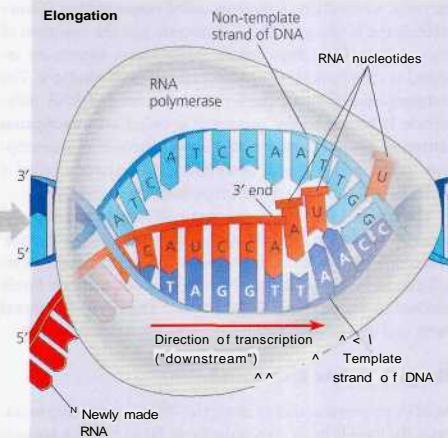

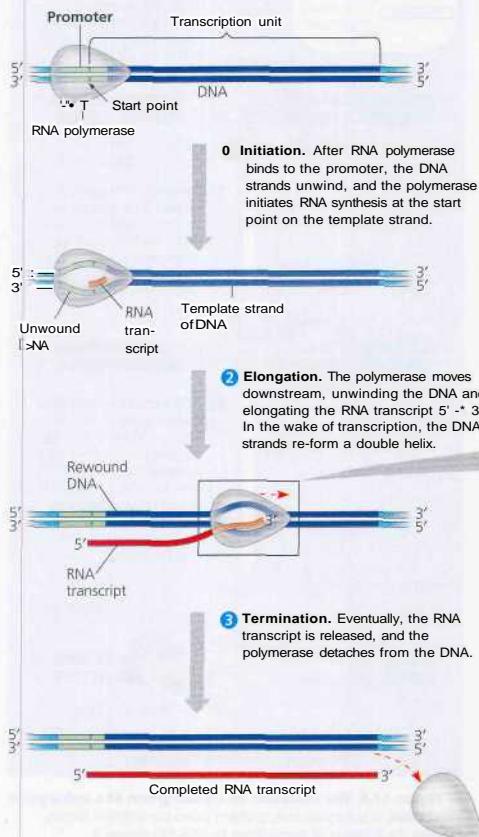

Molecular Components of Transcription

Messenger RNA, the carrier of information from DNA to the cell's protein-synthesizing machinery, is transcribed from the

template strand of a gene. An enzyme called an RNA polymerase pries the two strands of DNA apart and hooks together the RNA nucleotides as they base-pair along the DNA template (**Figure 17.7**). Like the DNA polymerases that function in DNA replication, RNA polymerases can only assemble a polynucleotide in its 5' → 3' direction. Unlike DNA polymerases, however, RNA polymerases are able to start a chain from scratch; they don't need a primer.

Specific sequences of nucleotides along the DNA mark where transcription of a gene begins and ends. The DNA sequence where RNA polymerase attaches and initiates transcription is known as the promoter; in prokaryotes, the sequence that signals the end of transcription is called the terminator. (The termination mechanism is different in eukaryotes, which we'll describe later.) Molecular biologists refer to the direction of transcription as "downstream" and the other direction as "upstream." These terms are also used to describe the positions of nucleotide sequences within the DNA or RNA. Thus, the promoter sequence in DNA is said to be upstream from the terminator. The stretch of DNA that is transcribed into an RNA molecule is called a transcription unit.

Bacteria have a single type of RNA polymerase that synthesizes not only mRNA but also other types of RNA that function in

▲ **Figure 17.7 The stages of transcription: initiation, elongation, and termination.** This general depiction of transcription applies to both prokaryotes and eukaryotes, but the details of termination vary for prokaryotes and eukaryotes, as described in the text. Also, in a prokaryote, the RNA transcript is immediately usable as mRNA, whereas in a eukaryote, it must first undergo processing to become mRNA.

protein synthesis. In contrast, eukaryotes have three types of RNA polymerase in their nuclei, numbered I, II, and III. The one used for mRNA synthesis is RNA polymerase II. The other two RNA polymerases transcribe RNA molecules that are not translated into protein. In the discussion of transcription that follows, we start with the features of mRNA synthesis common to both prokaryotes and eukaryotes and then describe some key differences.

Synthesis of an RNA Transcript

The three stages of transcription, as shown in Figure 17.7 and described next, are initiation, elongation, and termination of the RNA chain. Study Figure 17.7 to familiarize yourself with the stages and the terms used to describe them.

RNA Polymerase Binding and Initiation of Transcription

The promoter of a gene includes within it the transcription start point (the nucleotide where RNA synthesis actually begins) and typically extends several dozen nucleotide pairs "upstream" from the start point. In addition to serving as a binding site for RNA polymerase and determining where transcription starts, the promoter determines which of the two strands of the DNA helix is used as the template.

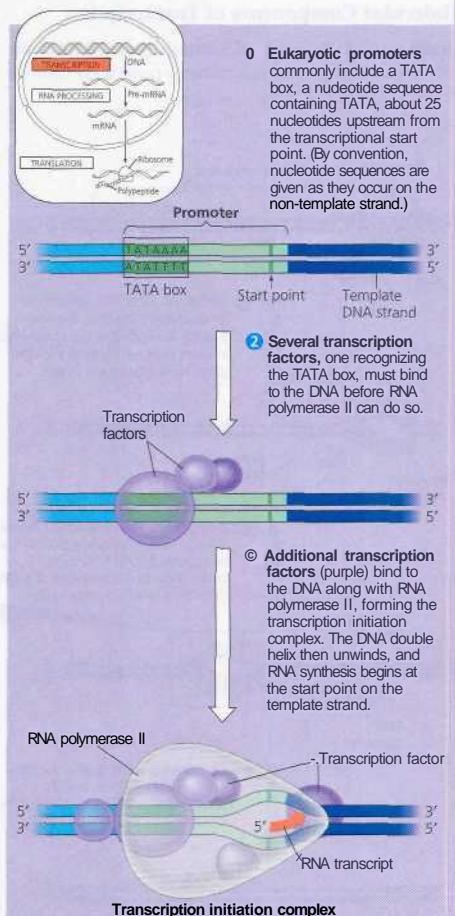

Certain sections of a promoter are especially important for binding RNA polymerase. In prokaryotes, the RNA polymerase itself specifically recognizes and binds to the promoter. In eukaryotes, a collection of proteins called **transcription factors** mediate the binding of RNA polymerase and the initiation of transcription. Only after certain transcription factors are attached to the promoter does RNA polymerase II bind to it. The completed assembly of transcription factors and RNA polymerase II bound to the promoter is called a **transcription initiation complex**. Figure 17.8 shows the role of transcription factors and a crucial promoter DNA sequence called a **TATA box** in forming the initiation complex in eukaryotes.

The interaction between eukaryotic RNA polymerase II and transcription factors is an example of the importance of protein-protein interactions in controlling eukaryotic transcription (as we will discuss further in Chapter 19). Once the polymerase is firmly attached to the promoter DNA, the two DNA strands unwind there, and the enzyme starts transcribing the template strand.

Elongation of the RNA Strand

As RNA polymerase moves along the DNA, it continues to untwist the double helix, exposing about 10 to 20 DNA bases at a time for pairing with RNA nucleotides (see Figure 17.7). The enzyme adds nucleotides to the 3' end of the growing RNA molecule as it continues along the double helix. In the wake of this advancing wave of RNA synthesis, the new RNA molecule peels away from its DNA template and the DNA double helix re-forms. Transcription progresses at a rate of about 60 nucleotides per second in eukaryotes.

A single gene can be transcribed simultaneously by several molecules of RNA polymerase following each other like trucks in a convoy. A growing strand of RNA trails off from each polymerase, with the length of each new strand reflecting how far along the template the enzyme has traveled from the start point (see Figure 17.22). The congregation of many polymerase molecules simultaneously transcribing a single gene increases the amount of mRNA transcribed from it, which helps the cell make the encoded protein in large amounts.

A. Figure 17.8 The initiation of transcription at a eukaryotic promoter. In eukaryotic cells, proteins called transcription factors mediate the initiation of transcription by RNA polymerase II.

Termination of Transcription

The mechanism of termination differs between prokaryotes and eukaryotes. In prokaryotes, transcription proceeds through a terminator sequence in the DNA. The transcribed terminator (an RNA sequence) functions as the termination signal, causing the polymerase to detach from the DNA and release the transcript, which is available for immediate use as mRNA. In eukaryotes, however, the pre-mRNA is cleaved from the growing RNA chain while RNA polymerase II continues to transcribe the DNA. Specifically, the polymerase transcribes a sequence on the DNA called the polyadenylation signal sequence, which codes for a polyadenylation signal C^AUAAA in the pre-mRNA. Then, at a point about 10 to 35 nucleotides downstream from the AAUAAA signal, proteins associated with the growing RNA transcript cut it free from the polymerase, releasing the pre-mRNA. The polymerase continues transcribing for hundreds of nucleotides past the site where the pre-mRNA was released. Transcription is terminated when the polymerase eventually falls off the DNA (by a mechanism that is not fully understood). Once the pre-mRNA has been made, it is modified during RNA processing, the topic of our next section.

Concept 17.3

Eukaryotic cells modify RNA after transcription

Enzymes in the eukaryotic nucleus modify pre-mRNA in specific ways before the genetic messages are dispatched to the cytoplasm. During this RNA processing, both ends of the primary transcript are usually altered. Also, in most cases, certain interior sections of the molecule are cut out and the remaining parts spliced together. These modifications help form an mRNA molecule that is ready to be translated.

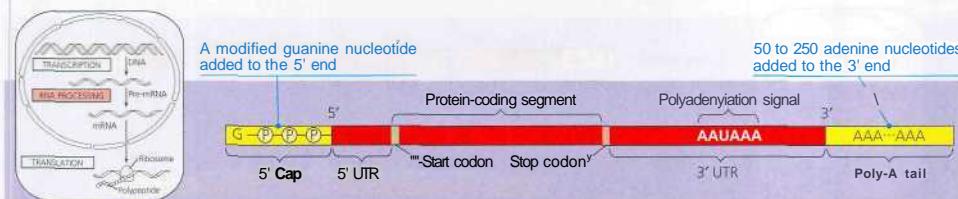

Alteration of mRNA Ends

Each end of a pre-mRNA molecule is modified in a particular way (Figure 17.9). The 5' end, the end transcribed first, is capped off with a modified form of a guanine (G) nucleotide after transcription of the first 20 to 40 nucleotides, forming a 5' cap. The 3' end of the pre-mRNA molecule is also modified before the mRNA exits the nucleus. Recall that the pre-mRNA is released soon after the polyadenylation signal, AAUAAA, is transcribed. At the 3' end, an enzyme adds 50 to 250 adenine (A) nucleotides, forming a poly-A tail. The 5' cap and poly-A tail share several important functions. First, they seem to facilitate the export of the mature mRNA from the nucleus. Second, they help protect the mRNA from degradation by hydrolytic enzymes. And third, once the mRNA reaches the cytoplasm, both structures help ribosomes attach to the 5' end of the mRNA. Figure 17.9 shows a diagram of a eukaryotic mRNA molecule with cap and tail. The figure also shows the untranslated regions (UTRs) at the 5' and 3' ends of the mRNA (referred to as the 5' UTR and 3' UTR). The UTRs are parts of the mRNA that will not be translated into protein, but they have other functions, such as ribosome binding.

Concept Check 17.2

1. Compare and contrast the functioning of DNA polymerase and RNA polymerase.
2. Is the promoter at the upstream or downstream end of a transcription unit?
3. In a prokaryote, how does RNA polymerase "know" where to start transcribing a gene? In a eukaryote?
4. How is the primary transcript produced by a prokaryotic cell different from that produced by a eukaryotic cell?

For suggested answers, see Appendix A.

A Figure 17.9 RNA processing: addition of the 5' cap and poly-A tail. Enzymes modify the two ends of a eukaryotic pre-mRNA molecule. The modified ends may promote the export of mRNA from the nucleus and

help protect the mRNA from degradation. When the mRNA reaches the cytoplasm, the modified ends, in conjunction with certain cytoplasmic proteins, facilitate ribosome attachment. The 5' cap and poly-A tail are not

translated into protein, nor are the regions called the 5' untranslated region (5' UTR) and 3' untranslated region (3' UTR).

Split Genes and RNA Splicing

The most remarkable stage of RNA processing in the eukaryotic nucleus is the removal of a large portion of the RNA molecule that is initially synthesized—a cut-and-paste job called **RNA splicing** (Figure 17.10). The average length of a transcription unit along a eukaryotic DNA molecule is about 8,000 nucleotides, so the primary RNA transcript is also that long. But it takes only about 1,200 nucleotides to code for an average-sized protein of 400 amino acids. (Remember, each amino acid is encoded by a triplet of nucleotides.) This means that most eukaryotic genes and their RNA transcripts have long noncoding stretches of nucleotides, regions that are not translated. Even more surprising is that most of these non-coding sequences are interspersed between coding segments of the gene and thus between coding segments of the pre-mRNA. In other words, the sequence of DNA nucleotides that codes for a eukaryotic polypeptide is usually not continuous; it is split into segments. The noncoding segments of nucleic acid that lie between coding regions are called intervening sequences, or **introns** for short. The other regions are called **exons**, because they are eventually expressed, usually by being translated into amino acid sequences. (Exceptions include the UTRs of the exons at the ends of the RNA, which make up part of the mRNA but are not translated into protein. Because of these exceptions, you may find it helpful to think of exons as sequences of RNA that *exit* the nucleus.) The terms *intron* and *exon* are used for both RNA sequences and the DNA sequences that encode them.

In making a primary transcript from a gene, RNA polymerase II transcribes both introns and exons from the DNA, but the mRNA molecule that enters the cytoplasm is an abridged version. The introns are cut out from the molecule and the exons joined together, forming an mRNA molecule with a continuous coding sequence. This is the process of RNA splicing.

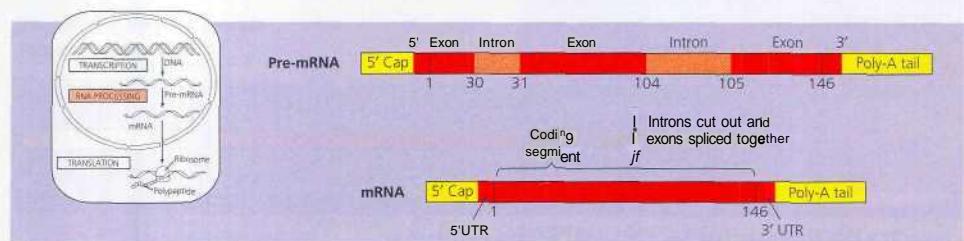

How is pre-mRNA splicing carried out? Researchers have learned that the signal for RNA splicing is a short nucleotide

sequence at each end of an intron. Particles called *small nuclear ribonucleoproteins*, abbreviated snRNPs (pronounced "snurps") recognize these splice sites. As the name implies, snRNPs are located in the cell nucleus and are composed of RNA and protein molecules. The RNA in a snRNP particle is called a *small nuclear RNA* (*snRNA*); each molecule is about 150 nucleotides long. Several different snRNPs join with additional proteins to form an even larger assembly called a **spliceosome**, which is almost as big as a ribosome. The spliceosome interacts with certain sites along an intron, releasing the intron and joining together the two exons that flanked the intron (Figure 17.11). There is strong evidence that snRNAs play a major role in these catalytic processes, as well as in spliceosome assembly and splice site recognition.

Ribozymes

The idea of a catalytic role for snRNA arose from the discovery of ribozymes, RNA molecules that function as enzymes. In some organisms, RNA splicing can occur without proteins or additional RNA molecules; the intron RNA functions as a ribozyme and catalyzes its own excision! For example, in the protozoan *Tetrahymena*, self-splicing occurs in the production of ribosomal RNA (rRNA), a component of the organisms ribosomes. The pre-rRNA actually removes its own introns.

The fact that RNA is single-stranded plays an important role in allowing certain RNA molecules to function as ribozymes. A region of an RNA molecule may base-pair with a complementary region elsewhere in the same molecule, thus imparting specific structure to the RNA molecule as a whole. Also, some of the bases contain functional groups that may participate in catalysis. Just as the specific shape of an enzymatic protein and the functional groups on its amino acid side chains allow the protein to function as a catalyst, the structure of some RNA molecules allows them to function as catalysts, too. The discovery of ribozymes rendered obsolete the belief that all biological catalysts were proteins.

A Figure 17.10 RNA processing: RNA splicing. The RNA molecule shown here codes for p-globin, one of the polypeptides of hemoglobin. The numbers under the RNA refer

to codons; (3-globin is 146 amino acids long. The p-globin gene and its pre-mRNA transcript have three exons, corresponding to sequences that will leave the nucleus as mRNA. (The 5' UTR and 3'

UTR are parts of exons because they are included in the mRNA; however, they do not code for protein.) During RNA processing, the introns are cut out and the exons spliced together.

Termination of Transcription

This mechanism of termination differs between prokaryotes and eukaryotes. In prokaryotes, transcription proceeds through a terminator sequence in the DNA. The transcribed terminator (an RNA sequence) functions as the termination signal, causing the polymerase to detach from the DNA and release the transcript, which is available for immediate use as mRNA. In eukaryotes, however, the pre-mRNA is cleaved from the growing RNA chain while RNA polymerase II continues to transcribe the DNA. Specifically, the polymerase transcribes a sequence on the DNA called the polyadenylation signal sequence, which codes for a polyadenylation signal (AAUAAA) in the pre-mRNA. Then, at a point about 10 to 35 nucleotides downstream from the AAUAAA signal, proteins associated with the growing RNA transcript cut it free from the polymerase, releasing the pre-mRNA. The polymerase continues transcribing for hundreds of nucleotides past the site where the pre-mRNA was released. Transcription is terminated when the polymerase eventually falls off the DNA (by a mechanism that is not fully understood). Once the pre-mRNA has been made, it is modified during RNA processing, the topic of our next section.

Concept 17.3

In making a primary transcript from a gene, RNA polymerase II transcribes both introns and exons from the DNA, but the mRNA molecule that enters the cytoplasm is an abridged version. The introns are cut out from the molecule and the exons joined together, forming an mRNA molecule with a continuous coding sequence. This is the process of RNA splicing.

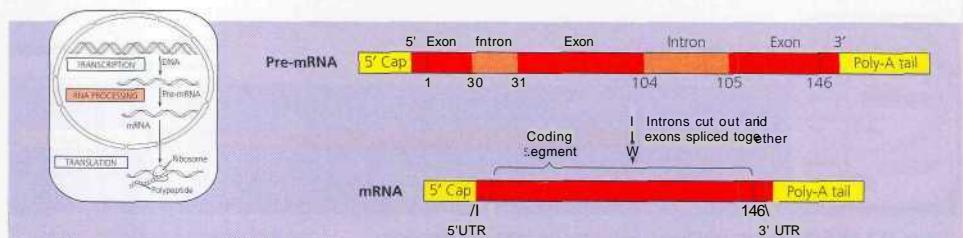

How is pre-mRNA splicing carried out? Researchers have learned that the signal for RNA splicing is a short nucleotide

sequence at each end of an intron. Particles called *small nuclear ribonucleoproteins*, abbreviated *snRNPs* (pronounced "snurps"), recognize these splice sites. As the name implies, snRNPs are located in the cell nucleus and are composed of RNA and **protein** molecules. The RNA in a snRNP particle is called a *small nuclear RNA* (*snRNA*); each molecule is about 150 nucleotides long. Several different snRNPs join with additional proteins to form an even larger assembly called a **spliceosome**, which is almost as big as a ribosome. The spliceosome interacts with certain sites along an intron, releasing the intron and joining together the two exons that flanked the intron (Figure 17.11). There is strong evidence that snRNAs play a major role in these catalytic processes, as well as in spliceosome assembly and splice site recognition.

Ribozymes

The idea of a catalytic role for snRNA arose from the discovery of **ribozymes**, RNA molecules that function as enzymes. In some organisms, RNA splicing can occur without proteins or additional RNA molecules: The intron RNA functions as a ribozyme and catalyzes its own excision! For example, in the protozoan *Tetrahymena*, self-splicing occurs in the production of ribosomal RNA (rRNA), a component of the organism's ribosomes. The pre-rRNA actually removes its own introns.

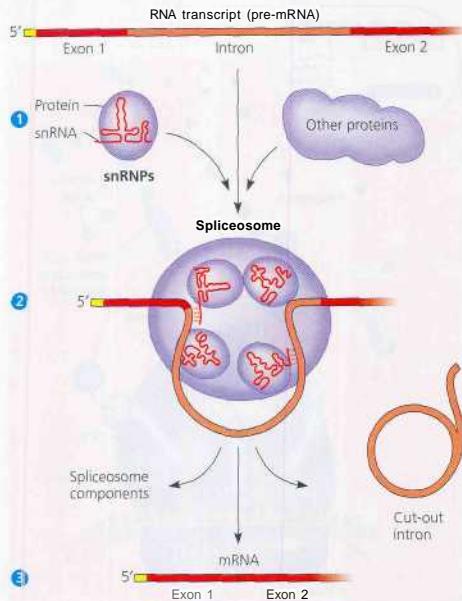

The fact that RNA is single-stranded plays an important role in allowing certain RNA molecules to function as ribozymes. A region of an RNA molecule may base-pair with a complementary region elsewhere in the same molecule, thus imparting specific structure to the RNA molecule as a whole. Also, some of the bases contain functional groups that **may** participate in catalysis, just as the specific shape of an enzymatic protein and the functional groups on its amino acid side chains allow the protein to function as a catalyst, the structure of some RNA molecules allows them to function as catalysts, too. The discovery of ribozymes rendered obsolete the belief that all biological catalysts were proteins.

A Figure 17.10 RNA processing: RNA splicing. The RNA molecule shown here codes for p-globin, one of the polypeptides of hemoglobin. The numbers under the RNA refer

to codons; p-globin is 146 amino acids long. The β -globin gene and its pre-mRNA transcript have three exons, corresponding to sequences that will leave the nucleus as mRNA. (The 5' UTR and 3'

UTR are parts of exons because they are included in the mRNA; however, they do not code for protein.) During RNA processing, the introns are cut out and the exons spliced together.

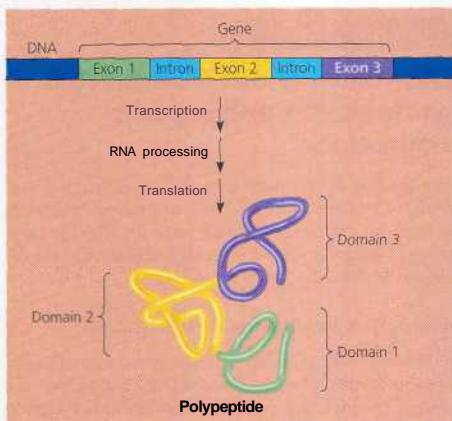

A Figure 17.11 The roles of snRNPs and spliceosomes in pre-mRNA splicing. The diagram shows only a portion of the pre-mRNA transcript; additional introns and exons lie downstream from the ones pictured here. © Small nuclear ribonucleoproteins (snRNPs) and other proteins form a molecular complex called a spliceosome on a pre-mRNA containing exons and introns. © Within the spliceosome, snRNA base-pairs with nucleotides at specific sites along the intron. & The RNA transcript is cut, releasing the intron and at the same time splicing the exons together. The spliceosome then comes apart, releasing spliced mRNA, which now contains only exons.

The Functional and Evolutionary Importance of Introns

What are the biological functions of introns and RNA splicing? One idea is that introns play regulatory¹¹ roles in the cell; at least some introns contain sequences that control gene activity in some way. And the splicing process itself is necessary for the passage of mRNA from the nucleus to the cytoplasm.

One established benefit of the presence of exons and introns in genes is to enable a single gene to encode more than one kind of polypeptide. A number of genes are known to give rise to two or more different polypeptides, depending on which segments are treated as exons during RNA processing; this is called alternative RNA splicing (see Figure 19.8). For example, sex differences in fruit flies are largely due to differences in how males and females splice the RNA transcribed from certain genes. Early results from the Human Genome Project (discussed in Chapter 20) suggest that alternative RNA splicing may be one reason humans can get along with a

A Figure 17.12 Correspondence between exons and protein domains. In a large number of genes, different exons encode separate domains of the protein product.

relatively small number of genes—not quite twice as many as a fruit fly. Because of alternative splicing, the number of different protein products an organism can produce is much greater than its number of genes.

Proteins often have a modular architecture consisting of discrete structural and functional regions called domains. One domain of an enzymatic protein, for instance, might include the active site, while another might attach the protein to a cellular membrane. In many cases, different exons code for the different domains of a protein (Figure 17.12). The presence of introns in a gene may facilitate the evolution of new and potentially useful proteins as a result of a process known as *exon shuffling*. Introns increase the probability of potentially beneficial crossing over between the exons of alleles—simply by providing more terrain for crossovers without interrupting coding sequences. We can also imagine the occasional mixing and matching of exons between completely different (nonallelic) genes. Exon shuffling of either sort could lead to new proteins with novel combinations of functions. While most of the shuffling would result in nonbeneficial changes, occasionally a beneficial variant might arise.

Concept Check 17.3

- How does alteration of the 5' and 3' ends of pre-mRNA affect the mRNA that exits the nucleus?
- Describe the role of snRNPs in RNA splicing.
- How can alternative RNA splicing generate a greater number of polypeptide products than there are genes?

For suggested answers, see Appendix A.

Concept 17.4

Translation is the RNA-directed synthesis of a polypeptide: a closer look

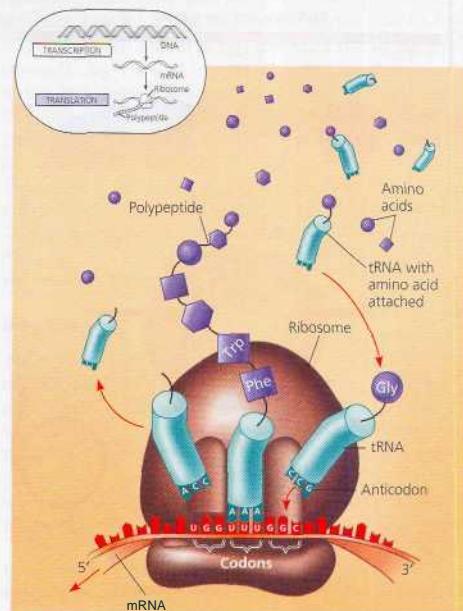

We will now examine in greater detail how genetic information flows from mRNA to protein—the process of translation. As we did for transcription, we'll concentrate on the basic steps of translation that occur in both prokaryotes and eukaryotes while pointing out key differences.

Molecular Components of Translation

In the process of translation, a cell interprets a genetic message and builds a polypeptide accordingly. The message is a series of codons along an mRNA molecule, and the interpreter is called transfer RNA (tRNA). The function of tRNA is to transfer amino acids from the cytoplasmic pool of amino acids to a ribosome. A cell keeps its cytoplasm stocked with all 20 amino acids, either by synthesizing them from other compounds or by taking them up from the surrounding solution. The ribosome adds each amino acid brought to it by tRNA to the growing end of a polypeptide chain (Figure 17.13).

Molecules of tRNA are not all identical. The key to translating a genetic message into a specific amino acid sequence is that each type of tRNA molecule translates a particular mRNA codon into a particular amino acid. As a tRNA molecule arrives at a ribosome, it bears a specific amino acid at one end. At the other end of the tRNA is a nucleotide triplet called an anticodon, which base-pairs with a complementary codon on mRNA. For example, consider the mRNA codon UUU, which is translated as the amino acid phenylalanine. The tRNA that base-pairs with this codon by hydrogen bonding has AAA as its anticodon and carries phenylalanine at its other end (see the middle tRNA in Figure 17.13). As an mRNA molecule is moved through a ribosome, phenylalanine will be added to the polypeptide chain whenever the codon UUU is presented for translation. Codon by codon, the genetic message is translated as tRNAs deposit amino acids in the order prescribed, and the ribosome joins the amino acids into a chain. The tRNA molecule is a translator because it can read a nucleic acid word (the mRNA codon) and interpret it as a protein word (the amino acid).

Translation is simple in principle but complex in its biochemistry and mechanics, especially in the eukaryotic cell. In dissecting translation, we'll concentrate on the slightly less complicated version of the process that occurs in prokaryotes. Let's first look at some of the major players in this cellular drama, then see how they act together to make a polypeptide.

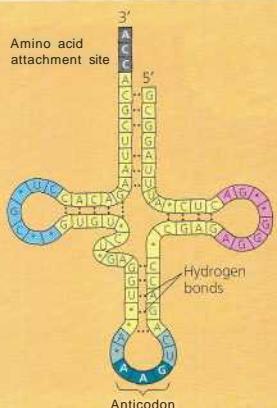

& Figure 17.13 Translation: the basic concept. As a molecule of mRNA is moved through a ribosome, codons are translated into amino acids, one by one. The interpreters are tRNA molecules, each type with a specific anticodon at one end and a corresponding amino acid at the other end. A tRNA adds its amino acid cargo to a growing polypeptide chain when the anticodon bonds to a complementary codon on the mRNA. The figures that follow show some of the details of translation in the prokaryotic cell.

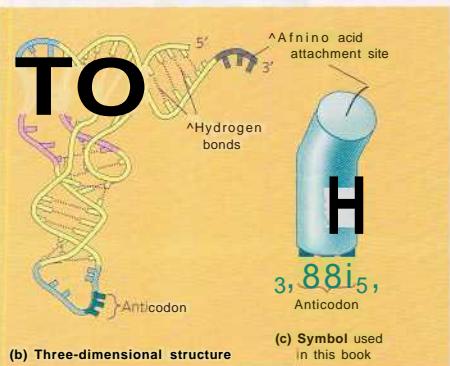

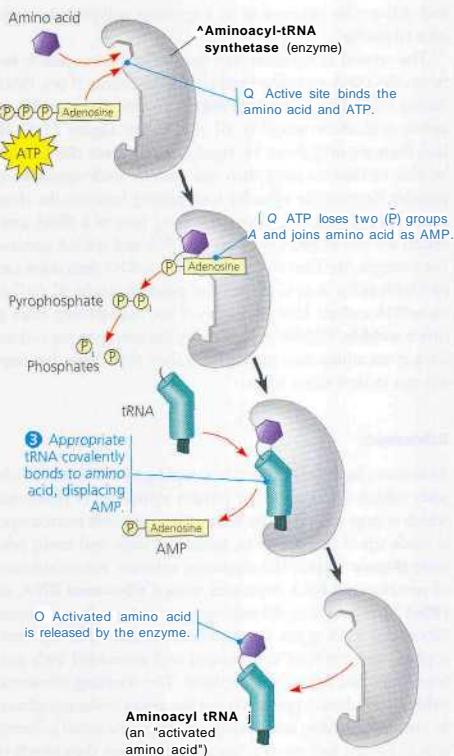

The Structure and Function of Transfer RNA

Like mRNA and other types of cellular RNA, transfer RNA molecules are transcribed from DNA templates. In a eukaryotic cell, tRNA, like mRNA, is made in the nucleus and must travel from the nucleus to the cytoplasm, where translation occurs. In both prokaryotic and eukaryotic cells, each tRNA molecule is used repeatedly, picking up its designated amino acid in the cytosol, depositing this cargo at the ribosome, and then leaving the ribosome to pick up another amino acid.

As illustrated in Figure 17.14, a tRNA molecule consists of a single RNA strand that is only about 80 nucleotides long (compared to hundreds of nucleotides for most mRNA molecules). Because of the presence of complementary stretches of bases that can hydrogen-bond to each other, this single strand can fold back upon itself, forming a molecule with a three-dimensional structure. Flattened into one plane to reveal this base pairing, a tRNA molecule looks like a cloverleaf (Figure 17.14a). The tRNA actually twists and folds into i

(a) Two-dimensional structure. The four base-paired regions and three loops are characteristic of all tRNAs, as is the base sequence of the amino acid attachment site at the 3' end. The anticodon triplet is unique to each tRNA type. (The asterisks mark bases that have been chemically modified, a characteristic of tRNA.)

lik Figure 17.14 The structure of transfer RNA (tRNA).

Anticodons are conventionally written 3' → 5' to align properly with codons written 5' → 3' (see Figure 17.13). For base pairing, RNA strands must be antiparallel, like DNA. For example, anticodon :·'-AAG-5' pairs with mRNA codon 5'-UUC-3'.

compact three-dimensional structure that is roughly L-shaped (Figure 17.14b). The loop protruding from one end of the L includes the anticodon, the special base triplet that binds to a specific mRNA codon. From the other end of the L-shaped tRNA molecule protrudes its 3' end, which is the attachment site for an amino acid. Thus, the structure of a tRNA molecule fits its function.

A Figure 17.15 An aminoacyl-tRNA synthetase joins a specific amino acid to a tRNA. Linkage of the tRNA and amino acid is an endergonic process that occurs at the expense of ATP. The ATP loses two phosphate groups, becoming AMP (adenosine monophosphate).

The accurate translation of a genetic message requires two recognition steps. First, there must be a correct match between a tRNA and an amino acid. A tRNA that binds to an mRNA codon specifying a particular amino acid must carry *only* that amino acid to the ribosome. Each amino acid is joined to the correct tRNA by a specific enzyme called an aminoacyl-tRNA synthetase (Figure 17.15). The active site of each type of aminoacyl-tRNA synthetase fits only a specific combination of amino acid and tRNA. There are 20 different synthetases, one for each amino acid; each synthetase is able to bind all the different tRNAs that code for its specific amino acid. The synthetase catalyzes the covalent attachment of the amino acid to its tRNA in a process driven by the hydrolysis of ATP. The resulting aminoacyl tRNA, also called an activated amino acid, is released from the enzyme

and delivers its amino acid to a growing polypeptide chain on a ribosome.

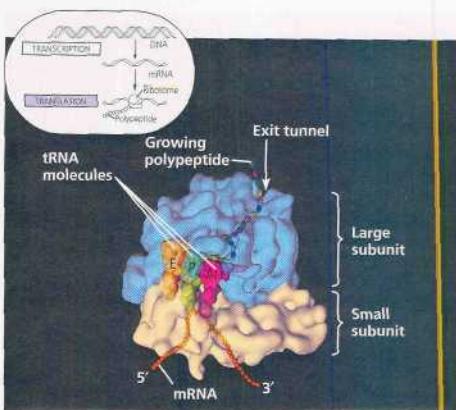

The second recognition step involves a correct match between the tRNA anticodon and an mRNA codon. If one tRNA variety existed for each of the mRNA codons that specifies an amino acid, there would be 61 tRNAs (see Figure 17.5). In fact, there are only about 45, signifying that some tRNAs must be able to bind to more than one codon. Such versatility is possible because the rules for base pairing between the third base of a codon and the corresponding base of a tRNA anticodon are not as strict as those for DNA and mRNA codons. For example, the base U at the 5' end of a tRNA anticodon can pair with either A or G in the third position (at the 3' end) of an mRNA codon. This relaxation of the base-pairing rules is called wobble. Wobble explains why the synonymous codons for a given amino acid can differ in their third base, but usually not in their other bases.

Ribosomes

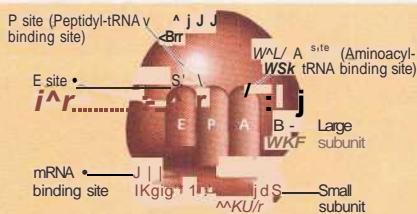

Ribosomes facilitate the specific coupling of tRNA anticodons with mRNA codons during protein synthesis. A ribosome, which is large enough to be seen with an electron microscope, is made up of two subunits, called the large and small subunits (Figure 17.16). The ribosomal subunits are constructed of proteins and RNA molecules named ribosomal RNA, or rRNA. In eukaryotes, the subunits are made in the nucleolus. Ribosomal RNA genes on the chromosomal DNA are transcribed, and the RNA is processed and assembled with proteins imported from the cytoplasm. The resulting ribosomal subunits are then exported via nuclear pores to the cytoplasm. In both prokaryotes and eukaryotes, large and small subunits join to form a functional ribosome only when they attach to an mRNA molecule. About two-thirds of the mass of a ribosome is rRNA. Because most cells contain thousands of ribosomes, rRNA is the most abundant type of RNA.

Although the ribosomes of prokaryotes and eukaryotes are very similar in structure and function, those of eukaryotes are slightly larger and differ somewhat from prokaryotic ribosomes in their molecular composition. The differences are medically significant. Certain antibiotic drugs can inactivate prokaryotic ribosomes without inhibiting the ability of eukaryotic ribosomes to make proteins. These drugs, including tetracycline and streptomycin, are used to combat bacterial infections.

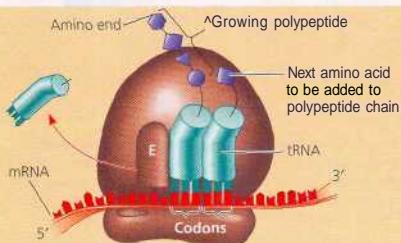

The structure of a ribosome reflects its function of bringing mRNA together with amino acid-bearing tRNAs. In addition to a binding site for mRNA, each ribosome has three binding sites for tRNA (see Figure 17.16). The P site (peptidyl-tRNA site) holds the tRNA carrying the growing polypeptide chain, while the A site (aminoacyl-tRNA site) holds the tRNA carrying the next amino acid to be added to the chain. Discharged tRNAs leave the ribosome from the E site (exit site). The ribosome holds the tRNA and mRNA in close proximity and

(a) Computer model of functioning ribosome. This is a model of a bacterial ribosome, showing its overall shape. The eukaryotic ribosome is roughly similar. A ribosomal subunit is an aggregate of ribosomal RNA molecules and proteins.

(b) Schematic model showing binding sites. A ribosome has an mRNA binding site and three tRNA binding sites, known as the A, P, and E sites. This schematic ribosome will appear in later diagrams.

(c) Schematic model with mRNA and tRNA. A tRNA fits into a binding site when its anticodon base-pairs with an mRNA codon. The P site holds the tRNA attached to the growing polypeptide. The A site holds the tRNA carrying the next amino acid to be added to the polypeptide chain. Discharged tRNA leaves from the E site.

A Figure 17.16 The anatomy of a functioning ribosome.

positions the new amino acid for addition to the carboxyl end of the growing polypeptide. It then catalyzes the formation of the peptide bond. As the polypeptide becomes longer, it passes through an *exit* tunnel in the ribosome's large subunit. When the polypeptide is complete, it is released to the cytosol through the exit tunnel.

Four decades of genetic and biochemical research on ribosomes have culminated in the detailed structure of the bacterial ribosome, which appears as a ribbon model in Figure 17.1. Recent research strongly supports the hypothesis that rRNA, not protein, is primarily responsible for both structure and function of the ribosome. The proteins, which are largely on the exterior, support the conformational changes of the rRNA molecules as they carry out catalysis during translation. RNA is the main constituent of the interface between the two subunits and of the A and P sites, and it is the catalyst of peptide bond formation. Thus, a ribosome can be regarded as one colossal ribozyme!

Building a Polypeptide

We can divide translation, the synthesis of a polypeptide chain, into three stages (analogous to those of transcription): initiation, elongation, and termination. All three stages require protein "factors" that aid mRNA, tRNA, and ribosomes in the translation process. For certain aspects of chain initiation and elongation, energy is also required. It is provided by the hydrolysis of GTP (guanosine triphosphate), a molecule closely related to ATP.

Ribosome Association and Initiation of Translation

The initiation stage of translation brings together mRNA, a tRNA bearing the first amino acid of the polypeptide, and the two subunits of a ribosome (Figure 17.17). First, a small ribosomal subunit binds to both mRNA and a specific initiator tRNA, which carries the amino acid methionine. The small subunit then moves, or scans, downstream along the mRNA until it reaches the start codon, AUG, which signals the start of translation; this is important because it establishes the codon reading frame for the mRNA. The initiator tRNA, already associated with the complex, then hydrogen-bonds with the start codon.

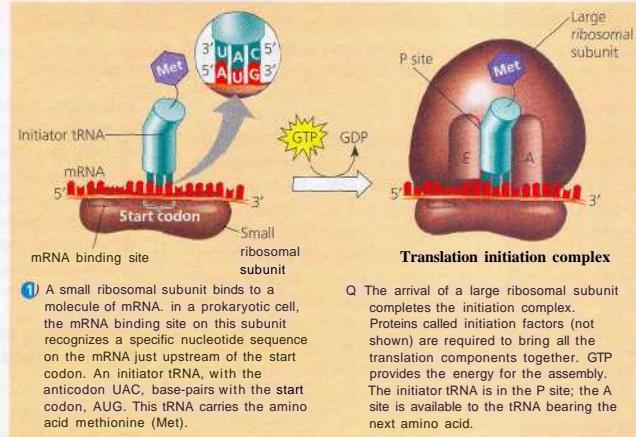

The union of mRNA, initiator tRNA, and a small ribosomal subunit is followed by the attachment of a large ribosomal subunit, completing a translation initiation

complex. Proteins called *initiation factors*, are required to bring all these components together. The cell also spends energy in the form of a GTP molecule to form the initiation complex. At the completion of the initiation process, the initiator tRNA sits in the P site of the ribosome, and the vacant A site is ready for the next aminoacyl tRNA. Note that a polypeptide is always synthesized in one direction, from the initial methionine at the amino end, also called the N-terminus, toward the final amino acid at the carboxyl end, also called the C-terminus (see Figure 17.18).

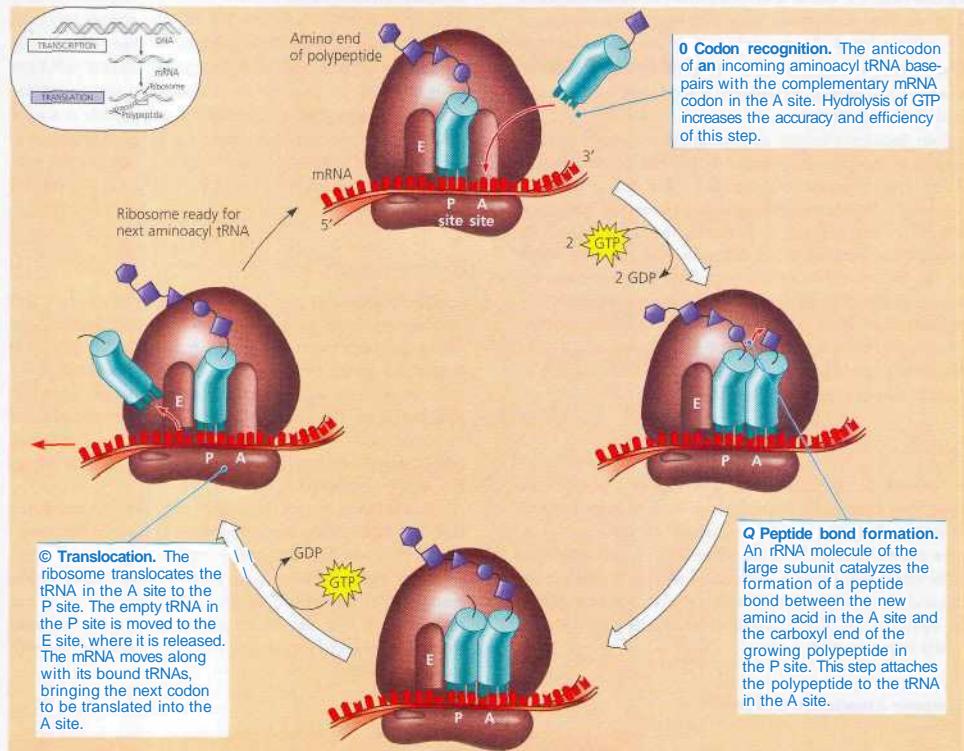

Elongation of the Polypeptide Chain

In the elongation stage of translation, amino acids are added one by one to the preceding amino acid. Each addition involves the participation of several proteins called *elongation factors* and occurs in a three-step cycle described in Figure 17.18 on the next page. Energy expenditure occurs in the first and third steps. Codon recognition requires hydrolysis of two molecules of GTP, which increases the accuracy and efficiency of this step. One more GTP is hydrolyzed to provide energy for the translocation step.

The mRNA is moved through the ribosome in one direction only, 5' end first; this is equivalent to the ribosome moving 5' → 3' on the mRNA. The important point is that the ribosome and the mRNA move relative to each other, unidirectionally, codon by codon. The elongation cycle takes less than a tenth of a second in prokaryotes and is repeated as each amino acid is added to the chain until the polypeptide is completed.

▲ Figure 17.17 The initiation of translation.

A Figure 17.18 The elongation cycle of translation. Not shown in this diagram are the proteins called elongation factors. The hydrolysis of GTP plays an important role in the elongation process.

Termination of Translation

The final stage of translation is termination (Figure 17.19). Elongation continues until a stop codon in the mRNA reaches the A site of the ribosome. The base triplets UAG, UAA, and UGA do not code for amino acids but instead act as signals to stop translation. A protein called a *release factor* binds directly to the stop codon in the A site. The release factor causes the addition of a water molecule instead of an amino acid to the polypeptide chain. This reaction hydrolyzes the completed polypeptide from the tRNA in the P site, releasing the polypeptide through the exit tunnel of the ribosome's large subunit (see Figure 17.16a). The remainder of the translation assembly then comes apart.

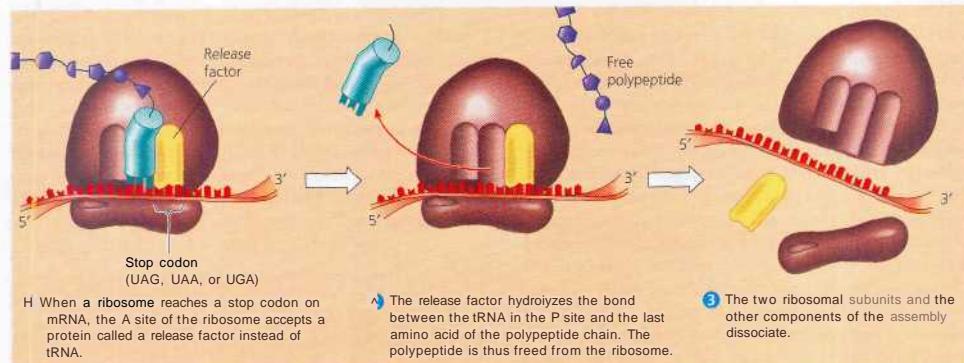

Polyribosomes

A single ribosome can make an average-sized polypeptide in less than a minute. Typically, however, a single mRNA is used to

make many copies of a polypeptide simultaneously because several ribosomes can translate the message from one mRNA at the same time. Once a ribosome moves past the start codon, a second ribosome can attach to the mRNA; thus, a number of ribosomes may trail along one mRNA. Such strings of ribosomes, called polyribosomes (or polysomes), can be seen with an electron microscope (Figure 17.20). Polyribosomes are found in both prokaryotic and eukaryotic cells. They enable a cell to make many copies of a polypeptide very quickly.

Completing and Targeting the Functional Protein

The process of translation is often not sufficient to make a functional protein. In this section, you will learn about modifications that polypeptide chains undergo after the translation process as well as some of the mechanisms used to target completed proteins to specific sites in the cell.

A Figure 17.19 The termination of translation.

Protein Folding and Post-Translational Modifications

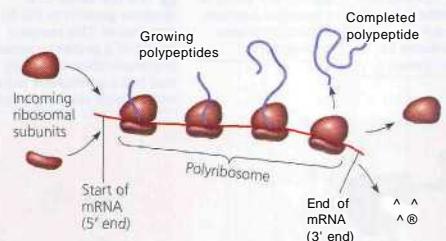

During its synthesis, a polypeptide chain begins to coil and fold spontaneously, forming a functional protein of specific conformation: a three-dimensional molecule with secondary and tertiary structure (see Figure 5.20). A gene determines primary structure, and primary structure in turn determines conformation. In many cases, a chaperone protein (chaperonin) helps the polypeptide fold correctly (see Figure 5.23).

Additional steps—*post-translational modifications*—may be required before the protein can begin doing its particular job in the cell. Certain amino acids may be chemically modified by the attachment of sugars, lipids, phosphate groups, or other additions. Enzymes may remove one or more amino acids from the leading (amino) end of the polypeptide chain. In some cases, a single polypeptide chain may be enzymatically cleaved into two or more pieces. For example, the protein insulin is first synthesized as a single polypeptide chain but becomes active only after an enzyme cuts out a central part of the chain, leaving a protein made up of two polypeptide chains connected by disulfide bridges. In other cases, two or more polypeptides that are synthesized separately may come together, becoming the subunits of a protein that has quaternary structure.

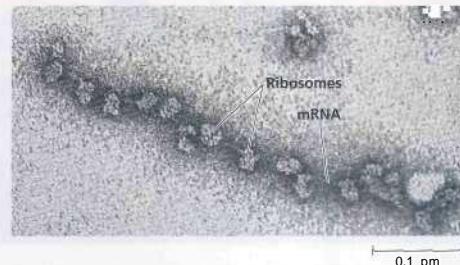

Targeting Polypeptides to Specific Locations

In electron micrographs of eukaryotic cells active in protein synthesis, two populations of ribosomes (and polyribosomes) are evident: free and bound (see Figure 6.11). Free ribosomes are suspended in the cytosol and mostly synthesize proteins that dissolve in the cytosol and function there. In contrast, bound ribosomes are attached to the cytosolic side of the endoplasmic reticulum (ER), or to the nuclear envelope. Bound

ribosomes make proteins of the endomembrane system (the nuclear envelope, ER, Golgi apparatus, lysosomes, vacuoles, and plasma membrane) as well as proteins secreted from the cell, such as insulin. The ribosomes themselves are identical and can switch their status from free to bound.

(a) An mRNA molecule is generally translated simultaneously by several ribosomes in clusters called polyribosomes.

(b) This micrograph shows a large polyribosome in a prokaryotic cell (TEM).

A Figure 17.20 Polyribosomes.

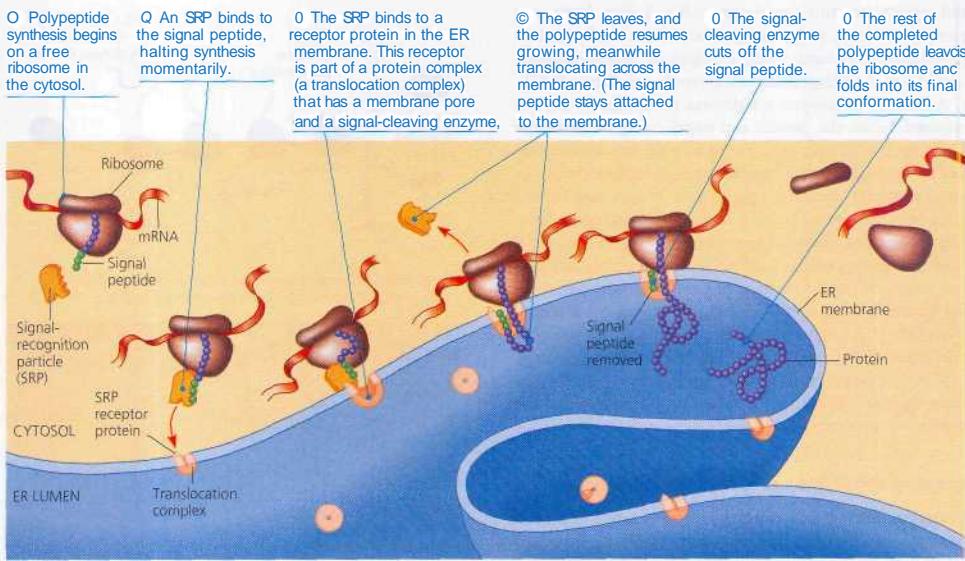

What determines whether a ribosome will be free in the cytosol or bound to rough ER at any particular time? Polypeptide synthesis always begins in the cytosol, when a free ribosome starts to translate an mRNA molecule. There the process continues to completion—unless the growing polypeptide itself cues the ribosome to attach to the ER. The polypeptides of proteins destined for the endomembrane system or for secretion are marked by a signal peptide, which targets the protein to the ER (**Figure 17.21**). The signal peptide, a sequence of about 20 amino acids at or near the leading (amino) end of the polypeptide, is recognized as it emerges from the ribosome by a protein-RNA complex called a signal-recognition particle (SRP). This particle functions as an adapter that brings the ribosome to a receptor protein built into the ER membrane. This receptor is part of a multiprotein translocation complex. Polypeptide synthesis continues there, and the growing polypeptide snakes across the membrane into the ER lumen via a protein pore. The signal peptide is usually removed by an enzyme. The rest of the completed polypeptide, if it is to be a secretory protein, is released into solution within the ER lumen (as in Figure 17.21). Alternatively, if the polypeptide is to be a membrane protein, it remains partially embedded in the ER membrane.

Other kinds of signal peptides are used to target polypeptides to mitochondria, chloroplasts, the interior of the nucleus, and other organelles that are not part of the endomembrane system. The critical difference in these cases is that translation is completed in the cytosol before the polypeptide is imported into the organelle. The mechanisms of translocation also vary, but in all cases studied to date, the "zip codes" that address proteins for secretion or to cellular locations are signal peptides of some sort. Prokaryotes also employ signal sequences to target proteins for secretion.

Concept Check 17.4

- Which two processes ensure that the correct amino acid is added to a growing polypeptide chain?
- Describe how the formation of polyribosomes can benefit the cell.
- Describe how a polypeptide to be secreted is transported to the endomembrane system.

For suggested answers, see Appendix A.

A Figure 17.21 The signal mechanism for targeting proteins to the ER. A polypeptide destined for the endomembrane system or for secretion from the cell begins

with a signal peptide, a series of amino acids that targets it for the ER. This figure shows the synthesis of a secretory protein and its simultaneous import into the ER. In the ER

and then in the Golgi, the protein is further processed. Finally, a transport vesicle conveys it to the plasma membrane for release from the cell (see Figure 7.9).

Concept 17.5

RNA plays multiple roles in the cell: *a review*

As we have seen, the cellular machinery of protein synthesis (and ER targeting) is dominated by RNA of various kinds. In addition to mRNA, these include tRNA, rRNA, and, in eukaryotes, snRNA and SRP RNA (**Table 17.1**). A type of RNA called small nucleolar RNA (*snoRNA*) aids in processing pre-rRNA transcripts in the nucleolus, a process necessary for ribosome formation. The diverse functions of these small RNA molecules range from structural to informational to catalytic. Recent research has also revealed the presence of small, single- and double-stranded RNA molecules that play unexpectedly important roles in regulating which genes get expressed. These types of RNA are called small interfering RNA (*siRNA*) and microRNA (*miRNA*) (see Chapter 19).

The ability of RNA to perform so many different functions is based on three properties. First, RNA can hydrogen-bond to other nucleic acid molecules (DNA or RNA). Second, it can assume a specific three-dimensional shape by forming hydrogen

bonds between bases in different parts of its own polynucleotide chain (as seen in tRNA; see Figure 17.14). Third, it has functional groups that allow it to act as a catalyst (ribozyme). These three properties make RNA quite multifunctional.

DNA may be the genetic material of all living cells, but RNA is much more versatile. You will learn in Chapter 18 that many viruses use RNA rather than DNA as their genetic material. In the past few years, scientists have begun to appreciate the diverse functions carried out by RNA molecules, in fact, the journal *Science* bestowed its 2002 "Breakthrough of the Year" award on the discoverer¹ of the small regulatory RNA molecules siRNA and miRNA.

Concept Check 17.5

- Describe three properties of RNA that allow it to perform diverse roles in the cell.

for suggested answers, see Appendix A.

Concept 17.6

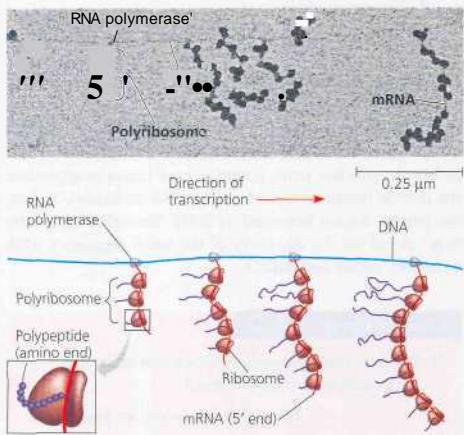

Comparing gene expression in prokaryotes and eukaryotes reveals key differences

Although prokaryotes and eukaryotes carry out transcription and translation in very similar ways, we have noted certain differences in cellular machinery and in details of the processes. Prokaryotic and eukaryotic RNA polymerases are different, and those of eukaryotes depend on a complex set of transcription factors. Transcription is terminated differently in the two kinds of cells. Also, prokaryotic and eukaryotic ribosomes are slightly different. The most important differences, however, arise from the eukaryotic cell's compartmental organization. Like a one-room workshop, a prokaryotic cell ensures a streamlined operation. In the absence of a nucleus, it can simultaneously transcribe and translate the same gene (**Figure 17.22**, on the next page), and the newly made protein can quickly diffuse to its site of function. In contrast, the eukaryotic cell's nuclear envelope segregates transcription from translation and provides a compartment for extensive RNA processing. This processing stage provides additional steps whose regulation can help coordinate the eukaryotic cell's elaborate activities (see Chapter 19). Finally, eukaryotic cells have complicated mechanisms for targeting proteins to the appropriate cellular compartment (organelle).

Where did eukaryotes and prokaryotes get the genes that encode the huge diversity of proteins they synthesize? For the past few billion years, the ultimate source of new genes has been the mutation of preexisting genes, the topic of the next section.

Table 17.1 Types of RNA in a Eukaryotic Cell

| Type of RNA | Functions |
|--|--|
| Messenger RNA (mRNA) | Carries information specifying amino acid sequences of proteins from DNA to ribosomes. |
| Transfer RNA (tRNA) | Serves as adapter molecule in protein synthesis; translates mRNA codons into amino acids. |
| Ribosomal RNA (rRNA) | Plays catalytic (ribozyme) roles and structural roles in ribosomes. |
| Primary transcript | Serves as a precursor to mRNA, rRNA, or tRNA, before being processed by splicing or cleavage. Some intron RNA acts as a ribozyme, catalyzing its own splicing. |
| Small nuclear RNA (snRNA) | Plays structural and catalytic roles in spliceosomes, the complexes of protein and RNA that splice pre-mRNA. |
| SRP RNA | Is a component of the signal-recognition particle (SRP), the protein-RNA complex that recognizes the signal peptides of polypeptides targeted to the ER. |
| Small nucleolar RNA (snoRNA) | Aids in processing of pre-rRNA transcripts for ribosome subunits in the nucleolus. |
| Small interfering RNA (siRNA) and microRNA (miRNA) | An: in)olve-d in regulation of gene expression. |

A Figure 17.22 Coupled transcription and translation in bacteria. In prokaryotic cells, the translation of mRNA can begin as soon as the leading (5') end of the mRNA molecule peels away from the DNA template. The micrograph (TEM) shows a strand of *E. coli*/DNA being transcribed by RNA polymerase molecules. Attached to each RNA polymerase molecule is a growing strand of mRNA, which is already being translated by ribosomes. The newly synthesized polypeptides are not visible in the micrograph but are shown in the diagram.

Concept Check 17.6

- In Figure 17.22, number the RNA polymerases in order of their initiation of transcription. Then number each mRNA's ribosomes in order of their initiation of translation.
- Would the arrangement shown in Figure 17.22 be found in a eukaryotic cell? Explain.

For suggested answers, see Appendix A.

Concept 17.7

Point mutations can affect protein structure and function

Mutations are changes in the genetic material of a cell (or virus). In Figure 15.14, we considered large-scale mutations, chromosomal rearrangements that affect long segments of DNA. Now we can examine point mutations, chemical changes in just one base pair of a gene.

If a point mutation occurs in a gamete or in a cell that gives rise to gametes, it may be transmitted to offspring and to a succession of future generations. If the mutation has an adverse ef-

fect on the phenotype of an organism, the mutant condition is referred to as a genetic disorder, or hereditary disease. For example, we can trace the genetic basis of sickle-cell disease to a mutation of a single base pair in the gene that codes for one of the polypeptides of hemoglobin. The change of a single nucleotide in the DNA's template strand leads to the production of an abnormal protein (Figure 17.23, and see Figure 5.2 I). In individuals who are homozygous for the mutant allele, the sickling of red blood cells caused by the altered hemoglobin produces the multiple symptoms associated with sickle-cell disease (see Chapter 14). Let's see how different types of point mutations translate into altered proteins.

Types of Point Mutations

Point mutations within a gene can be divided into two general categories: base-pair substitutions and base-pair insertions or deletions. While reading about how these mutations affect proteins, refer to Figures 17.24 and 17.25, on the next two pages.

Substitutions

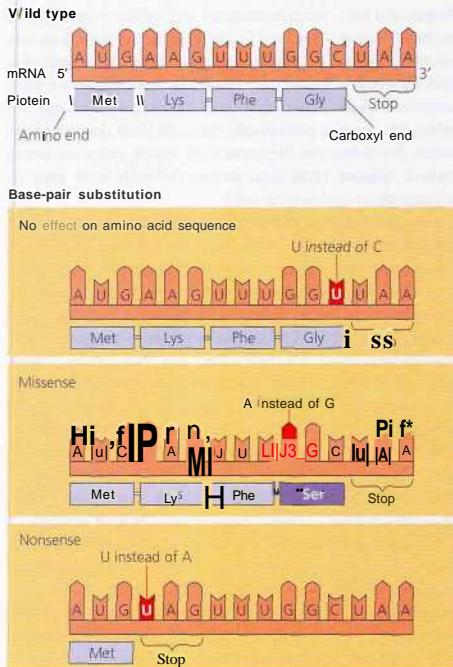

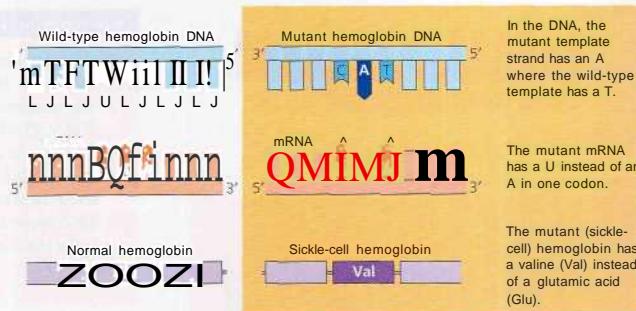

A base-pair substitution is the replacement of one nucleotide and its partner with another pair of nucleotides. Some substitutions are called *silent mutations* because, owing to the redundancy of the genetic code, they have no effect on the encoded protein. In other words, a change in a base pair may transform one codon into another that is translated into the same amino acid. For example, if 3'-CCG-5' on the template strand mutated to 3'-CCA-5', the mRNA codon that used to be GGC would become GGU, and a glycine would still be inserted at the proper location in the protein (see Figure 17.5). Other substitutions may change an amino acid but have little effect on the protein. The new amino acid may have properties similar to those of the amino acid it replaces, or it may be in a region of the protein where the exact sequence of amino acids is not essential to the protein's function.

However, the base-pair substitutions of greatest interest are those that cause a readily detectable change in a protein. The alteration of a single amino acid in a crucial area of a protein—in the active site of an enzyme, for example—will significantly alter protein activity. Occasionally, such a mutation leads to an improved protein or one with novel capabilities, but much more often such mutations are detrimental, leading to a useless or less active protein that impairs cellular function.

Substitution mutations are usually missense mutations; that is, the altered codon still codes for an amino acid and thus makes sense, although not necessarily the *right* sense. But a point mutation can also change a codon for an amino acid into a stop codon. This is called a nonsense mutation, and it causes translation to be terminated prematurely; the resulting polypeptide will be shorter than the polypeptide encoded by the normal gene (see Figure 17.24). Nearly all nonsense mutations lead to nonfunctional proteins.

• **Figure 17.23 The molecular basis of sickle-cell disease: a point mutation.**

The allele that causes sickle-cell disease differs from the wild-type (normal) allele by a single DNA base pair.

II Figure 17.24 Base-pair substitution. Mutations are changes in DNA, but they are represented here as they are reflected in mRNA and its protein product. Base-pair substitutions may lead to silent, missense, or nonsense mutations.

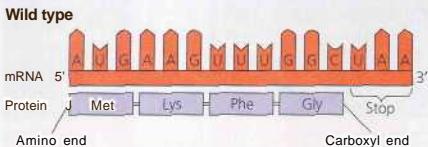

Insertions and Deletions

Insertions and deletions are additions or losses of nucleotide pairs in a gene. These mutations have a disastrous effect on the resulting protein more often than substitutions do. Because mRNA is read as a series of nucleotide triplets during translation, the insertion or deletion of nucleotides may alter the reading frame (triplet grouping) of the genetic message. Such a mutation, called a **frameshift mutation**, will occur whenever the number of nucleotides inserted or deleted is not a multiple of three (see Figure 17.25, on the next page). All the nucleotides that are downstream of the deletion or insertion will be improperly grouped into codons, and the result will be extensive missense probably ending sooner or later in nonsense and premature termination. Unless the frameshift is very near the end of the gene, it will produce a protein that is almost certain to be nonfunctional.

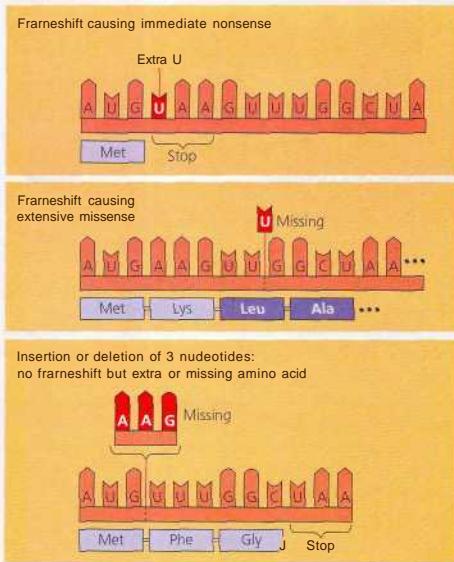

Mutagens

Mutations can arise in a number of ways. Errors during DNA replication, repair, or recombination can lead to base-pair substitutions, insertions, or deletions, as well as to mutations affecting longer stretches of DNA. Mutations resulting from such errors are called spontaneous mutations. It is difficult to calculate the rate at which such mutations occur. Rough estimates have been made of the rate of mutation during DNA replication for both *E. coli* and eukaryotes, and the numbers are similar: About 1 nucleotide in every 10^{10} is altered and passed on to the next generation of cells.

A number of physical and chemical agents, called **mutagens**, interact with DNA in ways that cause mutations. In the 1920s, Hermann Muller discovered that X-rays caused genetic changes in fruit flies. With X-rays, he was able to make *Drosophila* mutants that he could use in his genetic studies. But he also recognized an alarming implication of his discovery: X-rays and other forms of high-energy radiation pose hazards to the genetic material of people as well as laboratory

Base-pair insertion or deletion

A Figure 17.25 Base-pair insertion or deletion. Strictly speaking, the example at the bottom is not a point mutation because it involves insertion or deletion of more than one nucleotide.

organisms. Mutagenic radiation, a physical mutagen, includes ultraviolet (UV) light, which can cause disruptive thymine dimers in DNA (see Figure 1.6.17).

Chemical mutagens fall into several categories. Base analogs are chemicals that are similar to normal DNA bases but that pair incorrectly during DNA replication. Some other chemical mutagens interfere with correct DNA replication by inserting themselves into the DNA and distorting the double helix. Still other mutagens cause chemical changes in bases that change their pairing properties.

Researchers have developed various methods to test the mutagenic activity of different chemicals. A major application of these tests is the preliminary screening of chemicals to identify those that may cause cancer. This approach makes sense because most carcinogens (cancer-causing chemicals) are mutagenic and, conversely, most mutagens are carcinogenic.

Concept Check 17.7

- What happens when one nucleotide pair is lost from the middle of the coding sequence of a gene?
- The template strand of a gene contains the sequence 3'-TACTTGTCCGATATC-5'. Draw the double strand of DNA and the resulting mRNA, labeling all 5' and 3' ends. Determine the amino acid sequence. Then show the same after a mutation changes the template DNA sequence to 3'-TACTTGTCCAATATC-5'. What is the effect on the amino acid sequence?

For suggested answers, see Appendix A.

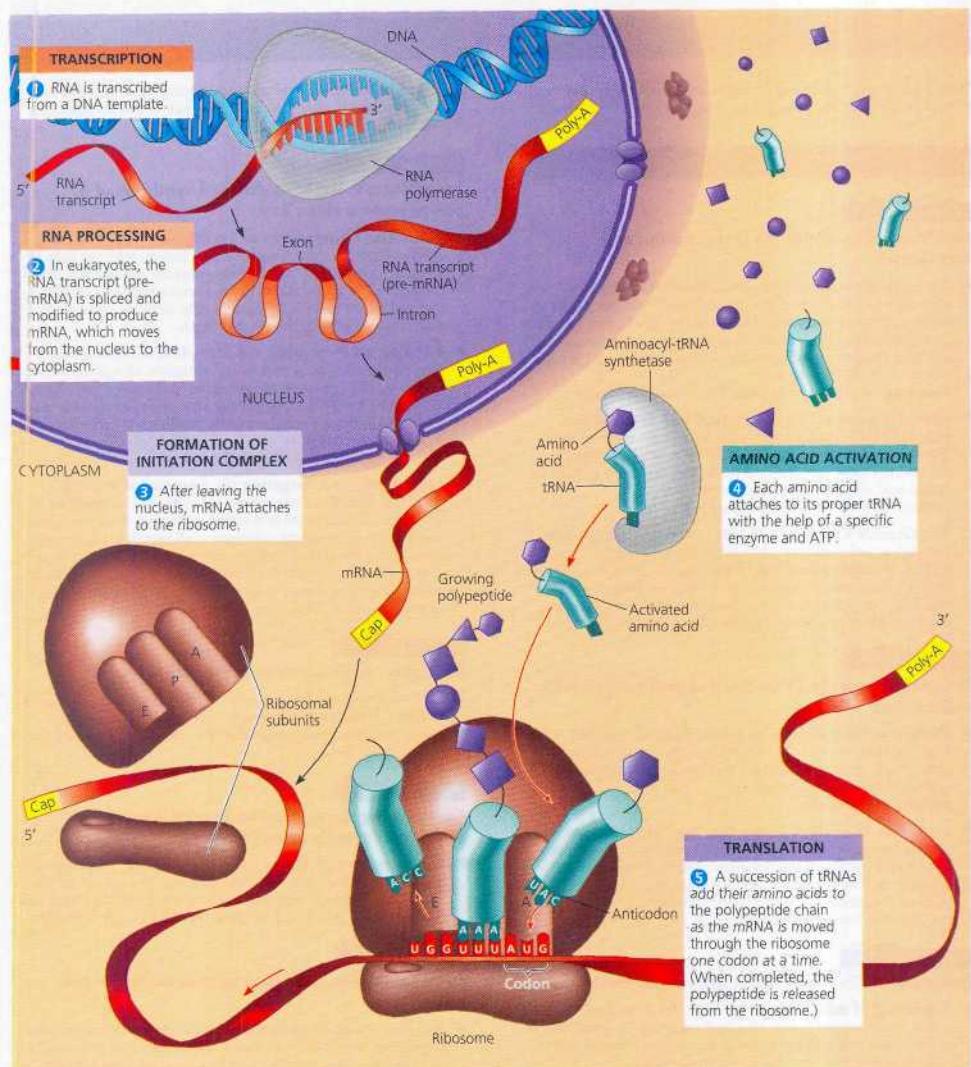

What is a gene? revisiting the question

Our definition of a gene has evolved over the past few chapters, as it has through the history of genetics. We began with the Mendelian concept of a gene as a discrete unit of inheritance that affects a phenotypic character (Chapter 14). We saw that Morgan and his colleagues assigned such genes to specific loci on chromosomes (Chapter 15). We went on to view a gene as *i* region of specific nucleotide sequence along the length of a DNA molecule (Chapter 16). Finally, in this chapter, we have considered a functional definition of a gene as a DNA sequence coding for a specific polypeptide chain. All these definitions are useful, depending on the context in which genes are being studied. (Figure 17.26 summarizes the path from gene to polypeptide in a eukaryotic cell)

Even the one gene-one polypeptide model must be refined and applied selectively. Most eukaryotic genes contain non-coding segments (introns), so large portions of these genes have no corresponding segments in polypeptides. Molecular biologists also often include promoters and certain other regulatory regions of DNA within the boundaries of a gene. These DNA sequences are not transcribed, but they can be considered part of the functional gene because they must be present for transcription to occur. Our molecular definition of a gene must also be broad enough to include the DNA that is transcribed into rRNA, tRNA, and other RNAs that are not translated. These genes have no polypeptide products. Thus, we arrive at the following definition: *A gene is a region of DNA whose final product is either a polypeptide or an RNA molecule.*

For most genes, however, it is still useful to retain the one gene-one polypeptide idea. In this chapter, you have learned in molecular terms how a typical gene is expressed—by transcription into RNA and then translation into a polypeptide that forms a protein of specific structure and function. Proteins, in turn, bring about an organism's observable phenotype.

Genes are regulated. We will explore the regulation of gene expression in eukaryotes in Chapters 19 and 21. In the next chapter, we begin our discussion of gene regulation by focusing on the simpler molecular biology of bacteria and viruses.

A Figure 17.26 A summary of transcription and translation in a eukaryotic cell. This diagram shows the path from one gene to one polypeptide. Keep in mind that each gene in the DNA can be transcribed repeatedly into many RNA molecules, and that each mRNA can be

translated repeatedly to yield many polypeptide molecules. (Also, remember that the final products of some genes are not polypeptides but RNA molecules, including tRNA and rRNA.) In general, the steps of transcription and translation are similar in prokaryotic and eukaryotic cells. The major difference is the

occurrence of RNA processing in the eukaryotic nucleus. Other significant differences are found in the initiation stages of both transcription and translation and in the termination of transcription.

SUMMARY OF KEY CONCEPTS

Concept 17.1

Genes specify proteins via transcription and translation

- **Evidence from the Study of Metabolic Defects**

(pp. 309–311) DNA controls metabolism by directing cells to make specific enzymes and other proteins. Beadle and Tatum's experiments with mutant strains of *Neurospora* supported the one gene—one enzyme hypothesis. Genes code for polypeptide chains or for RNA molecules.

Investigation How Is a Metabolic Pathway Analyzed?

- **Basic Principles of Transcription and Translation**

(pp. 311–312) Transcription is the nucleotide-to-nucleotide transfer of information from DNA to RNA, while translation is the informational transfer from nucleotide sequence in RNA to amino acid sequence in a polypeptide.

Activity Overview of Protein Synthesis

- **The Genetic Code** (pp. 312–314) Genetic information is encoded as a sequence of nonoverlapping base triplets, or codons. A codon in messenger RNA (mRNA) either is translated into an amino acid (61 codons) or serves as a translational stop signal (3 codons). Codons must be read in the correct reading frame for the specified polypeptide to be produced.

Concept 17.2

Transcription is the DNA-directed synthesis of RNA: *a closer look*

- **Molecular Components of Transcription** (pp. 315–316)

RNA synthesis is catalyzed by RNA polymerase. It follows the same base-pairing rules as DNA replication, except that in RNA, uracil substitutes for thymine.

Activity Transcription

- **Synthesis of an RNA Transcript** (pp. 316–317) The three stages of transcription are initiation, elongation, and termination.

Promoters signal the initiation of RNA synthesis. Transcription factors help eukaryotic RNA polymerase recognize promoter sequences. The mechanisms of termination are different in prokaryotes and eukaryotes.

Concept 17.3

Eukaryotic cells modify RNA after transcription

- **Alteration of mRNA Ends** (p. 317) Eukaryotic mRNA molecules are processed before leaving the nucleus by modification of their ends and by RNA splicing. The 5' end receives a modified nucleotide cap, and the 3' end a poly-A tail.

Activity RNA Processing

- **Split Genes and RNA Splicing** (pp. 318–319) Most eukaryotic genes have introns interspersed among the coding regions, the exons. In RNA splicing, introns are removed and exons joined. RNA splicing is carried out by spliceosomes, but

in some cases, RNA alone catalyzes splicing. Catalytic RNA molecules are called ribozymes. The presence of introns allows for alternative RNA splicing.

Concept 17.4

Translation is the RNA-directed synthesis of a polypeptide: *a closer look*

- **Molecular Components of Translation** (pp. 320–323) A cell translates an mRNA message into protein with the help of transfer RNA (tRNA). After binding specific amino acids, tRNAsⁱ molecules line up by means of their anticodons at complementary codons on mRNA. Ribosomes help facilitate this coupling with binding sites for mRNA and tRNA.

- **Building a Polypeptide** (pp. 323–325) Ribosomes coordinate the three stages of translation: initiation, elongation, and termination. The formation of peptide bonds between amino acids is catalyzed by rRNA. A number of ribosomes can translate a single mRNA molecule simultaneously, forming a polyribosome.

Activity Translation

Biology tabs On-line *TranslationLab*

- **Completing and Targeting the Functional Protein**

(pp. 324–326) After translation, proteins may be modified in ways that affect their three-dimensional shape. Free ribosomes in the cytosol initiate the synthesis of all proteins, but proteins destined for the endomembrane system or for secretion must be transported into the ER. Such proteins have signal peptides to which a signal-recognition particle (SRP) binds, enabling the translating ribosome to bind to the ER.

Concept 17.5

RNA plays multiple roles in the cell; *a review*

- RNA can hydrogen-bond to other nucleic acid molecules (DNA or RNA). It can assume a specific three-dimensional shape. And it has functional groups that allow it to act as a catalyst, a ribozyme (p. 327).

Concept 17.6

Comparing gene expression in prokaryotes and eukaryotes reveals key differences

- Because prokaryotic cells lack a nuclear envelope, translation can begin while transcription is still in progress. In a eukaryotic cell, the nuclear envelope separates transcription from translation, and extensive RNA processing occurs in the nucleus (pp. 327–328).

Concept 17.7

Point mutations can affect protein structure and function

- **Types of Point Mutations** (pp. 328–330) A point mutation is a change in one DNA base pair, which may lead to production of a nonfunctional protein or no protein at all. Base-pair substitutions can cause missense or nonsense mutations. Base-pair insertions or deletions may produce frameshift mutations.

- **Mutagens** (pp. 329–330) Spontaneous mutations can occur during DNA replication, recombination, or repair. Chemical and physical mutagens can also alter genes.

TESTING YOUR KNOWLEDGE

Evolution Connection

The genetic code (see Figure 17.5) is rich with evolutionary implications. For instance, notice that the 20 amino acids are not randomly scattered; most amino acids are coded for by a similar set of codons. What evolutionary explanations can be given for this pattern? (Hint: There is one explanation relating to historical ancestry and some less obvious ones of a "form-fits-function" type.)

Scientific Inquiry

A biologist inserts a gene from a human liver cell into the chromosome of a bacterium. The bacterium then transcribes and translates this gene. The protein produced is useless and is found to contain many more amino acids than does the protein made by the eukaryotic cell. Explain why.

Investigation How Is a Metabolic Pathway Analyzed?

The Genetics of Viruses and Bacteria

A Figure 18.1 T4 bacteriophage infecting an *E. coli* cell.

Key Concepts

- 18.1 A virus has a genome but can reproduce only within a host cell
- 18.2 Viruses, viroids, and prions are formidable pathogens in animals and plants
- 18.3 Rapid reproduction, mutation, and genetic recombination contribute to the genetic diversity of bacteria
- 18.4 Individual bacteria respond to environmental change by regulating their gene expression

Overview

Microbial Model Systems

The photo in **Figure 18.1** shows a remarkable event: the attack of a bacterial cell by numerous structures that resemble miniature lollipops. These structures, a type of virus called T4 bacteriophage, are seen infecting the bacterium *Escherichia coli* in this colorized SEM. By injecting its DNA into the cell, the virus sets in motion a genetic takeover of the bacterium. Molecular biology was born in the laboratories of microbiologists studying viruses and bacteria. Microbes such as *E. coli* and its viruses are called *model systems* because of their frequent use by researchers in studies that reveal broad biological principles. Experiments with viruses and bacteria provided most of the evidence that genes are made of DNA, and they were critical in working out the molecular mechanisms of the fundamental processes of DNA replication, transcription, and translation.

Beyond their value as model systems, viruses and bacteria have unique genetic mechanisms that are interesting in their own right. These specialized mechanisms have important applications for understanding how viruses and bacteria cause

disease. In addition, techniques enabling scientists to manipulate genes and transfer them from one organism to another have emerged from the study of microbes. These techniques are having an important impact on both basic research and biotechnology (see Chapter 20).

In this chapter, we explore the genetics of viruses and bacteria. Recall that bacteria are prokaryotes, with cells much smaller and more simply organized than those of eukaryotes, such as plants and animals. Viruses are smaller and simpler still (**Figure 18.2**). Lacking the structures and metabolic machinery found in cells, most viruses are little more than genes packaged in protein coats. We will begin with the structure of these simplest of all genetic systems and their role as disease-causing agents, or pathogens. Then we will discuss the genetics of bacteria and regulation of their gene expression.

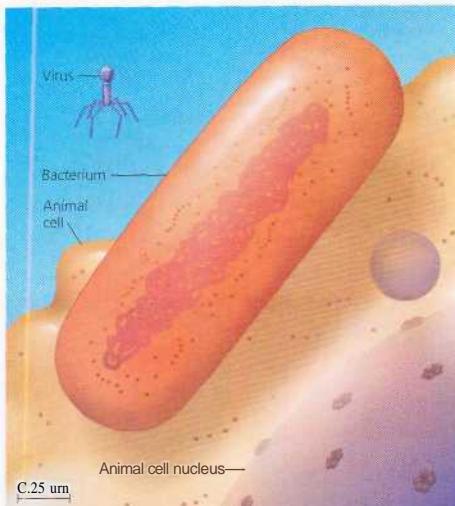

Concept 18.1

A virus has a genome but can reproduce only within a host cell

Scientists were able to detect viruses indirectly long before they were actually able to see them. The story of how viruses were discovered begins near the end of the 19th century.

The Discovery of Viruses: Scientific Inquiry

Tobacco mosaic disease stunts the growth of tobacco plants and gives their leaves a mottled, or mosaic, coloration (**Figure 18.3**). In 1883, Adolf Mayer, a German scientist, discovered that he could transmit the disease from plant to plant by rubbing sap extracted from diseased leaves onto healthy plants. After

A Figure 18.2 Comparing the size of a virus, a bacterium, and an animal cell. Only a portion of a typical animal cell is shown. Its diameter is about ten times greater than the length of *B. coli*.

an unsuccessful search for an infectious microbe in the sap, Mayer concluded that the disease was caused by unusually small bacteria that could not be seen with the microscope. This hypothesis was tested a decade later by Dimitri Ivanovsky, a Russian who passed sap from infected tobacco leaves through a filter designed to remove bacteria. After filtering, the sap still produced mosaic disease.

Ivanovsky clung to the hypothesis that bacteria caused tobacco mosaic disease. Perhaps, he reasoned, the bacteria were so small that they passed through the filter or made a filterable toxin that caused the disease. This latter possibility was ruled out when the Dutch botanist Martinus Beijerinck discovered that the infectious agent in the filtered sap could reproduce, tie rubbed plants with filtered sap, and after these plants developed mosaic disease, he used *their* sap to infect more plants, continuing this process through a series of infections. The pathogen must have been reproducing, for its ability to cause disease was undiluted after several transfers from plant to plant.

In fact, the pathogen reproduced only within the host it infected. Unlike bacteria, the mysterious agent of mosaic disease could not be cultivated on nutrient media in test tubes or petri dishes. Beijerinck imagined a reproducing particle much smaller and simpler than bacteria. His suspicions were confirmed in 1935 when the American scientist Wendell Stanley crystallized the infectious particle, now known as

• Figure 18.3 Infection by tobacco mosaic virus (TMV). A healthy, uninjected tobacco leaf (left) compared with a leaf experimentally infected with TMV (right).

tobacco mosaic virus (TMV). Subsequently TMV and many other viruses were actually seen with the help of the electron microscope.

Structure of Viruses

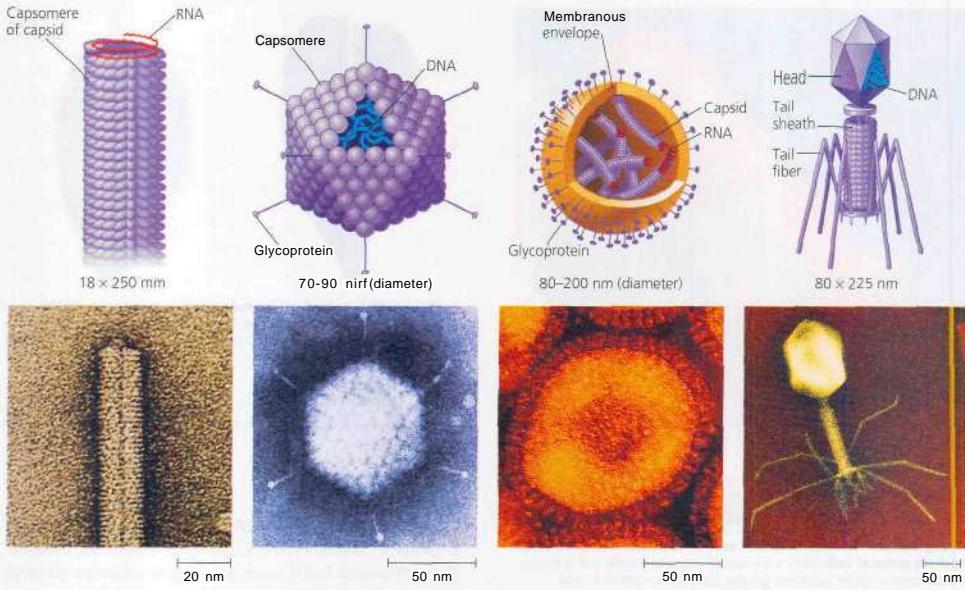

The tiniest viruses are only 20 nm in diameter—smaller than a ribosome. Millions could easily fit on a pinhead. Even the largest viruses are barely visible in the light microscope. Stanley's discovery that some viruses could be crystallized was exciting and puzzling news. Not even the simplest of cells can aggregate into regular crystals. But if viruses are not cells, then what are they? They are infectious particles consisting of nucleic acid enclosed in a protein coat and, in some cases, a membranous envelope. Let's examine the structure of viruses more closely and then how they reproduce.

Viral Genomes

We usually think of genes as being made of double-stranded DNA—the conventional double helix—but many viruses defy this convention. Their genomes may consist of double-stranded DNA, single-stranded DNA, double-stranded RNA, or single-stranded RNA, depending on the kind of virus. A virus is called a DNA virus or an RNA virus, according to the kind of nucleic acid that makes up its genome, in either case, the genome is usually organized as a single linear or circular molecule of nucleic acid. The smallest viruses have only four genes, while the largest have several hundred.

Capsids and Envelopes

The protein shell enclosing the viral genome is called a **capsid**. Depending on the type of virus, the capsid maybe rod-shaped, polyhedral, or more complex in shape (like T4). Capsids are built from a large number of protein subunits called **capsomeres**, but the number of different kinds of proteins is usually small. Tobacco mosaic virus has a rigid, rod-shaped capsid

(a) Tobacco mosaic virus has a helical capsid with the overall shape of a rigid rod.

(b) Adenoviruses have a polyhedral capsid with a glycoprotein spike at each vertex.

(c) Influenza viruses have an outer envelope studded with glycoprotein spikes. The genome consists of eight different RNA molecules, each wrapped in a helical capsid.

(d) Bacteriophage T4, like other "T-even" phages, has a complex capsid consisting of a polyhedral head and a tail apparatus.

A Figure 18.4 Viral structure. Viruses are made up of nucleic acid (DNA or RNA) enclosed in a protein coat (the capsid) and sometimes further wrapped in a membranous envelope. The individual protein subunits making up the capsid are called capsomeres. Although diverse in size and shape, viruses have common structural features, most of which appear in the four examples shown here. (All the micrographs are colorized TEMs.)

made from over a thousand molecules of a single type of protein arranged in a helix (**Figure 18.4a**). Adenoviruses, which infect the respiratory tracts of animals, have 252 identical protein molecules arranged in a polyhedral capsid with 20 triangular facets—an icosahedron (**Figure 18.4b**).

Some viruses have accessory structures that help them infect their hosts. For instance, a membranous envelope surrounds the capsids of influenza viruses and many other viruses found in animals (**Figure 18.4c**). These viral envelopes, which are derived from the membrane of the host cell, contain host cell phospholipids and membrane proteins. They also contain proteins and glycoproteins of viral origin (glycoproteins are proteins with carbohydrate covalently attached). Some viruses carry a few viral enzyme molecules within their capsids.

The most complex capsids are found among viruses that infect bacteria, called bacteriophages, or simply phages. The first phages studied included seven that infect *E. coli*. These

seven phages were named type 1 (T1), type 2 (T2), and so forth, in the order of their discovery. The three T-even phages (T2, T4, and T6) turned out to be very similar in structure. Their capsids have elongated icosahedral heads enclosing their DNA. Attached to the head is a protein tail piece with fibers that the phages use to attach to a bacterium (**Figure 18.4d**).

General Features of Viral Reproductive Cycles

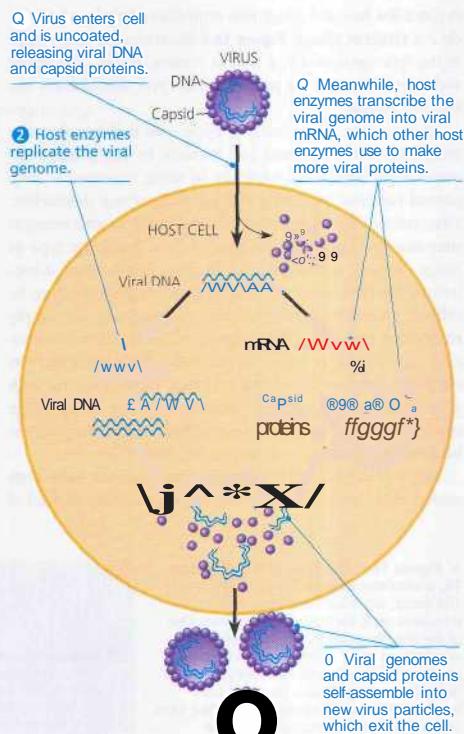

Viruses are obligate intracellular parasites; they can reproduce only within a host cell. An isolated virus is unable to reproduce or do anything else except infect an appropriate host cell. Viruses lack metabolic enzymes, ribosomes, and other equipment for making proteins. Thus, isolated viruses are merely packaged sets of genes in transit from one host cell to another.

Each type of virus can infect only a limited range of host cells, called its host range. This host specificity results from the evolution of recognition systems by the virus. Viruses identify their host cells by a "lock-and-key" fit between protein 5 on the outside of the virus and specific receptor molecules on the surface of cells. (Presumably, the receptors first evolved because they carried out functions of benefit to the organism.) Some viruses have broad host ranges. West Nile virus, for example, can infect mosquitoes, birds, and humans, and equine encephalitis virus can infect mosquitoes, birds, horses, and humans. Other viruses have host ranges so narrow that they infect only a single species. Measles virus and poliovirus, for example, can infect only humans. Furthermore, infection by viruses of multicellular eukaryotes is usually limited to particular tissues. Human cold viruses infect only the cells lining the upper respiratory tract, and the AIDS virus binds to specific receptors on certain types of white blood cells.

A viral infection begins when the genome of a virus makes its way into a host cell (**Figure 18.5**). The mechanism by which this nucleic acid enters the cell varies, depending on the type of virus and the type of host cell. For example, the T-even phages use their elaborate tail apparatus to inject DNA into a bacterium (see Figure 18.4d). Once inside, the viral genome can commandeer its host, reprogramming the cell to copy the viral nucleic acid and manufacture viral proteins. The host provides the nucleotides for making viral nucleic acids, as well as enzymes, ribosomes, tRNAs, amino acids, ATP, and other components needed for making the viral proteins dictated by viral genes. Most DNA viruses use the DNA polymerases of the host cell to synthesize new genomes along the templates provided by the viral DNA. In contrast, to replicate their genomes, RNA viruses use special virus-encoded polymerases that can use RNA as a template. (Uninfected cells generally make no enzymes for carrying out this latter process.)

After the viral nucleic acid molecules and capsomeres are produced, their assembly into new viruses is often a spontaneous process of self-assembly; in fact, the RNA and capsomeres of TMV can be separated in the laboratory and then reassembled to form complete viruses simply by mixing the components together under the right conditions. The simplest type of viral reproductive cycle ends with the exit of hundreds or thousands of viruses from the infected host cell, a process that often damages or destroys the cell. Such cellular damage and death, as well as the body's responses to this destruction, cause some of the symptoms associated with viral infections. The viral progeny that exit a cell have the potential to infect additional cells, spreading the viral infection.

There are many variations on the simplified viral reproductive cycle we have traced in this overview. We will now take a closer look at some of these variations in bacterial viruses (phages) and animal viruses; later in the chapter, we will consider plant viruses.

A Figure 18.5 A simplified viral reproductive cycle. A virus is an obligate intracellular parasite that uses the equipment and small precursors of its host cell to reproduce. In this simplest of viral cycles, the parasite is a DNA virus with a capsid consisting of a single type of protein.

Reproductive Cycles of Phages

Phages are the best understood of all viruses, although some of them are also among the most complex. Research on phages led to the discovery that some double-stranded DNA viruses can reproduce by two alternative mechanisms; the lytic cycle and the lysogenic cycle.

The Lytic Cycle

A phage reproductive cycle that culminates in death of the host cell is known as a **lytic cycle**. The term refers to the last stage of infection, during which the bacterium lyses (breaks open) and releases the phages that were produced within the cell. Each of these phages can then infect a healthy cell, and a few successive lytic cycles can destroy an entire bacterial population.

in just a few hours. A phage that reproduces only by a lytic cycle is a virulent phage. **Figure 18.6** illustrates the major steps in the lytic cycle of T4, a typical virulent phage. The figure and legend describe the process, which you should study before proceeding.

After reading about the lytic cycle, you may wonder why phages haven't exterminated all bacteria. In fact, phage treatments have been used medically in some countries to help control bacterial infections. But bacteria are not defenseless. First, natural selection favors bacterial mutants with receptor sites that are no longer recognized by a particular type of phage. Second, when phage DNA successfully enters a bacterium, the DNA often is recognized as foreign and cut up by cellular enzymes called *restriction endonucleases*, or simply restriction enzymes. The bacterial cell's own DNA is chemically modified in a way that prevents attack by restriction enzymes. But just as natural selection favors bacteria with effective restriction enzymes, natural selection favors phage mutants that are resistant to these enzymes. Thus, the parasite-host relationship is in constant evolutionary flux.

There is yet a third important reason bacteria have been spared from extinction as a result of phage activity. Instead of

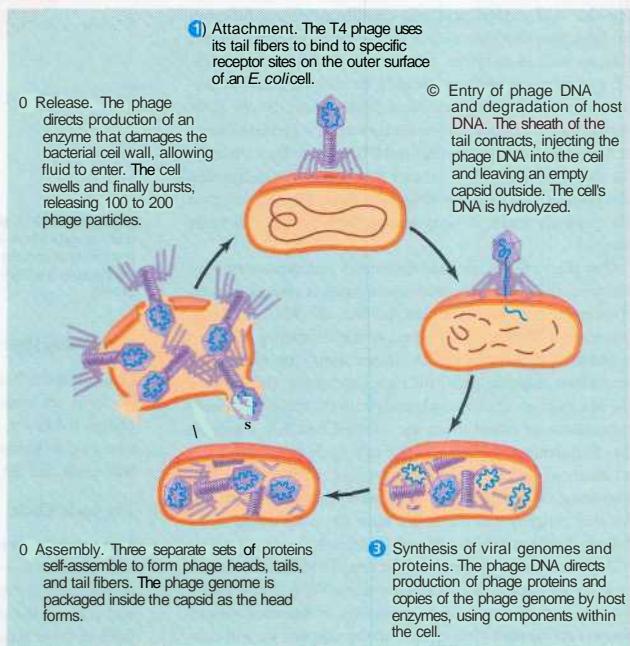

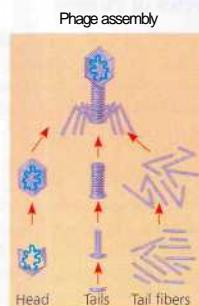

lysing their host cells, many phages coexist with them in what is called the lysogenic cycle.

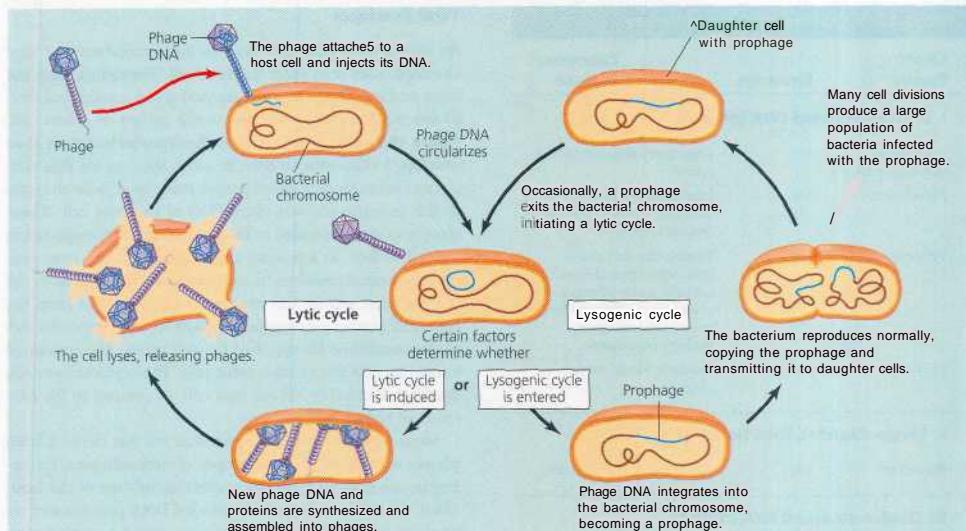

The Lysogenic Cycle

In contrast to the lytic cycle, which kills the host cell, the lysogenic cycle replicates the phage genome without destroying the host. Phages capable of using both modes of reproducing within a bacterium are called temperate phages. A temperate phage called lambda, written with the Greek letter *λ*, is widely used in biological research. Phage *λ* resembles T4, but its tail has only one short tail fiber.

Infection of an *E. coli* cell by phage X begins when the phage binds to the surface of the cell and injects its DNA (Figure 18.7). Within the host, the *λ* DNA molecule form; a circle. What happens next depends on the reproductive mode: lytic cycle or lysogenic cycle. During a lytic cycle, the viral genes immediately turn the host cell into a X-producing factory, and the cell soon lyses and releases its viral products. During a lysogenic cycle, however, the X DNA molecule is incorporated by genetic recombination (crossing over) into a specific site on the host cell's chromosome. When integrated into the bacterial chromosome in this way, the viral DNA is

- **Figure 18.6 The lytic cycle of phage T4, a virulent phage.** Phage T4 has about 100 genes, which are transcribed and translated using the host cell's machinery. One of the first phage genes translated after the viral DNA enters the host cell codes for an enzyme that degrades the host cell's DNA (step 2); the phage DNA is protected from breakdown because it contains a modified form of cytosine that is not recognized by the enzyme. The entire lytic cycle, from the phage's first contact with the cell surface to cell lysis, takes only 20–30 minutes at 37°C.

A Figure 18.7 The lytic and lysogenic cycles of phage λ, a temperate phage.
After entering the bacterial cell and circularizing, the X-DNA can immediately initiate the production of a large number of

progeny phages (lytic cycle) or integrate into the bacterial chromosome (lysogenic cycle). In most cases, phage X follows the lytic pathway, which is similar to that detailed in Figure 18.6. However, once a lysogenic cycle begins, the

prophage may be carried in the host cell's chromosome for many generations. Phage λ has one main tail fiber, which is short.

known as a **prophage**. One prophage gene codes for a protein that prevents transcription of most of the other prophage genes. Thus, the phage genome is mostly silent within the bacterium. Every time the *E. coli* cell prepares to divide, it replicates the phage DNA along with its own and passes the copies on to daughter cells. A single infected cell can quickly give rise to a large population of bacteria carrying the virus in prophage form. This mechanism enables viruses to propagate without killing the host cells on which they depend.

The term *lysogenic* implies that prophages are capable of giving rise to active phages that lyse their host cells. This occurs when the λ genome exits the bacterial chromosome and initiates a lytic cycle. What triggers the switch from the lysogenic to the lytic mode is usually an environmental signal, such as radiation or the presence of certain chemicals.

In addition to the gene for the transcription-preventing protein, a few other prophage genes may also be expressed during lysogenic cycles. Expression of these genes may alter the host's phenotype, a phenomenon that can have important medical significance. For example, the bacteria that cause the human diseases diphtheria, botulism, and scarlet fever would be harmless to humans if it were not for certain prophage genes that cause the host bacteria to make toxins.

Reproductive Cycles of Animal Viruses

Everyone has suffered from viral infections, whether cold sores, influenza, or the common cold. Like all viruses, those that cause illness in humans and other animals can reproduce only inside host cells. Many variations on the basic scheme of viral infection and reproduction are represented among the animal viruses. One key variable is the nature of the viral genome: Is it composed of DNA or RNA? Is it double-stranded or single-stranded? The nature of the genome is the basis for the common classification of viruses shown in Table 18.1 on the next page. Single-stranded RNA viruses are further classified into three classes (IV-VI) according to how the RNA genome functions in a host cell.

Another important characteristic of a virus is the presence or absence of a membranous envelope derived from host cell membrane. Rather than consider all the mechanisms of viral infection and reproduction, we will focus on the roles of viral envelopes and on the functioning of RNA as the genetic material of many animal viruses. Whereas few bacteriophages have an envelope or RNA genome, nearly all the animal viruses with RNA genomes have an envelope, as do some with DNA genomes (see Table 18.1).

Table 18.1 Classes of Animal Viruses

| Class/ Family | Envelope | Examples/ Disease |
|--|----------|---|
| I. Double-stranded DNA (dsDNA) | | |
| Adeno virus (see Figure 18.4b) | No | Respiratory diseases; animal tumors |
| Papovavirus | No | Papillomavirus (warts, cervical cancer); polyomavirus (animal tumors) |
| Herpesvirus | Yes | Herpes simplex I and II (cold sores, genital sores); varicella zoster (shingles, chicken pox); Epstein-Barr virus (mononucleosis, Burkitt's lymphoma) |
| Poxvirus | Yes | Smallpox virus; cowpox virus |
| II. Single-stranded DNA (ssDNA) | | |
| Parvovirus | No | B19 parvovirus (mild rash) |
| III. Double-stranded RNA (dsRNA) | | |
| Reovirus | No | Rotavirus (diarrhea); Colorado tick fever virus |
| IV. Single-stranded RNA (ssRNA); serves as mRNA | | |
| Picornavirus | No | Rhino virus (common cold); poliovirus; hepatitis A virus, and other enteric (intestinal) viruses |
| Coronavirus (see Figure 18.11b) | Yes | Severe acute respiratory syndrome (SARS) |
| Flavivirus | Yes | Yellow fever virus; West Nile virus; hepatitis C virus |
| Togavirus | Yes | Rubella virus; equine encephalitis viruses |
| V. ssRNA; template for mRNA synthesis | | |
| Filovirus | Yes | Ebola virus (hemorrhagic fever) |
| Orthomyxovirus (see Figure 18.4c) | Yes | Influenza virus |
| Paramyxovirus | Yes | Measles virus; mumps virus |
| Rhabdovirus | Yes | Rabies virus |
| VI. ssRNA; template for DNA synthesis | | |
| Retrovirus (see Figure 18.9) | Yes | HIV human immunodeficiency virus (AIDS); RNA tumor viruses (leukemia) |

Viral Envelopes

An animal "virus equipped with an outer membrane, or viral envelope, uses it to enter the host cell. Protruding from the outer surface of this envelope are viral glycoproteins that bind to specific receptor molecules on the surface of a host cell.

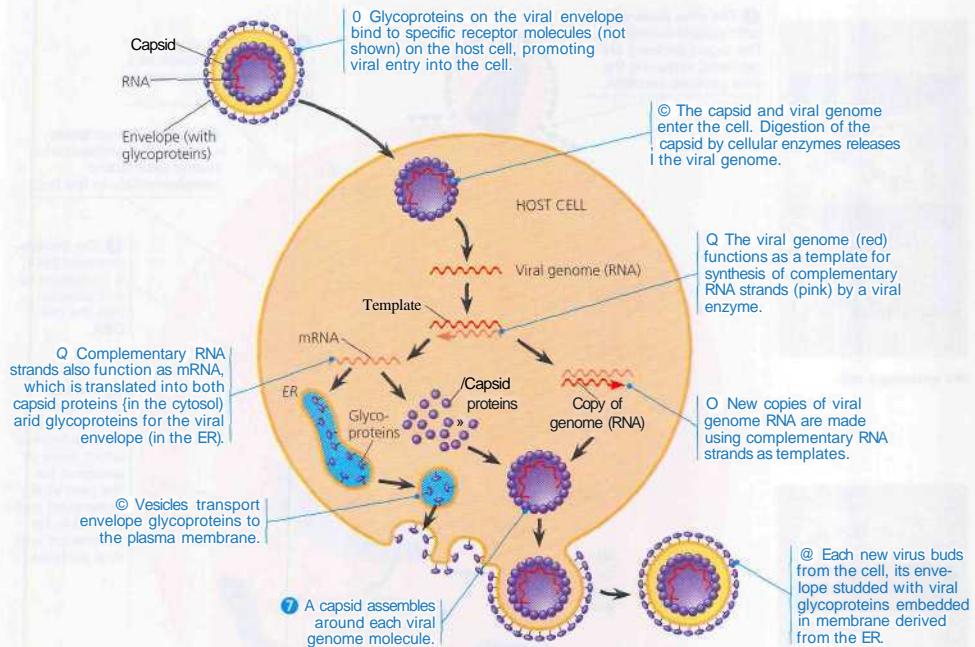

Figure 18.8 outlines the events in the reproductive cycle of an enveloped virus with an RNA genome. You can see that viral glycoproteins for new envelopes are made by cellular enzymes in the endoplasmic reticulum (ER) of the host cell. These glycoproteins, embedded in ER membrane, are transported to the cell surface. In a process much like exocytosis, new virus capsids wrap themselves in membrane as they bud from the cell. In other words, the viral envelope is derived from the host cell's plasma membrane, although some of the molecules of this membrane are specified by **viral genes**. The enveloped viruses are now free to infect other cells. This reproductive cycle does not necessarily kill the host cell, in contrast to the 100 cycles of phages.

Some viruses have envelopes that are not derived from plasma membrane. The envelopes of herpesviruses, for example, are derived from the nuclear membrane of the host. These viruses have a double-stranded DNA genome and reproduce within the host cell nucleus, using a combination of viral and cellular enzymes to replicate and transcribe their DNA. In some cases, copies of the herpesvirus DNA remain behind as minichromosomes in the nuclei of certain nerve cells. There they remain latent until some sort of physical or emotional stress triggers a new round of active virus production. The infection of other cells by these new viruses causes the blisters characteristic of herpes, such as cold sores or genital sores. Once someone acquires a herpesvirus infection, flare-ups may recur throughout the person's life.

RNA as Viral Genetic Material

Although some phages and most plant viruses are RNA viruses, the broadest variety of RNA genomes is found among the viruses that infect animals. Among the three types of single-stranded RNA genomes found in animal viruses, the genome of class IV viruses can directly serve as mRNA and thus can be translated into viral protein immediately after infection. Figure 18.8 shows a virus of class V, in which the RNA genome serves as a *template* for mRNA synthesis. The RNA genome is transcribed into complementary RNA strands, which function both as mRNA and as templates for the synthesis of additional copies of genome RNA. Like all viruses that require RNA → RNA synthesis to make mRNA, this one uses a viral enzyme that is packaged with the genome inside the capsid.

The RNA animal viruses with the most complicated reproductive cycles are the retroviruses (class VI). These viruses are

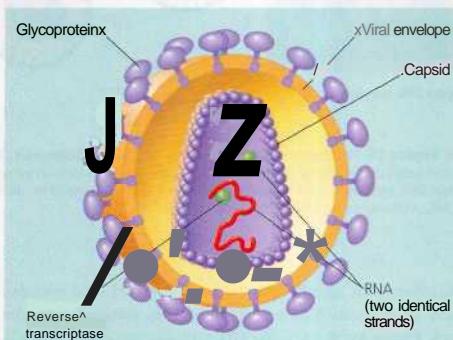

A **Figure 18.8** The reproductive cycle of an enveloped RNA virus. Shown here is a virus with a single-stranded RNA genome that also functions as a template for synthesis of mRNA.

Some enveloped viruses enter the host cell by fusion of the envelope with the cell's plasma membrane; others enter by endocytosis. For all enveloped RNA viruses, the formation of new

envelopes for progeny viruses occurs by the mechanism depicted in this figure.

equipped with an enzyme called **reverse transcriptase**, which transcribes an RNA template into DNA, providing an RNA → DNA information flow, the opposite of the usual direction. This unusual phenomenon gave rise to the name retroviruses (*reiro* means "backward"). Of particular medical importance is **HIV** (human immunodeficiency virus), the retrovirus that causes **AIDS** (acquired immunodeficiency syndrome). HIV and other retroviruses are enveloped viruses that contain two identical molecules of single-stranded RNA and two molecules of reverse transcriptase (Figure 18.9).

After HIV enters a host cell, its reverse transcriptase **molecules** are released into the cytoplasm and catalyze synthesis of viral DNA. The newly made viral DNA then enters the cell's nucleus and integrates into the DNA of a chromosome. The integrated viral DNA, called a **provirus**, never leaves the host's genome, remaining a permanent resident of the cell. (Unlike a prophage, a provirus never leaves.) The host's RNA polymerase transcribes the proviral DNA into RNA molecules, which can

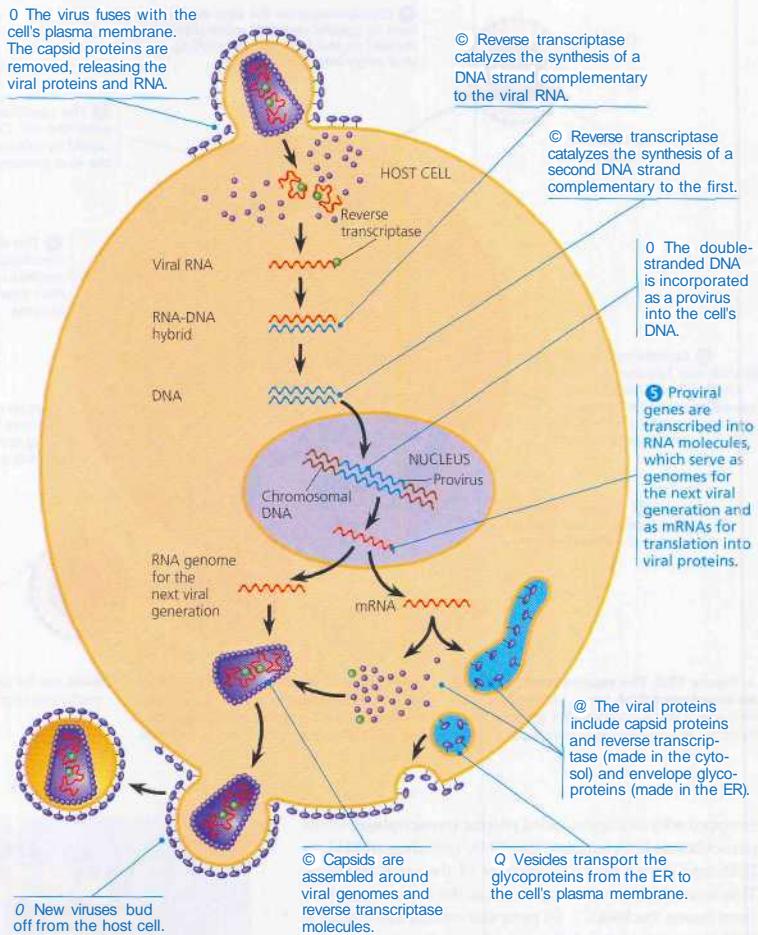

A **Figure 18.9** The structure of HIV, the retrovirus that causes AIDS. The envelope glycoproteins enable the virus to bind to specific receptors on certain white blood cells.

HIV entering a cell

New HIV leaving a cell

A Figure 18.10 The reproductive cycle of HIV, a retrovirus. The photos on the left (artificially colored TEMs) reveal HIV entering and leaving a human white blood cell. Note in step 4 that DNA synthesized from the viral RNA genome is integrated into the host cell chromosomal DNA, a characteristic unique to retroviruses.

function both as mRNA for the synthesis of viral proteins and as genomes for new virus particles released from the cell. **Figure 18.10** traces the HIV reproductive cycle, which is typical of a retrovirus. In Chapter 43, we will describe how HIV causes the deterioration of the immune system that occurs in AIDS.

Evolution of Viruses

Viruses do not really fit our definition of living organisms. An isolated virus is biologically inert, unable to replicate its genes or regenerate its own supply of ATE. Yet it has a genetic program written in the universal language of life. Do we think of viruses as nature's most complex molecules or as the simplest forms of life? Either way, we must bend our usual definitions. Although

viruses are obligate intracellular parasites that cannot reproduce independently, their use of the genetic code makes it hard to deny their evolutionary connection to the living world.

How did viruses originate? Because they depend on cells for their own propagation, viruses most likely are not the descendants of precellular forms of life, but evolved *after* the first cells appeared, possibly multiple times. Most molecular biologists favor the hypothesis that viruses originated from fragments of cellular nucleic acids that could move *from* one cell to another. Consistent with this idea is the observation that a viral genome usually has more in common with the genome of its host than with the genomes of viruses infecting other hosts. Indeed, some viral genes are essentially identical to genes of the host. On the other hand, recent sequencing of many viral genomes has found that the genetic sequences of some viruses are quite similar to those of seemingly distantly related viruses (such as an animal virus and a plant virus that share similar sequences). This genetic similarity may reflect the persistence of groups of viral genes that were evolutionarily successful during the early evolution of viruses and the eukaryotic cells serving as their hosts. The origin of viruses is still a topic of much debate.

Perhaps the earliest viruses were naked bits of nucleic acid that made it from one cell to another via injured cell surfaces. The evolution of genes coding for capsid proteins may have facilitated the infection of undamaged cells. Candidates for the original sources of viral genomes include plasmids and transposons, genetic elements that we will discuss in more detail later in the chapter. Plasmids are small, circular DNA molecules, found in bacteria and also in yeasts, which are unicellular eukaryotes. Plasmids exist apart from the cell's genome, can replicate independently of the genome, and are occasionally transferred between cells. Transposons are DNA segments that can move from one location to another within a cell's genome. Thus, plasmids, transposons, and viruses all share an important feature: They are mobile genetic elements.

The ongoing evolutionary relationship between viruses and the genomes of their host cells is an association that makes viruses very useful model systems in molecular biology. Knowledge about viruses also has many practical applications, since viruses have a tremendous impact on all living organisms through their ability to cause disease.

Concept Check 18.1

1. Compare the effect on the host cell of a lytic (virulent) phage and a lysogenic (temperate) phage.
2. How do some viruses reproduce without possessing or ever synthesizing DNA?
3. Why is HIV called a retrovirus?

For suggested answers, see Appendix A.

Concept 18.2

Viruses, viroids, and prions are formidable pathogens in animals and plants

Diseases caused by viral infections afflict humans, agricultural crops, and livestock worldwide. Other smaller, less complex entities known as viroids and prions also cause disease in plants and animals.

Viral Diseases in Animals

The link between a viral infection and the symptoms it produces is often obscure. Viruses may damage or kill cells by causing the release of hydrolytic enzymes from lysosomes. Some viruses cause infected cells to produce toxins that lead to disease symptoms, and some have molecular components that are toxic, such as envelope proteins. How much damage a virus causes depends partly on the ability of the infected tissue to regenerate by cell division. People usually recover completely from colds because the epithelium of the respiratory tract, which the viruses infect, can efficiently repair itself. In contrast, damage inflicted by poliovirus to mature nerve cells is permanent, because these cells do not divide and usually cannot be replaced. Many of the temporary symptoms associated with viral infections, such as fever and aches, actually result from the body's own efforts at defending itself against infection.

The immune system is a complex and critical part of the body's natural defenses (see Chapter 43). The immune system is also the basis for the major medical tool for preventing viral infections—vaccines. Vaccines are harmless variants or derivatives of pathogenic microbes that stimulate the immune system to mount defenses against the actual pathogen. Vaccination has eradicated smallpox, at one time a devastating scourge in many parts of the world. The viruses that cause smallpox, polio, and measles infect only humans. This very narrow host range was critical to the successful effort of the World Health Organization to eradicate smallpox; similar worldwide vaccination campaigns currently are under way to eradicate the other two viruses as well. Effective vaccines are also available against rubella, mumps, hepatitis B, and a number of other viral diseases.

Although vaccines can prevent certain viral illnesses, medical technology can do little, at present, to cure most viral infections once they occur. The antibiotics that help us recover from bacterial infections are powerless against viruses. Antibiotics kill bacteria by inhibiting enzyme-catalyzed processes specific to the pathogens, but viruses have few or no enzymes of their own. However, a few drugs effectively combat certain viruses. Most antiviral drugs resemble nucleosides and as a result interfere with viral nucleic acid synthesis. One such drug is acy-

clovir, which impedes herpesvirus reproduction by inhibiting the viral polymerase that synthesizes viral DNA. Similarly, azidothymidine (AZT) curbs HIV reproduction by interfering with the synthesis of DNA by reverse transcriptase. In the past ten years, much effort has gone into developing drugs against HIV. Currently, multidrug treatments, sometimes called "cocktails," have been found to be most effective. Such a regimen commonly includes a combination of two nucleoside mimics and a protease inhibitor, which interferes with an enzyme required for assembly of virus particles.

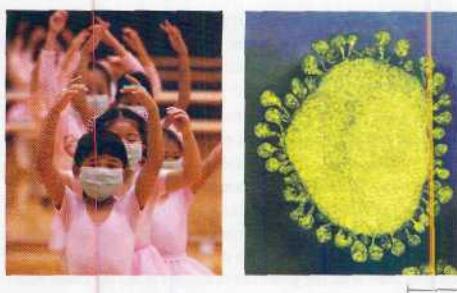

Emerging Viruses

Viruses that appear suddenly or that suddenly come to the attention of medical scientists are often referred to as *emerging viruses*. HIV the AIDS virus, is a classic example: This virus appeared in San Francisco in the early 1980s, seemingly out of nowhere. The deadly Ebola virus, recognized initially in 1976 in central Africa, is one of several emerging viruses that cause *hemorrhagic fever*, an often fatal syndrome characterized by fever, vomiting, massive bleeding, and circulatory system collapse. A number of other dangerous new viruses cause encephalitis, inflammation of the brain. One example is the West Nile virus, which appeared for the first time in North America in 1999 and has spread to all 48 contiguous states in the U.S.

An even more recent viral disease to emerge is *severe acute respiratory syndrome (SARS)*, which first appeared in southern China in November 2002 (Figure 18.11a). During a global outbreak from November 2002 to July 2003, about 8,000 people were known to be infected, of whom more than 700 subsequently died. Researchers quickly identified the agent causing SARS as a *coronavirus*, a virus with a single-stranded RNA genome (class IV) that was not previously known to cause disease in humans (Figure 18.11b).

From where and how do such viruses burst on the human scene, giving rise to previously rare or unknown diseases? Three processes contribute to the emergence of viral diseases. First, the mutation of existing viruses is a major source of these new diseases. RNA viruses tend to have an unusually high rate of mutation because errors in replicating their RNA genomes are not corrected by proofreading. Some mutations enable existing viruses to evolve into new genetic varieties (strains) that can cause disease in individuals who had developed immunity to the ancestral virus. Flu epidemics, for instance, are caused by new strains of influenza virus genetically different enough from earlier strains that people have little immunity to them.

An other source of new viral diseases is the spread of existing viruses from one host species to another. Scientists estimate that about three-quarters of new human diseases originate in other animals. For example, hantavirus is common in rodents, especially deer mice. The population of deer mice in the south-

A Figure 18.11 SARS (severe acute respiratory syndrome), a recently emerging viral disease.

western United States exploded in 1993 after unusually wet weather increased the rodents' food supply. Many people who inhaled dust containing traces of urine and feces from infected mice became infected with hantavirus, and dozens died. The source of the SARS-causing virus was still undetermined as of spring 2004, although candidates include the exotic animals found in food markets in China. And early 2004 brought reports of the first cases of people in southeast Asia infected with a flu virus previously seen only in birds. If this virus evolves so that it can spread easily from person to person, the potential for a major human outbreak is significant. Indeed, evidence is strong that the flu pandemic of 1918–1919, which killed about 40 million people, originated in birds.

Finally, the dissemination of a viral disease from a small, isolated population can lead to widespread epidemics. For instance, AIDS went unnamed and virtually unnoticed for decades before it began to spread around the world. In this case, technological and social factors, including affordable international travel, blood transfusions, sexual promiscuity; and the abuse of intravenous drugs, allowed a previously rare human disease to become a global scourge.

Thus, emerging viruses are generally not new; rather, they are existing viruses that mutate, spread to new host species, or disseminate more widely in the current host species. Changes in host behavior or environmental changes can increase the viral traffic responsible for emerging diseases. For example, new roads through remote areas can allow viruses to spread between previously isolated human populations. Another problem is the destruction of forests to expand cropland, an environmental disturbance that brings humans into contact with other animals that may host viruses capable of infecting humans.

Viral Diseases in Plants

More than 2,000 types of viral diseases of plants are known, and together they account for an estimated loss of \$15 billion annually worldwide due to agricultural and horticultural crop destruction. Common symptoms of viral infection include bleached or brown spots on leaves and fruits, stunted growth, and damaged flowers or roots, all tending to diminish the yield and quality of crops (**Figure 18.12**).

Plant viruses have the same basic structure and mode of replication as animal viruses. Most plant viruses discovered thus far, including tobacco mosaic virus (TMV), have an RNA genome. Many have a rod-shaped capsid, like TMV (see Figure 18.4a); others have a polyhedral capsid.

Plant viral diseases spread by two major routes. In the first route, called horizontal *transmission*, a plant is infected from an external source of the virus. Because the invading virus must get past the plant's outer protective layer of cells (the epidermis), the plant becomes more susceptible to viral infections if it has been damaged by wind, injury, or insects. Insects pose a double threat, because they can also act as carriers of viruses, transmuting disease from plant to plant. Farmers and gardeners may transmit plant viruses inadvertently on pruning shears and other tools. The other route of viral infection is vertical transmission, in which a plant inherits a viral infection from a parent. Vertical transmission can occur in

A Figure 18.12 Viral infection of plants. Infection with particular viruses causes "breaking" or streaking of tulip flower color (top), irregular brown patches on tomatoes (left center), and black blotching on squash (bottom).

asexual propagation (for example, by taking cuttings) or in sexual reproduction via infected seeds.

Once a virus enters a plant cell and begins reproducing, viral components can spread throughout the plant by passing through plasmodesmata, the cytoplasmic connections that penetrate the walls between adjacent plant cells (see Figure 6.28). Proteins encoded by viral genes are capable of altering the diameter of plasmodesmata to allow passage of viral proteins or genomes. Scientists have not yet devised cures for most viral plant diseases. So their efforts are focused largely on reducing the incidence and transmission of such diseases and on breeding varieties of crop plants that are relatively resistant to certain viruses.

Viroids and Prions: The Simplest Infectious Agents

As small and simple as viruses are, they dwarf another class of pathogens: viroids. These are circular RNA molecules, only several hundred nucleotides long, that infect plants. One viroid disease has killed over 10 million coconut palms in the Philippines. Viroids do not encode proteins but can replicate in host plant cells, apparently using cellular enzymes. These small RNA molecules seem to cause errors in the regulatory systems that control plant growth, and the symptoms typically associated with viroid diseases are abnormal development and stunted growth.

An important lesson from viroids is that a single molecule can be an infectious agent that spreads a disease. But "viroids are nucleic acid, whose ability to be replicated is well known. Even more surprising is the evidence for infectious proteins, called prions, which appear to cause a number of degenerative brain diseases in various animal species. These diseases include scrapie in sheep; mad cow disease, which has plagued the European beef industry in recent years; and Creutzfeldt-Jakob disease in humans, which has caused the death of some 125 British people in the past decade. Prions are most likely transmitted in food, as in the consumption by people of prion-laden beef from cattle with mad cow disease. Two characteristics of prions are especially alarming. First, prions are very slow-acting agents; the incubation period until symptoms appear is around ten years. Second, prions are virtually indestructible; they are not destroyed or deactivated by heating to normal cooking temperatures. To date, there is no known cure for prion diseases, and the only hope for developing effective treatments lies in understanding the mechanism of infection.

How can a protein, which cannot replicate itself, be a transmissible pathogen? According to the leading hypothesis, a prion is a misfolded form of a protein normally present in brain cells. When the prion gets into a cell containing the normal form of the protein, the prion

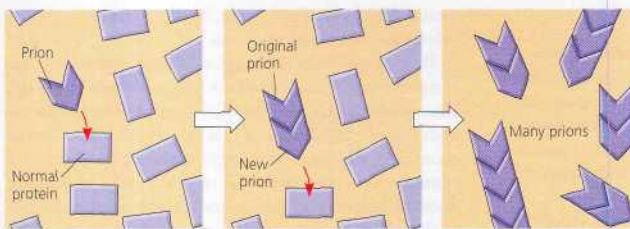

Figure 18.13 Model for how prions propagate. Prions are misfolded versions of normal brain proteins. When a prion contacts a normal "twin," it may induce the normal protein to assume the abnormal shape. The resulting chain reaction may continue until prions accumulate in aggregates to dangerous levels, causing cellular malfunction and eventual degeneration of the brain.

converts the normal protein to the prion version (Figure 18.13). In this way, prions may repeatedly trigger chain reactions that increase their numbers. This model, first proposed in the early 1980s, is now widely accepted.

Concept Check 18.2

- Describe two ways a preexisting virus can become an emerging virus.
- Compare horizontal versus vertical transmission of viruses in plants.
- Why does the long incubation period of prions increase their danger as a cause of human disease?

For suggested answers, see Appendix A.

Concept 18.3

Rapid reproduction, mutation, and genetic recombination contribute to the genetic diversity of bacteria

By studying the mechanisms by which viruses are replicated, researchers also learn about the mechanisms that regulate DNA replication and gene expression in cells. Bacteria are equally valuable as microbial models in genetics research, but for different reasons. As prokaryotic cells, bacteria allow researchers to investigate molecular genetics in the simplest true organisms. Information about numerous prokaryotic species has accumulated recently with the advent of large-scale genome sequencing. However, except where otherwise noted, we will focus on what has been learned from the well-studied intestinal bacterium *Escherichia coli*, sometimes called "the laboratory rat of molecular biology."

The Bacterial Genome and Its Replication

The main component of the genome in most bacteria is one double-stranded, circular DNA molecule that is associated with a small amount of protein. Although we will refer to this

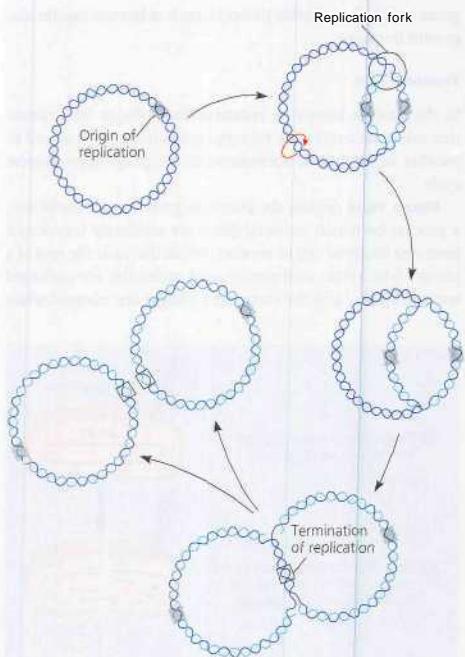

structure as the *bacterial chromosome*, it is very different from eukaryotic chromosomes, which have linear DNA molecules associated with a large amount of protein. In *E. coli*, the chromosomal DNA consists of about 4.6 million nucleotide pairs, representing about 4,400 genes. This is 100 times more DNA than is found in a typical virus, but only about one-thousandth as much DNA as in an average human cell. Still, this is a lot of DNA to be packaged in such a small container.

Stretched out, the DNA of an *E. coli* cell would measure about a millimeter in length, 500 times longer than the cell. Within a bacterium, however, certain proteins cause the chromosome to tightly coil and "supercoil," densely packing it so that it fills only part of the cell. This dense region of DNA, called the nucleoid, is not bounded by membrane like the nucleus of a eukaryotic cell. In addition to the chromosome, many bacteria also have plasmids, much smaller circles of DNA. Each plasmid has only a small number of genes, from just a few to several dozen. You will learn more about plasmids later in this section.

Bacterial cells divide by binary fission, which is preceded by replication of the bacterial chromosome (see Figure 12.11). From a single origin of replication, DNA synthesis progresses in both directions around the circular chromosome (Figure 18.14). Bacteria can proliferate very rapidly in a favorable environment, whether in a natural habitat or in a laboratory culture. For example, *E. coli* growing under optimal conditions can divide every 20 minutes. A laboratory culture started with a single cell on an agar plate containing nutrients can produce a mass, or *colony*, of 10^7 to 10^8 bacteria within 12 hours. Reproductive rates in the organism's natural habitat, the large intestine (colon) of mammals, can be much slower. One doubling in the human colon takes about 12 hours, for instance, but this is enough to replace the 2×10^{10} bacteria lost each day in feces.

Mutation and Genetic Recombination as Sources of Genetic Variation

Binary fission is an asexual process—the production of offspring from a single parent. Thus, most of the bacteria in a colony are genetically identical to the parent cell. Mutation, however, can cause some of the offspring to differ slightly in genetic makeup. The probability of a spontaneous mutation

A Figure 18.14 Replication of a bacterial chromosome.

From one origin, DNA replication progresses in both directions around the circular chromosome until the entire chromosome has been reproduced. Enzymes that cut, twirl (red arrow), and reseal the double helix prevent the DNA from tangling. Keep in mind that although the *overall* direction of DNA replication is outward from the origin in both directions, one new strand at each replication fork is made discontinuously in the direction back toward the origin (see Figure 16.16).

occurring in a given *E. coli* gene averages about 1×10^{-7} per cell division, only one in 10 million. But among the 2×10^{10} new *E. coli* cells that arise each day in a single human colon, there will be approximately $(2 \times 10^{10})(1 \times 10^{-7}) = 2,000$ bacteria that have a mutation in that gene. The total number of mutations when all 4,300 *E. coli* genes are considered is about $4,300 \times 2,000 = 9$ million per day per human host. The important point is that new mutations, though individually rare, can significantly increase genetic diversity when reproductive rates are very high because of short generation spans. This diversity, in turn, affects the evolution of bacterial populations: Bacterial populations composed of individuals that are genetically well equipped for the local environment will reproduce more prolifically than populations with less fit individuals.

In contrast, new mutations make a relatively small contribution to genetic variation in a population of slowly reproducing organisms, such as humans. Most of the heritable variation we observe in a human population is due not to the creation of novel alleles by *new* mutations, but to the recombination of existing alleles during sexual reproduction (see Chapter 15). Even in bacteria, where new mutations are a major source of individual variation, additional diversity arises from genetic recombination, defined as the combining of DNA from two sources. In most of the cases we will discuss here, the two sources of DNA are the genomes of two separate bacterial cells, with genomic DNA from one cell ending up in the genome of the other cell.

Figure 18.15 shows one type of experiment providing evidence that genetic recombination occurs in bacteria. This experiment made use of two mutant *E. coli* strains, each unable to synthesize a required amino acid, either tryptophan

Figure 18.15

Inquiry Can a bacterial cell acquire genes from another bacterial cell?

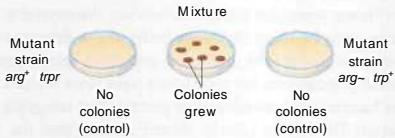

EXPERIMENT

Researchers had two mutant strains, one that could make arginine but not tryptophan (*arg⁺ trp⁻*) and one that could make tryptophan but not arginine (*arg⁻ trp⁺*). Each mutant strain and a mixture of both strains were grown in a liquid medium containing all the required amino acids. Samples from each liquid culture were spread on plates containing a solution of glucose and inorganic salts (minimal medium), solidified with agar.

RESULTS

Only the samples from the mixed culture, contained cells that gave rise to colonies on minimal medium, which lacks amino acids.

CONCLUSION

Because only cells that can make both arginine and tryptophan (*arg⁺ trp⁺* cells) can grow into colonies on minimal medium, the lack of colonies on the two control plates showed that no further mutations had occurred restoring this ability to cells of the mutant strains. Thus, each cell from the mixture that formed a colony on the minimal medium must have acquired one or more genes from a cell of the other strain by genetic recombination.

or arginine. As a result, the mutant strains were unable to grow on a minimal medium containing only glucose (as a source of organic carbon) and salts. When bacteria from the two strains were incubated together, however, cells emerged that could grow on minimal medium, indicating that they made *both* tryptophan and arginine. The number of such cells far exceeded what could be accounted for by mutation. Most of the cells that could synthesize both amino acids must have acquired one or more genes from the other strain, presumably by genetic recombination.

Mechanisms of Gene Transfer and Genetic Recombination in Bacteria

Bacteria differ from eukaryotes in the mechanisms used to bring DNA from two individuals together in one cell. In eukaryotes, the sexual processes of meiosis and fertilization combine DNA from two individuals in a single zygote (see Chapter 13). But meiosis and fertilization do not occur in prokaryotes. Instead, three other processes—transformation, transduction, and conjugation—bring together bacterial DNA from different individuals.

Transformation

In the context of bacterial genetics, the process of transformation is the alteration of a bacterial cell's genotype and phenotype by the uptake of naked, foreign DNA from the surrounding environment. For example, bacteria of a harmless strain of *Streptococcus pneumoniae* can be transformed to pneumonia-causing cells by the uptake of DNA from a medium containing dead, broken-open cells of the pathogenic strain (see Figure 16.2). This transformation occurs when a live nonpathogenic cell takes up a piece of DNA carrying the allele for pathogenicity, which codes for a cell coat that protects the bacterium from a host's immune system. The foreign allele is then incorporated into the chromosome of the nonpathogenic cell, replacing the allele for the "coatsless" condition by genetic recombination—an exchange of DNA segments by crossing over. The cell is now a recombinant: Its chromosome contains DNA derived from two different cells.

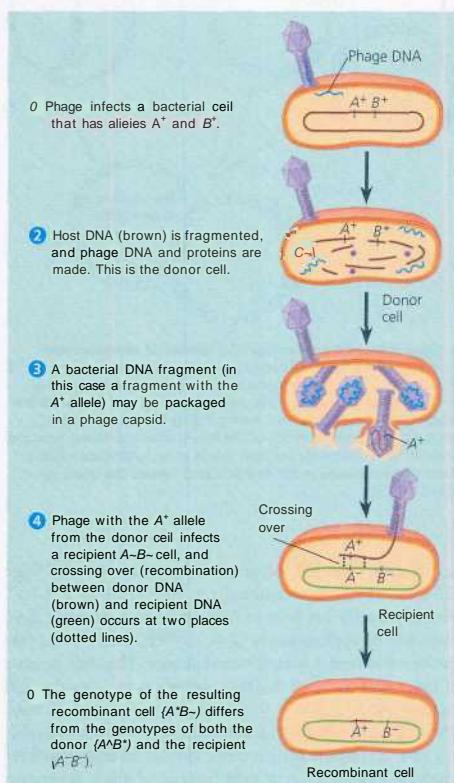

For many years after transformation was discovered in laboratory cultures, most biologists believed the process to be too rare and haphazard to play an important role in natural bacterial populations. But researchers have since learned that many bacteria possess cell-surface proteins that recognize and transport DNA from closely related species into the cell, which can then incorporate the foreign DNA into the genome. *E. coli* and some other bacteria appear to lack this transformation mechanism. However, placing *E. coli* in a culture medium containing a relatively high concentration of calcium ions will artificially stimulate the cells to take up small pieces of DNA. In biotechnology, this technique is applied to introduce foreign genes into the *E. coli* genome—

genes coding for valuable proteins, such as human insulin and growth hormone.

Transduction

In the process known as **transduction**, phages (the viruses that infect bacteria) carry bacterial genes from one host cell to another as a result of aberrations in the phage reproductive cycle.

Figure 18.16 depicts the events in *generalized transduction*, a process by which bacterial genes are randomly transferred from one bacterial cell to another. Recall that near the end of a phage's lytic cycle, viral nucleic acid molecules are packaged within capsids, and the completed phages are released when

A Figure 18.16 Generalized transduction. Phages occasionally carry random pieces of the host chromosome containing bacterial genes from one cell (the donor) to another (the recipient). The transferred DNA may recombine with the genome of the recipient, bringing about a recombinant cell.

the host cell lyses. Occasionally, a small piece of the host cell's degraded DNA is accidentally packaged within a phage capsid in place of the phage genome. Such a virus is defective because it lacks its own genetic material. However, after its release from the lysed host, the phage can attach to another bacterium (the recipient) and inject the piece of bacterial DNA acquired from the first cell (the donor). Some of this DNA can subsequently replace the homologous region of the recipient cell's chromosome, if a crossover takes place at each end of the piece. In this case, the recipient cell's chromosome becomes a combination of DNA derived from two cells; genetic recombination has occurred.

Temperate phages, those able to integrate their genome into the bacterial chromosome as a prophage (see Figure 18.7), can carry out *specialized transduction*. In this process, a prophage picks up just a few adjacent bacterial genes as it exits the chromosome and transfers them to a new host cell. This process can result in efficient transfer, but only of genes adjacent to the prophage site.

Conjugation and Plasmids

Sometimes referred to as bacterial "sex," **conjugation** is the direct transfer of genetic material between two bacterial cells that are temporarily joined. The DNA transfer is one-way: One cell donates DNA, and its "mate" receives the DNA. The donor, sometimes called the "male," uses appendages called sex pili (singular, sex pilus) to attach to the recipient, sometimes called the "female" (Figure 18.17). After contacting a recipient cell, a sex pilus retracts, pulling the two cells together, much like a grappling hook. A temporary cytoplasmic mating bridge then forms between the two cells, providing an avenue for DNA transfer.

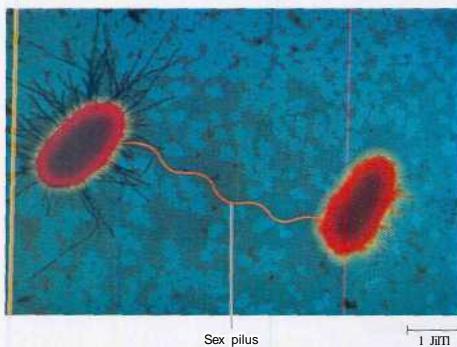

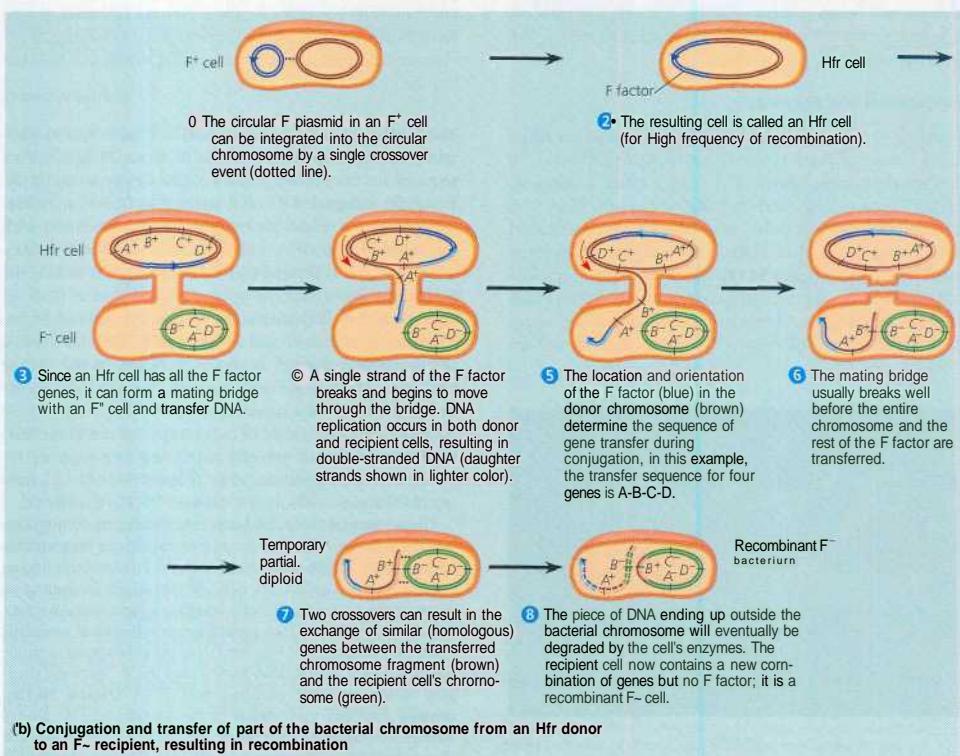

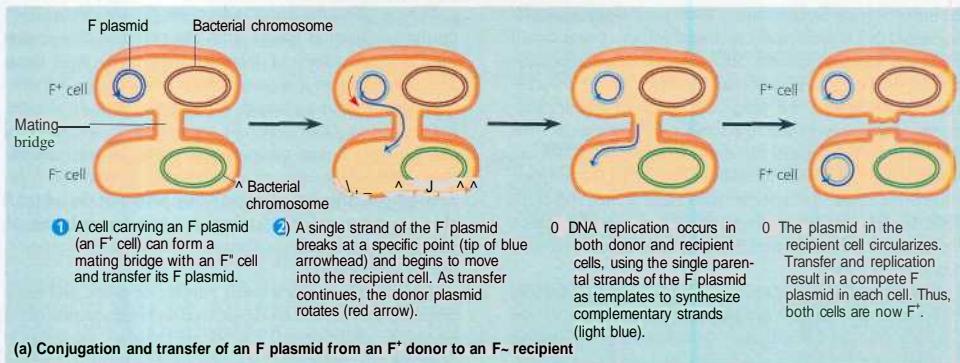

Figure 18.17 Bacterial conjugation. The *E. coli*/donor cell (left) extends sex pili, one of which is attached to a recipient cell. The two cells will be drawn close together, allowing a cytoplasmic mating bridge to form between them. Through this bridge, the donor will transfer DNA to the recipient (colorized TEM).

In most cases, the ability to form sex pili and donate DNA during conjugation results from the presence of a special piece of DNA called an **F factor** (*F* for fertility). An *F* factor can exist either as a segment of DNA within the bacterial chromosome or as a plasmid. A **plasmid** is a small, circular, self-replicating DNA molecule separate from the bacterial chromosome. Certain plasmids, such as *F* plasmids, can undergo reversible integration into the cell's chromosome. A genetic element that can replicate either as part of the bacterial chromosome or independently of it is called an **episome**. In addition to some plasmids, temperate viruses, such as phage *X*, qualify as episomes.

A plasmid has only a small number of genes, and these genes are not required for the survival and reproduction of the bacterium under normal conditions. However, the genes of plasmids can confer advantages on bacteria living in stressful environments. For example, the *F* plasmid facilitates genetic recombination, which may be advantageous in a changing environment that no longer favors existing strains in a bacterial population.

The F Plasmid and Conjugation. The *F* factor and its plasmid form, the ***F* plasmid**, consist of about 25 genes, most required for the production of sex pili. Cells containing the *F* plasmid, designated *F⁺* cells, function as DNA donors during conjugation. The *F* plasmid replicates in synchrony with the chromosomal DNA, and division of an *F⁺* cell usually gives rise to two offspring that are both *F⁺*. Cells lacking the *F* factor in either form, designated *F⁻*, function as DNA recipients during conjugation. The *F⁺* condition is transferable in the sense that an *F⁺* cell converts an *F⁻* cell to *F⁺* when the two cells conjugate, as shown in Figure 18.18a, on the next page. The original cell remains *F⁺* because the process of transfer involves a special type of DNA replication: One parental strand of *F* factor DNA is transferred across the mating bridge, and each parental strand acts as a template for synthesis of the second strand in its respective cell. In a mating of *F⁺* and *F⁻* cells, only *F* plasmid DNA is transferred.

Chromosomal genes can be transferred during conjugation when the donor cell's *F* factor is integrated into the chromosome (Figure 18.18b, top). A cell with the *F* factor built into its chromosome is called an *Hfr* cell (for High frequency of recombination). Like an *F⁺* cell, an *Hfr* cell functions as a donor during conjugation: DNA replication is initiated at a specific point on the integrated *F* factor DNA; from that point, a single strand of the *F* factor DNA moves into the *F⁻* partner, dragging along adjacent chromosomal DNA (Figure 18.18b, center). Random movements of the bacteria almost always disrupt conjugation long before an entire strand of the *Hfr* chromosome can be passed to the *F⁻* cell. The single strand in each cell serves as a template for synthesis of a second strand. Thus, the *Hfr* cell's DNA remains the same, while the *F⁻* cell acquires new DNA, some of it chromosomal. Temporarily, the recipient cell is a partial diploid, containing its own complete

A Figure 18.18 Conjugation and recombination in *E. coli*. The DNA replication that accompanies transfer of an F plasmid or part of an Hfr bacterial chromosome is called *rolling circle replication*. This is sometimes referred to as the "toilet paper" model because of the way the single strand rolls off the donor cell DNA and moves into the recipient cell.

F^- chromosome plus transferred chromosomal DNA from the Hfr donor. If part of the newly acquired DNA aligns with the homologous region of the F^- chromosome, segments of DNA can be exchanged (**Figure 18.18b, bottom**). Reproduction of this cell gives rise to a population of recombinant bacteria with genes derived from two different cells. This process of conjugation and recombination accounts for the results of the experiment shown in Figure 18.15, in which one of the bacterial strains was Hfr and the other F^- .

R Plasmids and Antibiotic Resistance. In the 1950s, Japanese physicians began to notice that some hospital patients suffering from bacterial dysentery, which produces severe diarrhea, did not respond to antibiotics that had generally been effective in the past. Apparently, resistance to these antibiotics had evolved in certain strains of *Shigella*, the pathogen. Eventually, researchers began to identify the specific genes that confer antibiotic resistance in *Shigella* and other pathogenic bacteria. Sometimes, mutation in a chromosomal gene of the pathogen can cause resistance. For example, a mutation in one gene may reduce the pathogen's ability to transport a particular antibiotic into the cell. Mutation in a different gene may alter the intracellular target protein for an antibiotic molecule, reducing its inhibitory effect. Some bacteria have resistance genes coding for enzymes that specifically destroy certain antibiotics, such as teixacycline or ampicillin. Genes conferring this type of resistance are generally carried by plasmids known as R plasmids (R for resistance).

Exposure of a bacterial population to a specific antibiotic, whether in a laboratory culture or within a host organism, will kill antibiotic-sensitive bacteria but not those that happen to have R plasmids with genes that counter the antibiotic. The theory of natural selection predicts that under these circumstances, the fraction of the bacterial population carrying genes for antibiotic resistance will increase, and that is exactly what happens. The medical consequences are also predictable: Resistant strains of pathogens are becoming more common, making the treatment of certain bacterial infections more difficult. The problem is compounded by the fact that many R plasmids, like F plasmids, have genes that encode sex pili and enable plasmid transfer from one bacterial cell to another by conjugation. Making the problem still worse, some R plasmids carry as many as ten genes for resistance to that many antibiotics. How do so many antibiotic resistance genes become part of a single plasmid? The answer involves another type of mobile genetic element, which we investigate next.

Transposition of Genetic Elements

In the previous section, you learned how DNA from one bacterial cell can be transferred to another cell and recombined into the genome of the recipient. The DNA of a single cell can also undergo recombination owing to movement of so-called *transposable genetic elements*, or simply transposable elements,

within the cell's genome. Unlike a plasmid or prophage, transposable elements never exist independently but are always part of chromosomal or plasmid DNA. During the movement of these elements, called *transposition*, the transposable element moves from one site in a cell's DNA to another site—a target site—by a type of recombination process. In a bacterial cell, a transposable element may move within the chromosome, from a plasmid to the chromosome (or vice versa), or from one plasmid to another.

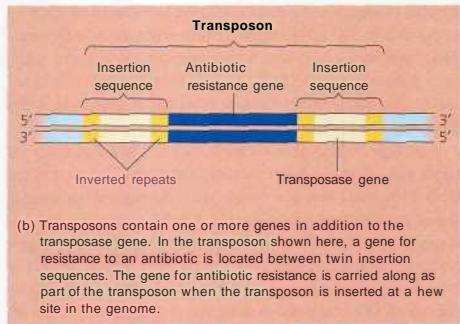

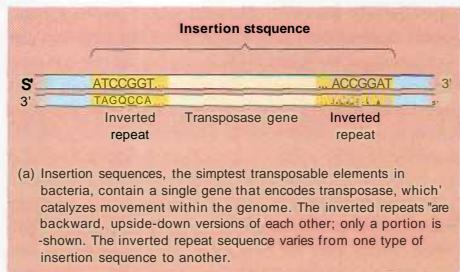

Transposable elements are sometimes called "jumping genes," but the phrase is misleading because they never completely detach from the cell's DNA. (The original and new DNA sites are brought together by DNA folding.) Some transposable elements move from one DNA location to another by a "cut-and-paste" mechanism. Others move by a "copy-and-paste" mechanism, in which the transposable element replicates at its original site, and a copy inserts elsewhere. In other words, the transposable element is added at a new site without being lost from the old site.

Although transposable elements vary in their selectivity for target sites, most can move to many alternative locations in the DNA. This ability to scatter certain genes throughout the genome makes transposition fundamentally different from other mechanisms of genetic shuffling. During bacterial transformation, generalized transduction, and conjugation (and during meiosis in eukaryotes as well), recombination occurs between homologous regions of DNA, regions of identical or very similar base sequence that can undergo base pairing. In contrast, the insertion of a transposable element in a new site does not depend on complementary base sequences. A transposable element can move genes to a site where genes of that sort have never before existed.

Insertion Sequences

The simplest transposable elements, called insertion sequences, exist only in bacteria. An insertion sequence contains a single gene, which codes for transposase, an enzyme that catalyzes movement of the insertion sequence from one site to another within the genome. The transposase gene is bracketed by a pair of noncoding DNA sequences about 20 to 40 nucleotides long. These sequences are called *inverted repeats* because the base sequence at one end of the insertion sequence is repeated upside down and backward (inverted) at the other end (**Figure 18.19a**, on the next page). Transposase recognizes these inverted repeats as the boundaries of the insertion sequence. During transposition, molecules of the enzyme bind to the inverted repeats and to a target site elsewhere in the genome and catalyze the necessary DNA cutting and resealing.

An insertion sequence can cause mutations if it transposes into the coding sequence of a gene or into a DNA region that regulates gene expression. This mechanism of mutation is intrinsic to the cell, in contrast to mutagenesis by extrinsic factors such as environmental radiation and chemicals. Insertion sequences account for about 1.5% of the *E. coli* genome.

A Figure 18.19 Transposable genetic elements in bacteria. These diagrams are not to scale; most transposons are considerably longer than insertion sequences.

However, mutation of a given gene by transposition occurs only rarely—about once in every 10 million generations. This is about the same as the spontaneous mutation rate due to other factors.

Transposons

Transposable elements longer and more complex than insertion sequences, called transposons, also move about in the bacterial genome, in addition to the DNA required for transposition, transposons include extra genes that go along for the ride, such as genes for antibiotic resistance; in some bacterial transposons, the extra genes are sandwiched between two insertion sequences (**Figure 18.19b**). It is as though two insertion sequences happened to land relatively close together in the genome and now travel together, along with all the DNA between them, as a single transposable element. Other bacterial transposons do not contain insertion sequences; these have different inverted repeats at their ends.

In contrast to insertion sequences, which are not known to benefit bacteria in any specific way, transposons may help bacteria adapt to new environments. We mentioned earlier that a single R plasmid can carry several genes for resistance

to different antibiotics. This is explained by transposons, which can add a gene for antibiotic resistance to a plasmid already carrying genes for resistance to other antibiotics. The transmission of this composite plasmid to other bacterial cells by cell division or conjugation can then spread resistance to a variety of antibiotics throughout a bacterial population. In an antibiotic-rich environment, natural selection favors bacteria that have built up R plasmids with multiple antibiotic resistance genes through a series of transpositions.

Transposons are not unique to bacteria and are important components of eukaryotic genomes as well. You will learn about transposable elements in eukaryotes in Chapter 19.

Concept Check 18.3

- Distinguish between the three mechanisms of transferring DNA from one bacterial cell to another.
- What are the similarities and differences between lysogenic phage DNA and a plasmid?
- Explain why the process of conjugation can lead to genetic recombination of chromosomal DNA in an $Hfr \times F^-$ mating, but not in an $F^+ \times F^-$ mating.

For suggested answers, see Appendix A.

Concept 18.4

Individual bacteria respond to environmental change by regulating their gene expression

Mutations and various types of gene transfer generate the genetic variation that makes natural selection possible. And natural selection, acting over many generations, can increase the proportion of individuals in a bacterial population that are adapted to some new environmental condition. But how can an individual bacterium, locked into the genome it has inherited, cope with environmental fluctuation?

Consider, for instance, an individual *E. coli* cell living in the erratic environment of a human colon, dependent for its nutrients on the whimsical eating habits of its host. If the environment is lacking in the amino acid tryptophan, which the bacterium needs to survive, the cell responds by activating a metabolic pathway that makes tryptophan from another compound. Later, if the human host eats a tryptophan-rich meal, the bacterial cell stops producing tryptophan, thus saving itself from squandering its resources to produce a substance that is available from the surrounding solution in prefabricated form. This is just one example of how bacteria tune their metabolism to changing environments.

Metabolic control occurs on two levels (**Figure 18.20**). First, cells can adjust the activity of enzymes already present. This is a fairly fast response, which relies on the sensitivity of many enzymes to chemical cues that increase or decrease their catalytic activity (see Chapter 8). For example, the activity of the first enzyme in the tryptophan synthesis pathway is inhibited by the pathway's end product. Thus, if tryptophan accumulates in a cell, it shuts down the synthesis of more tryptophan by inhibiting enzyme activity. Such *feedback inhibition*, typical of anabolic (biosynthetic) pathways, allows a cell to adapt to short-term fluctuations in the supply of a substance it needs.

Second, cells can adjust the amount being made of certain enzymes; that is, they can regulate the expression of the genes encoding the enzymes, if, in our example, the environment continues to provide all the tryptophan the cell needs, the cell stops making the enzymes that work in the tryptophan pathway. This control of enzyme production occurs at the level of transcription, the synthesis of messenger RNA coding for these enzymes. More generally, many genes of the bacterial genome are switched on or off by changes in the metabolic status of the cell. The basic mechanism for this control of gene expression in bacteria, described as the *operon model*, was discovered in 1961 by François Jacob and Jacques Monod at the Pasteur Institute in Paris. Let's see what an operon is and

how it works, using the control of tryptophan synthesis as our first example.

Operons: The Basic Concept

E. coli synthesizes tryptophan from a precursor molecule in a series of steps, each reaction catalyzed by a specific enzyme (see Figure 18.20). The five genes coding for these enzymes are clustered together on the bacterial chromosome. A single promoter serves all five genes, which constitute a transcription unit. (Recall from Chapter 17 that a promoter is a site where RNA polymerase can bind to DNA and begin transcription.) Thus, transcription gives rise to one long mRNA molecule that codes for all five enzymes in the tryptophan pathway. The cell can translate this mRNA into five separate polypeptides because the mRNA is punctuated with start and stop codons that signal where the coding sequence for each polypeptide begins and ends.

A key advantage of grouping genes of related function into one transcription unit is that a single on-off "switch" can control the whole cluster of functionally related genes. When an *E. coli* cell must make tryptophan for itself because the nutrient medium lacks this amino acid, all the enzymes for the metabolic pathway are synthesized at one time. The switch is a segment of DNA called an operator. Both its location and name suit its function: Positioned within the promoter or between the promoter and the enzyme-coding genes, the operator controls the access of RNA polymerase to the genes. All together, the operator, the promoter, and the genes they control—the entire stretch of DNA required for enzyme production for the tryptophan pathway—constitute an operon. Mere we are dissecting the *trp* operon (*trp* for tryptophan), one of many operons in the *E. coli* genome (**Figure 18.21**, on the next page).

If the operator is the switch for controlling transcription, how does this switch work? By itself, the *trp* operon is turned on; that is, RNA polymerase can bind to the promoter and transcribe the genes of the operon. The operon can be switched off by a protein called the *trp* repressor. The repressor binds to the operator and blocks attachment of RNA polymerase to the promoter, preventing transcription of the genes. A repressor protein is specific; that is, it recognizes and binds only to the operator of a particular operon. The repressor that switches off the *trp* operon by binding to the *trp* operator has no effect on other operons in the *E. coli* genome.

The *trp* repressor is the product of a regulatory gene called *trpR*, which is located some distance away from the operon it controls and has its own promoter. Regulatory genes are expressed continuously although at a low rate, and a few *trp* repressor molecules are always present in *E. coli* cells. Why, then, is the *trp* operon not switched off permanently? First, the binding of repressors to operators is reversible. An operator vacillates between two states: one

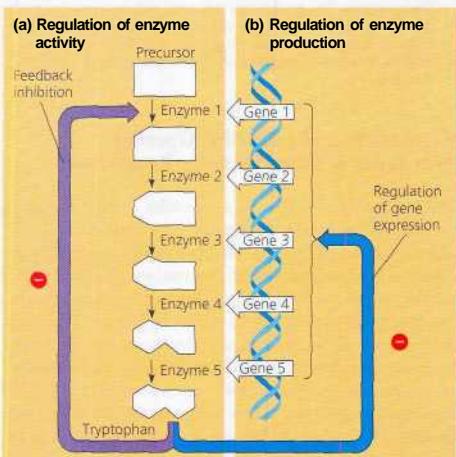

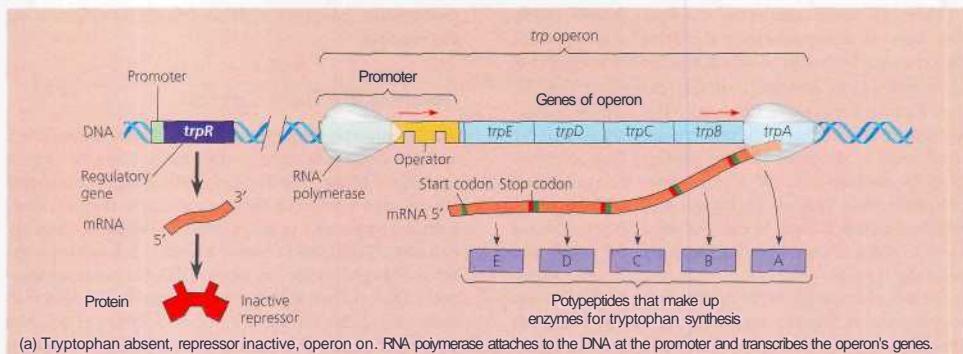

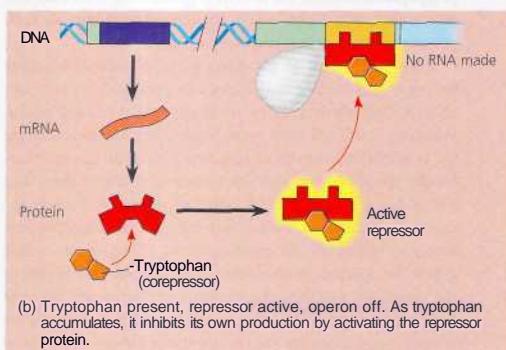

Figure 18.20 Regulation of a metabolic pathway. In the pathway for tryptophan synthesis, an abundance of tryptophan can both (a) inhibit the activity of the first enzyme in the pathway (feedback inhibition), a rapid response, and (b) repress expression of the genes for all the enzymes needed for the pathway, a longer-term response. The \$ symbol stands for inhibition.

(a) Tryptophan absent, repressor inactive, operon on. RNA polymerase attaches to the DNA at the promoter and transcribes the operon's genes.

(b) Tryptophan present, repressor active, operon off. As tryptophan accumulates, it inhibits its own production by activating the repressor protein.

< Figure 18.21 The *trp* operon: regulated synthesis of repressible enzymes. Tryptophan is an amino acid produced by an anabolic pathway catalyzed by repressible enzymes. (a) Five genes encoding the polypeptides that make up the enzymes of this pathway are grouped, along with a promoter and an operator, into the *trp* operon. The *trp* operator is located within the *trp* promoter. (b) Accumulation of tryptophan, the end product of the pathway, represses transcription of the *trp* operon, thus blocking synthesis of all the enzymes in the pathway. The mechanism in *E. coli* is shown here.

without the repressor bound and one with the repressor bound. The relative duration of each state depends on the number of active repressor molecules around. Second, the *trp* repressor, like most regulatory proteins, is an allosteric protein, with two alternative shapes, active and inactive (see Figure 8.20). The *trp* repressor is synthesized in an inactive form with little affinity for the *trp* operator. Only if tryptophan binds to the *trp* repressor at an allosteric site does the repressor protein change to the active form that can attach to the operator, turning the operon off.

Tryptophan functions in this system as a **corepressor**, a small molecule that cooperates with a repressor protein to switch an operon off. As tryptophan accumulates, more tryptophan molecules associate with *trp* repressor molecules, which can then bind to the *trp* operator and shut down production of the tryptophan pathway enzymes. If the cell's tryptophan level drops, transcription of the operon's genes resumes. This is one example of how gene expression responds rapidly to changes in the cell's internal and external environment.

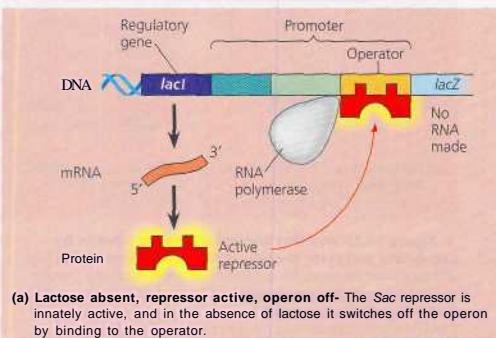

Repressible and Inducible Operons: Two Types of Negative Gene Regulation

The *Lrp* operon is said to be a **repressible operon** because its transcription is usually on but can be inhibited (repressed) when a specific small molecule (tryptophan) binds allosterically to a regulatory protein. In contrast, an **inducible operon** is usually off but can be stimulated (induced) when a specific small molecule interacts with a regulatory protein. The classic example of an inducible operon is the *lac* operon (*lac* for lactose), the subject of Jacob and Monod's pioneering research.

The disaccharide **lactose** (milk sugar) is available to *E. coli* if the human host drinks milk. Lactose metabolism begins with hydrolysis of the disaccharide into its component monosaccharides, glucose and galactose, a reaction catalyzed by the enzyme β -galactosidase. Only a few molecules of this enzyme are present in an *E. coli* cell growing in the absence of lactose. But if lactose is added to the bacterium's environment, the number of β -galactosidase molecules in the cell increases a thousandfold within about 15 minutes.

The gene for p-galactosidase is part of the *lac* operon, which includes two other genes coding for enzymes that function in lactose metabolism. The entire transcription unit is under the command of a single operator and promoter. The regulatory gene, *Idd*, located outside the operon, codes for an allosteric repressor protein that can switch off the *lac* operon by binding to the operator. So far, this sounds just like regulation of the *trp* operon, but there is one important difference. Recall that the *trp* repressor is inactive by itself and requires tryptophan as a co-repressor in order to bind to the operator. The *lac* repressor, in contrast, is active all by itself, binding to the operator and switching the *lac* operon off. In this case, a specific small molecule, called an inducer, *inactivates* the repressor.

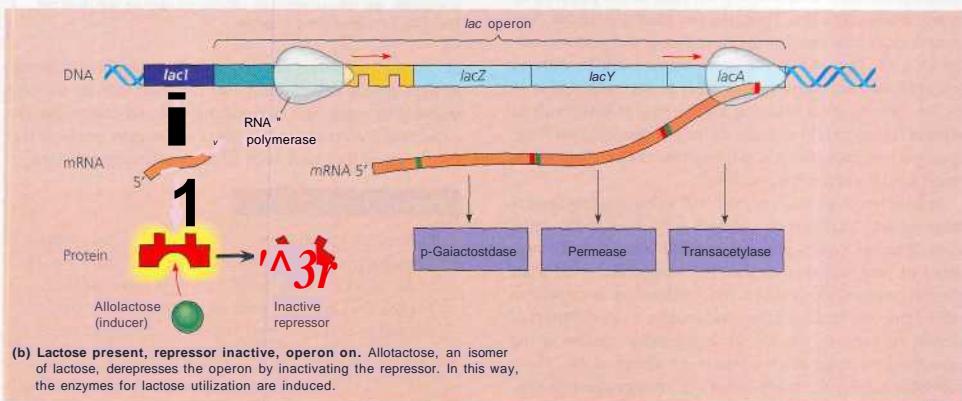

For the *lac* operon, the inducer is allolactose, an isomer of lactose formed in small amounts from lactose that enters the cell. In the absence of lactose (and hence allolactose), the lac repressor is in its active configuration, and the genes of the *lac* operon are silenced (Figure 18.22a). If lactose is added to the cells sur-

roundings, allolactose binds to the lac repressor and alters its conformation, nullifying the repressor's ability to attach to the operator. Without bound repressor, the *lac* operon is transcribed into mRNA for the lactose-utilizing enzymes (Figure 18.22b).

In the context of gene regulation, the enzymes of the lactose pathway are referred to as *inducible enzymes*, because their synthesis is induced by a chemical signal (allolactose, in this case). Analogously, the enzymes for tryptophan synthesis are said to be *repressible*. Repressive *enzymes* generally function in anabolic pathways, which synthesize essential end products from raw materials (precursors). By suspending production of an end product when it is already present in sufficient quantity, the cell can allocate its organic precursors and energy for other uses. In contrast, inducible enzymes usually function in catabolic pathways, which break down a nutrient to simpler molecules. By producing the appropriate enzymes only when the nutrient is available, the cell avoids wasting energy and precursors making proteins that are not needed.

*< **Figure 18.22 The lac operon: regulated synthesis of inducible enzymes.** *E. coli* uses three enzymes to take up and metabolize lactose. The genes for these three enzymes are clustered in the *lac* operon. One gene, *lacZ*, codes for *B*-galactosidase, which hydrolyzes lactose to glucose and galactose. The second gene, *lacY*, codes for a permease, the membrane protein that transports lactose into the cell. The third gene, *lacA*, codes for an enzyme called transacetylase, whose function in lactose metabolism is still unclear. The gene for the *lac* repressor, *lacI*, happens to be adjacent to the *lac* operon, an unusual situation. The function of the darker green region at the upstream (left) end of the promoter is revealed in Figure 18.23.

Regulation of both the *trp* and *lac* operons involves the *negative* control of genes, because the operons are switched off by the active form of the repressor protein. It may be easier to see this for the *trp* operon, but it is also true for the *lac* operon. AUolactose induces enzyme synthesis not by acting directly on the genome, but by freeing the *lac* operon from the negative effect of the repressor. Gene regulation is said to be *positive* only when a regulatory protein interacts directly with the genome to switch transcription on. Let's look at an example of positive control of genes, again involving the *lac* operon.

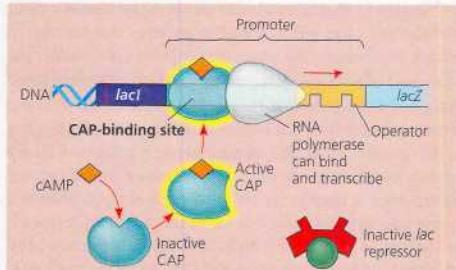

Positive Gene Regulation

For the lactose-utilizing enzymes to be synthesized in appreciable quantity, it is not sufficient for lactose to be present in the bacterial cell. The other requirement is that the simple sugar glucose be in short supply. Given a choice of substrates for glycolysis and other catabolic pathways, *E. coli* preferentially uses glucose. The enzymes for glucose breakdown (glycolysis; see Figure 9.9) are continually present.

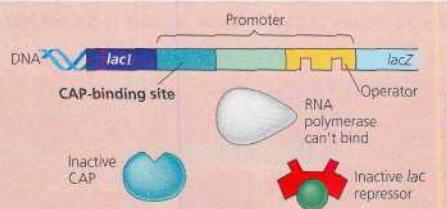

How does the *E. coli* cell sense the glucose concentration, and how is this information relayed to the genome? Again, the mechanism depends on the interaction of an allosteric regulator's protein with a small organic molecule, in this case cyclic AMP (cAMP), which accumulates when glucose is scarce (see Figure 11.9 for the structure of cAMP). The regulatory protein, called *catabolite activator protein* (CAP), is an activator of transcription. When cAMP binds to CAP, the regulatory protein (CAP) assumes its active shape and can bind to a specific site at the upstream end of the *lac* promoter (Figure 18.23a). The attachment of CAP to the promoter directly stimulates gene expression. Thus, this mechanism qualifies as positive regulation.

If the amount of glucose in the cell increases, the cAMP concentration falls, and without it, CAP detaches from the operon. Because CAP is inactive, transcription of the *lac* operon proceeds at only a low level, even in the presence of lactose (Figure 18.23b). Thus, the *lac* operon is under dual control: negative control by the *lac* repressor and positive control by CAP. The state of the *lac* repressor (with or without bound allolactose) determines whether or not transcription of the *lac* operon's genes occurs at all; the state of CAP (with or without bound cAMP) controls the rate of transcription if the operon is repressor-free. It is as though the operon has both an on-off switch and a volume control.

In addition to the *lac* operon, CAP helps regulate several other operons that encode enzymes used in catabolic pathways. When glucose is plentiful and CAP is inactive, the synthesis of enzymes that catabolize compounds other than glucose generally slows down. The cell's ability to catabolize other compounds, such as lactose, enables a cell deprived of glucose to survive. The specific compounds present at the moment determine which operons are switched on. These multiple contingency mechanisms suit an organism that cannot control what its host eats. Bacteria are remarkable in their

(a) Lactose present, glucose scarce (cAMP level high): abundant *lac* mRNA synthesized. If glucose is scarce, the high level of cAMP activates CAP, and the *lac* operon produces large amounts of mRNA for the lactose pathway.

(b) Lactose present, glucose present (cAMP level low): little *lac* mRNA synthesized. When glucose is present, cAMP is scarce, and CAP is unable to stimulate transcription.

A Figure 18.23 Positive control of the *lac* operon by catabolite activator protein (CAP). RNA polymerase has high affinity for the *lac* promoter only when catabolite activator protein (CAP) is bound to a DNA site at the upstream end of the promoter. CAP attaches to its DNA site only when associated with cyclic AMP (cAMP), whose concentration in the cell rises when the glucose concentration falls. Thus, when glucose is present, even if lactose is available, the cell preferentially catabolizes glucose and does not make the lactose-utilizing enzymes.

ability to adapt—over the long term by evolutionary changes in their genetic makeup and over the short term by the control of gene expression in individual cells. Of course, the various control mechanisms are also evolutionary products that exist because they have been favored by natural selection.

Concept Check 18.4

1. A certain mutation in *E. coli* changes the *lac* operator so that the active repressor cannot bind. How would this affect the cell's production of p-galactosidase?
2. How does binding of the *trp* corepressor and the *lac* inducer to their respective repressor proteins alter repressor function and transcription in each case?

For suggested answers, see Appendix A.

Chapter 18 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 18.1

A **ITMIS** has a genome but can reproduce only within a host cell

- **The Discovery of Viruses: Scientific Inquiry**

(pp. 334–335) Researchers discovered viruses in the late 1800s by studying a plant disease, tobacco mosaic disease.

- **Structure of Viruses** (pp. 335–336) A virus is a small nucleic acid genome enclosed in a protein capsid and sometimes a membranous envelope containing viral proteins that help viruses enter cells. The genome may be single- or double-stranded DNA or RNA.

- **General Features of Viral Reproductive Cycles**

(pp. 336–337) Viruses use enzymes, ribosomes, and small molecules of host cells to synthesize progeny viruses. Each type of virus has a characteristic host range.

Activity Simplified Viral Reproductive Cycle

- **Reproductive Cycles of Phages** (pp. 337–339) In the lytic cycle, entry of the viral genome into a bacterium programs destruction of host DNA, production of new phages, and digestion of the host's cell wall, releasing the progeny phages. In the lysogenic cycle, the genome of a temperate phage inserts into the bacterial chromosome as a prophage, which is passed on to host daughter cells until it is induced to leave the chromosome and initiate a lytic cycle.

Activity Phage Lytic Cycle

Activity Phage Lysogenic and Lytic Cycles

- **Reproductive Cycles of Animal Viruses** (pp. 339–342)

Many animal viruses have an envelope. Retroviruses (such as HIV) use the enzyme reverse transcriptase to copy their RNA genome into DNA, which can be integrated into the host genome as a provirus.

Activity Retrovirus (HIV) Reproductive Cycle

- **Evolution of Viruses** (pp. 342–343) Since viruses can reproduce only within cells, they probably evolved after the first cells appeared, perhaps as packaged fragments of cellular nucleic acids.

Concept 18.2

Viruses, viroids, and prions are formidable pathogens in animals and plants

- **Viral Diseases in Animals** (pp. 343–344) Symptoms may be caused by direct viral harm to cells or by the body's immune response. Vaccines stimulate the immune system to defend the host against specific viruses.

- **Emerging Viruses** (p. 344) Outbreaks of "new" viral diseases in humans are usually caused by existing viruses that expand their host territory.

Investigation What Causes Infections in AIDS Patients?

Investigation Why Do AIDS Rates Differ Across the U.S.?

- **Viral Diseases in Plants** (p. 345) Viruses enter plant cells through damaged cell walls (horizontal transmission) or are inherited from a parent (vertical transmission).

► Viroids and Prions: The Simplest Infectious Agents

(pp. 345–346) Viroids are naked RNA molecules that infect plants and disrupt their growth. Prions are slow-acting, virtually indestructible infectious proteins that cause brain diseases in mammals.

Concept 18.3

Rapid reproduction, mutation, and genetic recombination contribute to the genetic diversity of bacteria

- **The Bacterial Genome and Its Replication**

(p. 346) The bacterial chromosome is usually a circular DNA molecule with few associated proteins. Plasmids are smaller circular DNA molecules that can replicate independently of the chromosome.

- **Mutation and Genetic Recombination as Sources of Genetic Variation** (pp. 346–348) Because bacteria can proliferate rapidly, new mutations can quickly increase a population's genetic variation. Further diversity can arise by recombination of the DNA from two different bacterial cells.

- **Mechanisms of Gene Transfer and Genetic Recombination in Bacteria** (pp. 348–351) New bacterial strains can arise by the transfer of DNA from one cell to another cell. In transformation, naked DNA enters the cell from the surroundings. In transduction, bacterial DNA is carried from one cell to another by phages. In conjugation, an F⁺ donor cell, which contains the F plasmid, transfers plasmid DNA to an F⁻ recipient cell. The F factor of an Hfr cell which is integrated into the bacterial chromosome, brings some chromosomal DNA along with it when it is transferred to an F⁻ cell. R plasmids confer resistance to various antibiotics.

Investigation What Are the Patterns of Antibiotic Resistance?

- **Transposition of Genetic Elements** (pp. 351–352) DNA segments that can insert at multiple sites in a cell's DNA contribute to genetic shuffling in bacteria. Insertion sequences, the simplest bacterial transposable elements, consist of inverted repeats of DNA flanking a gene for transposase. Bacterial transposons have additional genes, such as those for antibiotic resistance.

Concept 18.4

Individual bacteria respond to environmental change by regulating their gene expression

- **Operons: The Basic Concept** (pp. 353–354) Cells control metabolism by regulating enzyme activity or the expression of genes coding for enzymes. In bacteria, genes are often clustered into operons, with one promoter serving several adjacent genes. An operator site on the DNA switches the operon on or off.

- **Repressible and Inducible Operons: Two Types of Negative Gene Regulation** (pp. 354–356) In a repressible operon, binding of a specific repressor protein to the operator shuts off transcription. The repressor is active when bound to a corepressor, usually the end product of an anabolic pathway. In an inducible operon, binding of an inducer to an innately active repressor inactivates the repressor and turns on transcription. Inducible enzymes usually function in catabolic pathways.

- **Positive Gene Regulation** (p. 356) Some operons are also subject to positive control via a stimulatory activator protein, such as catabolite activator protein (CAP), which promotes transcription when bound to a site within the promoter.

Activity The lac Operon in E. coli

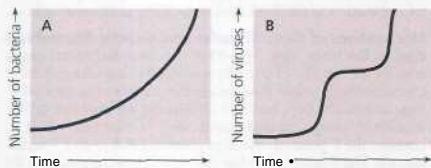

TESTING YOUR KNOWLEDGE

Evolution Connection

The success of some viruses lies in their ability to evolve within the host. Such a virus evades the host's defenses by rapidly mutating and producing many altered progeny viruses before the body can mount an attack. Thus, the viruses present late in infection differ from those that initially infected the body. Discuss this as an example of evolution in microcosm. "Which viral lineages tend to survive?"

Scientific Inquiry

When bacteria infect an animal, the number of bacteria in the body increases in an exponential fashion (graph A). After infection by a virulent animal virus with a lytic reproductive cycle, there is no evidence of infection for a while. Then, the number of viruses rises suddenly and subsequently increases in a series of steps (graph B). Explain the difference in the growth curves.

19 Eukaryotic Genomes Organization, Regulation, and Evolution

A Figure 19.1 DNA in a eukaryotic chromosome from a developing salamander egg.

Key Concepts

- 19.1 Chromatin structure is based on successive levels of DNA packing
- 19.2 Gene expression can be regulated at any stage, but the key step is transcription
- 19.3 Cancer results from genetic changes that affect cell cycle control
- 19.4 Eukaryotic genomes can have many noncoding DNA sequences in addition to genes
- 19.5 Duplications, rearrangements, and mutations of DNA contribute to genome evolution

Overview

How Eukaryotic Genomes Work and Evolve

Eukaryotic cells face the same challenges as prokaryotic cells in expressing their genes. However, the typical eukaryotic genome is much larger, and, in multicellular eukaryotes, cell specialization is crucial. These two features present a formidable information-processing task for the eukaryotic cell.

The human genome, for instance, has an estimated 25,000 genes—more than five times that of a typical prokaryote. It also includes an enormous amount of DNA that does not code for RNA or protein. Managing so much DNA requires that the genome be elaborately organized. In all organisms, DNA associates with proteins that condense it. In eukaryotes, the DNA-protein complex, called **chromatin**, is ordered into higher structural levels than the DNA-protein complex in prokaryotes. The fluorescence micrograph in **Figure 19.1**

gives a sense of the complex organization of the chromatin in a eukaryotic chromosome. Part of the chromatin is packed into the main axis (white) of the chromosome, while those parts that are being actively transcribed are spread out in loops (red).

Both prokaryotes and eukaryotes must alter their patterns of gene expression in response to changes in environmental conditions. Multicellular eukaryotes, in addition, must develop and maintain multiple cell types. Each of these cell types contains the same genome but expresses a different subset of genes, a significant challenge in gene regulation.

In this chapter, you will first learn about the structure of chromatin and how changes in chromatin structure affect gene expression. Then we will discuss other mechanisms for regulating expression of eukaryotic genes. As in prokaryotes, eukaryotic gene expression is most often regulated at the stage of transcription. Next, we will describe how disruptions in gene regulation can lead to cancer. In the remainder of the chapter, we will consider the various types of nucleotide sequences in eukaryotic genomes and explain how they arose and changed during genome evolution. Being aware of the forces that have shaped—and continue to shape—genomes will help you understand how biological diversity has evolved.

Concept 19.1

Chromatin structure is based on successive levels of DNA packing

Eukaryotic DNA is precisely combined with a large amount of protein, and the resulting chromatin undergoes striking changes in the course of the cell cycle (see Figure 12.6). In interphase cells stained for light microscopy, the chromatin

usually appears as a diffuse mass within the nucleus, suggesting that the chromatin is highly extended. As a cell prepares for mitosis, its chromatin coils and folds up (condenses), eventually forming a characteristic number of short, thick chromosomes that are distinguishable from each other with the light microscope.

Eukaryotic chromosomes contain an enormous amount of DNA relative to their condensed length. Each chromosome contains a single linear DNA double helix that, in humans, averages about 1.5×10^8 nucleotide pairs. If completely stretched out, such a DNA molecule would be about 4 cm long, thousands of times longer than the diameter of a cell nucleus. All this DNA—as well as the DNA of the other 45 human chromosomes—fits into the nucleus through the elaborate, multilevel system of DNA packing outlined in Figure 19.2.

Nucleosomes, or "Beads on a String"

Proteins called histones are responsible for the first level of DNA packing in chromatin. The mass of histone in chromatin is approximately equal to the mass of DNA. Histones have a high proportion of positively charged amino acids (lysine and arginine), and they bind tightly to the negatively charged DNA. (Recall that the phosphate groups of DNA give it a negative charge all along its length; see Figure 16.7.) Histones are very similar from one eukaryote to another, and similar proteins are found even in prokaryotes. The apparent conservation of histone genes during evolution probably reflects the pivotal role of histones in organizing DNA within cells.

In electron micrographs, unfolded chromatin has the appearance of beads on a string, as shown in Figure 19.2a. In this configuration, a chromatin fiber is 10 nm in diameter (the *10-nm fiber*). Each "bead" is a nucleosome, the basic unit of DNA packing; the "string" between the beads is called *linker DNA*. A nucleosome consists of DNA wound around a protein core composed of two molecules each of four types of histone; H2A, H2B, H3, and H4. The amino end (N-terminus) of each histone protein (the *histone tail*) extends outward from the nucleosome. A molecule of a fifth histone, called H1, attaches to the DNA near the nucleosome when a 10-nm chromatin fiber undergoes the next level of packing.

The association of DNA and histones in nucleosomes seems to remain essentially intact throughout the cell cycle. The histones leave the DNA only transiently during DNA replication, and, with very few exceptions, they stay with the DNA during transcription. How can DNA be transcribed when it is wrapped around histones in a nucleosome? Researchers have learned that changes in the shapes and positions of nucleosomes can allow RNA-synthesizing polymerases to move along the DNA. Later in this chapter, we will discuss some recent discoveries about the roles of histone tails and nucleosomes in the regulation of gene expression.

Higher Levels of DNA Packing

The next level of packing is due to interactions between the histone tails of one nucleosome and the linker DNA and nucleosomes to either side. With the aid of histone H1, these interactions cause the extended 10-nm fiber to coil or fold, forming a chromatin fiber roughly 30 nm in thickness, the *30-nm fiber* (Figure 19.2b). The 30-nm fiber, in turn, forms loops called *looped domains* attached to a chromosome scaffold made of non-histone proteins, thus making up a *300-nm fiber* (Figure 19.2c). In a mitotic chromosome, the looped domains themselves coil and fold, further compacting all the chromatin to produce the characteristic metaphase chromosome shown in the micrograph at the bottom of Figure 19.2d. Particular genes always end up located at the same places in metaphase chromosomes, indicating that the packing steps are highly specific and precise.

Though interphase chromatin is generally much less condensed than the chromatin of mitotic chromosomes, it shows several of the same levels of higher-order packing. Much of the chromatin comprising a chromosome is present as a 10-nm fiber, but some is compacted into a 30-nm fiber, which in some regions is further folded into looped domains. Although an interphase chromosome lacks an obvious scaffold, its looped domains seem to be attached to the nuclear lamina, on the inside of the nuclear envelope, and perhaps also to fibers of the nuclear matrix. These attachments may help organize regions of active transcription. The chromatin of each chromosome occupies a specific restricted area within the interphase nucleus, and the chromatin fibers of different chromosomes do not become entangled.

Even during interphase, the centromeres and telomeres of chromosomes, as well as other chromosomal regions in somatic cells, exist in the highly condensed state represented in Figure 19.2d. This type of interphase chromatin, visible as irregular clumps with a light microscope, is called **heterochromatin**, to distinguish it from the less compacted **euchromatin** ("true chromatin"). Because of its compaction, heterochromatin DNA is largely inaccessible to transcription enzymes and thus generally is not transcribed. In contrast, the looser packing of euchromatin makes its DNA accessible to enzymes and available for transcription. In the next section, we will consider how changes in chromatin and other mechanisms allow a cell to regulate which of its genes are expressed.

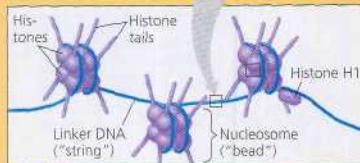

Concept Check 19.1

- Describe the structure of a nucleosome, the basic unit of DNA packing in eukaryotic cells.
- What chemical properties of histones and DNA enable these molecules to bind tightly together?
- In general, how does dense packing of DNA in chromosomes prevent gene expression?

For suggested answers, see Appendix A.

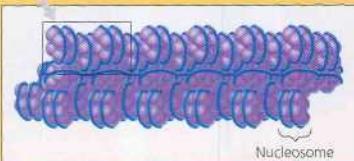

2 nm

10 nm

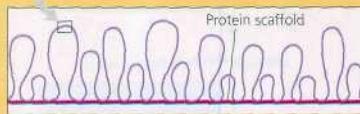

(a) Nucleosomes (10-nm fiber). DNA and histone molecules form “beads on a string,” the extended chromatin fiber seen during interphase. A nucleosome has eight histone molecules with the amino end (tail) of each projecting outward. A different type of histone, H1, can bind to DNA next to a nucleosome, where it helps to further compact the 10-nm fiber.

30 nm

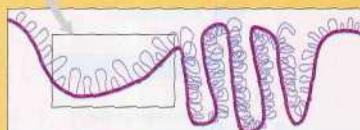

(b) 30-nm fiber. The string of nucleosomes coils to form a chromatin fiber that is 30 nm in diameter (tails not shown). This form is also seen during interphase.

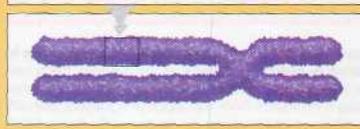

300 nm

(c) Looped domains (300-nm fiber). During prophase, further folding of the 30-nm fiber into looped domains forms a 300-nm fiber. The loops are attached to a scaffold of nonhistone proteins.

700 nm

1,400 nm

(d) Metaphase chromosome. The chromatin folds further, resulting in the maximally compacted chromosome seen at metaphase. Each metaphase chromosome consists of two chromatids.

A Figure 19.2 Levels of chromatin packing. This series of diagrams and transmission electron micrographs depicts a current model for the progressive stages of DNA coiling and folding.

Concept 19.2

Gene expression can be regulated at any stage, but the key step is transcription

All organisms must regulate which genes are expressed at any given time. Both unicellular organisms and the cells of multicellular organisms must continually turn genes on and off in response to signals from their external and internal environments. The cells of a multicellular organism must also regulate their gene expression on a more long-term basis. During development of a multicellular organism, its cells undergo a process of specialization in form and function called **cell differentiation**, resulting in several or many differentiated cell types. The mature human body, for instance, is composed of about 200 different cell types. Examples are muscle cells and nerve cells.

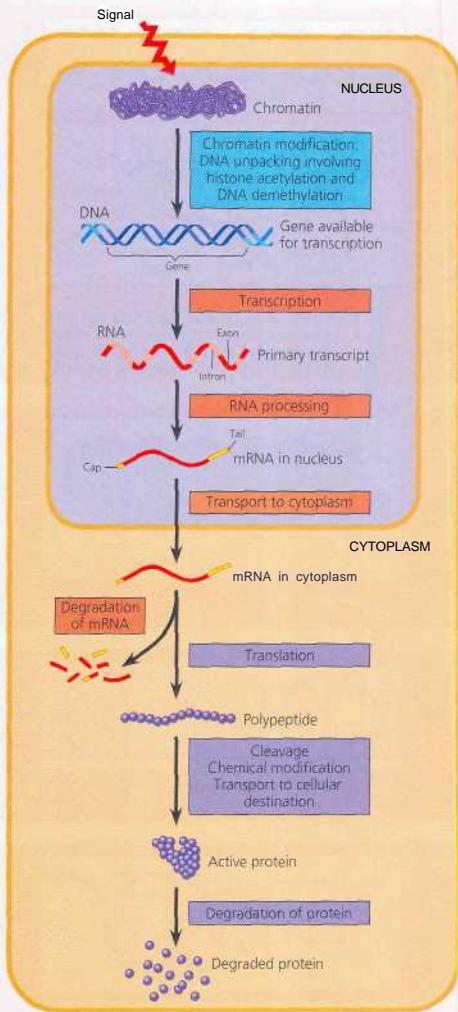

Differential Gene Expression

A typical human cell probably expresses about 20% of its genes at any given time. Highly differentiated cells, such as muscle cells, express an even smaller fraction of their genes. Although almost all the cells in an organism contain an identical genome,* the subset of genes expressed in the cells of each type is unique, allowing these cells to carry out their specific function. The differences between cell types, therefore, are due not to different genes being present, but to **differential** gene expression, the expression of different genes by cells with the same genome.

The genomes of eukaryotes may contain tens of thousands of genes, but for quite a few species, only a small amount of the DNA—about 1.5% in humans—codes for protein. Of the remaining DNA, a very small fraction consists of genes for RNA products such as ribosomal RNA and transfer RNA. Most of the rest of the DNA seems to be noncoding, although recently researchers have learned that a significant amount of it may be transcribed into RNAs of unknown function. In any case, the transcription proteins of a cell must locate the right genes at the right time, a task on a par with finding a needle in a haystack. When gene expression goes awry, serious imbalances and diseases, including cancer, can arise.

Figure 19.3 summarizes the entire process of gene expression in a eukaryotic cell, highlighting key stages in the expression of a protein-coding gene. Each stage depicted in Figure 19.3 is a potential control point at which gene expression can be turned on or off, accelerated, or slowed down.

*Cells of the immune system are an exception. During their differentiation, rearrangement of the immunoglobulin genes results in a change in the genome, which will be discussed in Chapter 43.

A Figure 19.3 Stages in gene expression that can be regulated in eukaryotic cells. In this diagram, the colored boxes indicate the processes most often regulated. The nuclear envelope separating transcription from translation in eukaryotic cells offers an opportunity for post-transcriptional control in the form of RNA processing that is absent in prokaryotes. In addition, eukaryotes have a greater variety of control mechanisms operating before transcription and after translation. The expression of any given gene, however, does not necessarily involve every stage shown; for example, not every polypeptide is cleaved. As in prokaryotes, transcription initiation is the most important control point.

Only 40 years ago, an understanding of the mechanisms that control gene expression in eukaryotes seemed almost hopelessly out of reach. Since then, new research methods, including advances in DNA technology (see Chapter 20), have empowered molecular biologists to uncover many of the details of eukaryotic gene regulation. In all organisms, the expression of specific genes is most commonly regulated at transcription, often in response to signals coming from outside the cell. For that reason, the term *gene* expression is often equated with transcription for both prokaryotes and eukaryotes. However, the greater complexity of eukaryotic cell structure and function provides opportunities for regulating gene expression at additional stages. In the following three sections, we'll examine some of the important control points of eukaryotic gene expression more closely.

Regulation of Chromatin Structure

As mentioned earlier, the structural organization of chromatin not only packs a cell's DNA into a compact form that fits inside the nucleus but also is important in helping regulate gene expression. Genes within heterochromatin, which is highly condensed, are usually not expressed. The repressive effect of heterochromatin has been seen in experiments in which a transcriptionally active gene was inserted into a region of heterochromatin in yeast cells; the inserted gene was no longer expressed. In addition, the location of a gene's promoter relative to nucleosomes and to the sites where the DNA attaches to the chromosome scaffold or nuclear lamina can also affect whether it is transcribed. A flurry of recent research indicates that certain chemical modifications to the histones and DNA of chromatin influence both chromatin structure and gene expression. Here we examine the effects of these modifications, which are catalyzed by specific enzymes.

Histone Modifications

There is mounting evidence that chemical modifications to histones play a direct role in the regulation of gene transcription. The N-terminus of each histone molecule in a nucleosome protrudes outward from the nucleosome (**Figure 19.4a**). These histone tails are accessible to various modifying enzymes, which catalyze the addition or removal of specific chemical groups.

In **histone acetylation**, acetyl groups ($-\text{COCH}_3$) are attached to positively charged lysines in histone tails; deacetylation is the removal of acetyl groups. When the histone tails of a nucleosome are acetylated, their positive charges are neutralized and they no longer bind to neighboring nucleosomes (**Figure 19.4b**). Recall that such binding promotes the folding of chromatin into a more compact structure; when this binding does not occur, chromatin has a looser structure. As a result, transcription proteins have easier access to genes in an

acetylated region. Researchers have shown that some enzymes that acetylate or deacetylate histones are closely associated with or even components of the transcription factors that bind to promoters (see Figure 17.8). In other words, histone acetylation enzymes may promote the initiation of transcription not only by modifying chromatin structure, but also by binding to, and thus "recruiting," components of the transcription machinery.

Several other chemical groups can be reversibly attached to amino acids in histone tails. For example, the addition of methyl groups ($-\text{CH}_3$) to histone tails (methylation) can lead

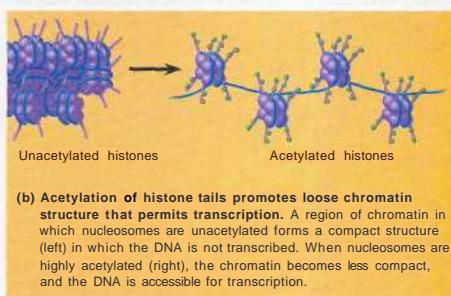

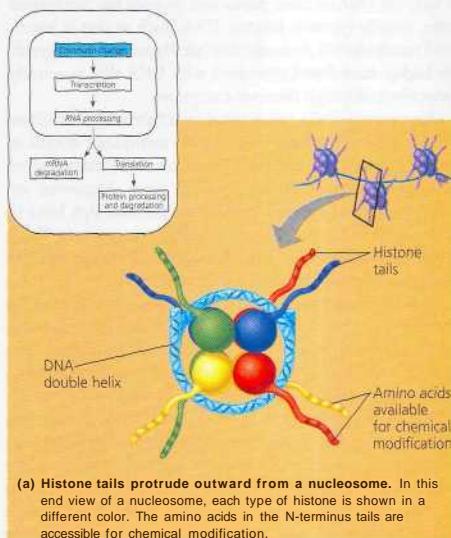

Figure 19.4 A simple model of histone tails and the effect of histone acetylation. In addition to acetylation, histones can undergo several other types of modifications that also help determine the chromatin configuration in a region.

to condensation of the chromatin. The recent discovery that this and many other modifications to histone tails can affect chromatin structure and gene expression has led to the *histone code hypothesis*. According to this model, specific combinations of modifications, rather than the overall level of histone acetylation, help determine the chromatin configuration, which in turn influences transcription.

DNA Methylation

Distinct from methylation of histone tails is the addition of methyl groups to certain bases in DNA after DNA is synthesized. In fact, the DNA of most plants and animals has methylated bases, usually cytosine. Inactive DNA, such as that of inactivated mammalian X chromosomes (see Figure 15.11), is generally highly methylated compared with DNA that is actively transcribed, although there are exceptions.

Comparison of the same genes in different tissues shows that the genes are usually more heavily methylated in cells in which they are not expressed. Removal of the extra methyl groups can turn on certain of these genes. Moreover, researchers have discovered that certain proteins that bind to methylated DNA recruit histone deacetylase enzymes. Thus, a dual mechanism, involving both DNA methylation and histone deacetylation, can repress transcription.

At least in some species, DNA methylation seems to be essential for the long-term inactivation of certain genes that occurs during normal cell differentiation in the embryo. For instance, experiments have shown that deficient DNA methylation due to lack of a methylating enzyme leads to abnormal embryonic development in organisms as different as mice and *Ambidopsis* (a plant). Once methylated, genes usually stay that way through successive cell divisions. At DNA sites where one strand is already methylated, methylation enzymes correctly methylate the daughter strand after each round of DNA replication. Methylation patterns are thus passed on, and cells forming specialized tissues keep a chemical record of what occurred during embryonic development. A methylation pattern maintained in this way also accounts for genomic imprinting in mammals, where methylation permanently regulates expression of either the maternal or paternal allele of certain genes at the start of development (see Chapter 15).

Epigenetic Inheritance

The chromatin modifications that we have just discussed do not involve a change in the DNA sequence, and yet they may be passed along to future generations of cells. Inheritance of traits transmitted by mechanisms not directly involving the nucleotide sequence is called epigenetic inheritance. Researchers are amassing more and more evidence for the importance of epigenetic information in regulation of gene expression. Clearly, enzymes that modify chromatin structure appear to be integral parts of the cell's machinery for regulating transcription.

Regulation of Transcription Initiation

Chromatin-modifying enzymes provide initial control of gene expression by making a region of DNA either more or less able to bind the transcription machinery. Once a gene is optimally modified for expression, the initiation of transcription is the most important and universally used stage at which gene expression is regulated. Before looking at how cells control their transcription, let's review the structure of a typical eukaryotic gene and its transcript.

Organization of a Typical Eukaryotic Gene

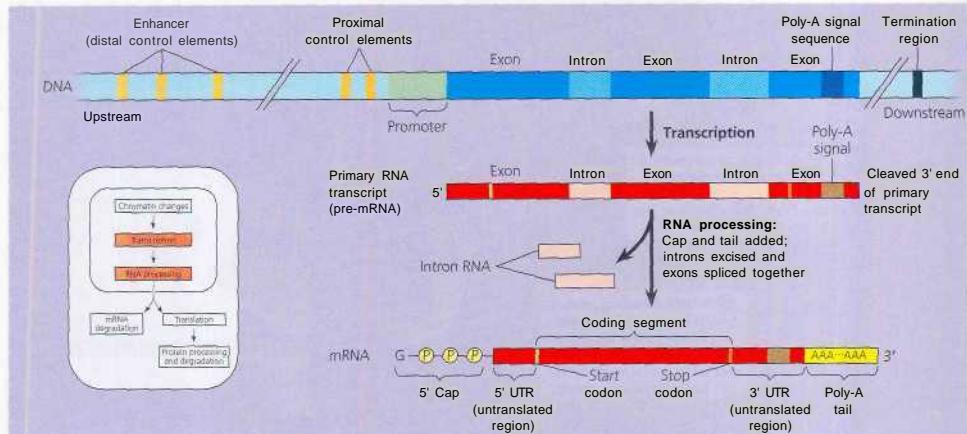

A eukaryotic gene and the DNA elements (segments) that control it are typically organized as shown in Figure 19.5, which extends what you learned about eukaryotic genes in Chapter 17. Recall that a cluster of proteins called a *transcription initiation complex* assembles on the promoter sequence at the "upstream" end of the gene. One of these proteins, RNA polymerase II, then proceeds to transcribe the gene, synthesizing a primary RNA transcript (pre-mRNA). RNA processing includes enzymatic addition of a 5' cap and a poly-A tail, as well as splicing out of introns, to yield a mature mRNA. Associated with most eukaryotic genes are multiple control elements, segments of noncoding DNA that help regulate transcription by binding certain proteins. These control elements and the proteins they bind are critical to the precise regulation of gene expression seen in different cell types.

The Roles of Transcription Factors

To initiate transcription, eukaryotic RNA polymerase requires the assistance of proteins called transcription factors (see Figure 17.8). Because the transcription factors mentioned in Chapter 17 are essential for the transcription of *all* protein-coding genes, they are sometimes called *general* transcription factors. Only a few general transcription factors independently bind a DNA sequence, such as the TATA box within the promoter; the others primarily bind proteins, including each other and RNA polymerase II. Protein-protein interactions are crucial to the initiation of eukaryotic transcription. Only when the complete initiation complex has assembled can the polymerase begin to move along the DNA template strand, producing a complementary strand of RNA.

The interaction of general transcription factors and RNA polymerase II with a promoter usually leads to only a low rate of initiation and production of few RNA transcripts. In eukaryotes, high levels of transcription of particular genes at the appropriate time and place depend on the interaction of control elements with other proteins that can be thought of as *specific* transcription factors.

Enhancers and Specific Transcription Factors. As you can see in Figure 19.5, some control elements, named *proximal*

A. Figure 19.5 A eukaryotic gene and its transcript. Each eukaryotic gene has a promoter, a DNA sequence where RNA polymerase binds and starts transcription, proceeding "downstream." A number of control elements (gold) are involved in regulating the initiation of transcription; these are DNA sequences located near (proximal to)

or far from (distal to) the promoter. Distal control elements can be grouped together as enhancers. A polyadenylation (poly-A) signal in the last exon of the gene is transcribed into an RNA sequence that determines where the transcript is cleaved and the poly-A tail added. Transcription may continue for hundreds of nucleotides beyond the poly-A signal before

terminating. RNA processing of the primary transcript into a functional mRNA involves three steps: addition of the 5' cap, addition of the poly-A tail, and splicing. In the cell, the 5' cap is added soon after transcription is initiated; splicing and poly-A tail addition may also occur while transcription is still under way (see Figure 17.9).

control elements, are located close to the promoter. (Although some biologists consider proximal control elements part of the promoter, we do not.) The more distant distal control elements, groups of which are called enhancers, may be thousands of nucleotides upstream or downstream of a gene or even within an intron. A given gene may have multiple enhancers, each active at a different time or in a different cell type or location in the organism.

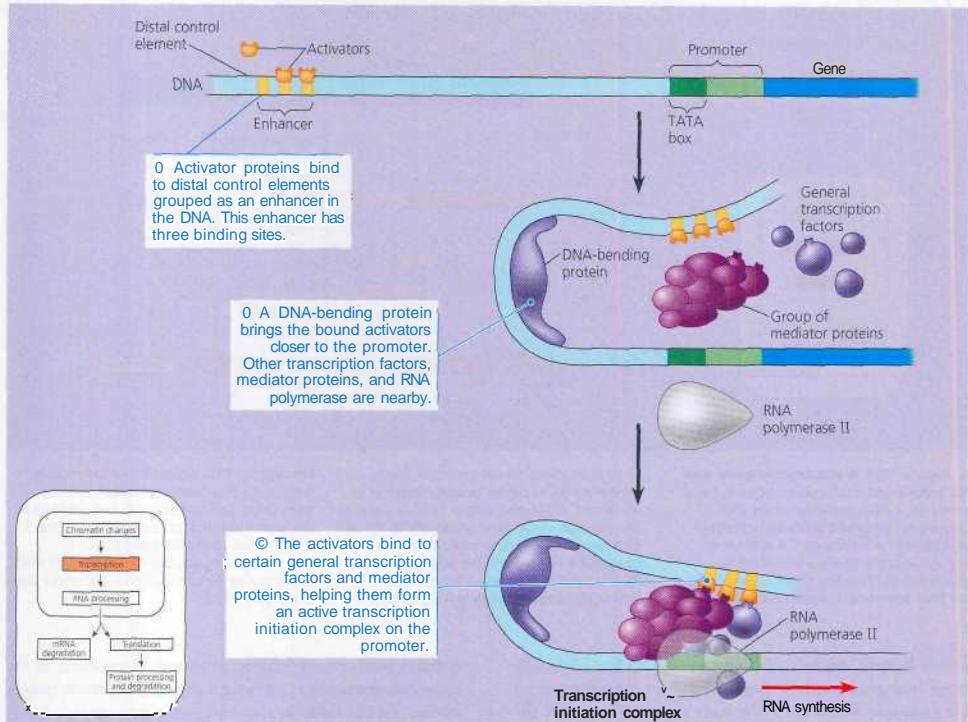

The interactions between enhancers and specific transcription factors called activators or repressors are particularly important in controlling gene expression. An activator is a protein that binds to an enhancer and stimulates transcription of a gene. Figure 19.6, on the next page, shows a current model for how binding of activators to enhancers located far from the promoter can influence transcription. Protein-mediated bending of the DNA is thought to bring the bound activators in contact with a group of so-called *mediator* proteins, which in turn interact with proteins at the promoter. These multiple protein-protein interactions help assemble and position the initiation complex on the promoter.

Hundreds of transcription activators have been discovered in eukaryotes. Researchers have identified two common structural elements in a large number of activator proteins: a DNA-binding domain—a part of the protein's three-dimensional structure that binds to DNA—and one or more activation domains. Activation

domains bind other regulatory proteins or components of the transcription machinery, allowing a sequence of protein-protein interactions that result in transcription of a given gene.

Some specific transcription factors function as repressors to inhibit expression of a particular gene. Eukaryotic repressors can cause inhibition of gene expression in several different ways. Certain repressors block the binding of activators either to their control elements or to components of the transcription machinery. Other repressors bind directly to their own control elements in an enhancer and act to turn off transcription even in the presence of activators.

In addition to affecting assembly of the transcription machinery directly, some activators and repressors act indirectly by influencing chromatin structure. Recall that a gene present in a region of chromatin with high levels of histone acetylation is able to bind the transcription machinery, whereas a gene in a region of chromatin with low levels of histone acetylation is not (see Figure 19.4). Studies in yeast and mammals show that some activators recruit proteins that acetylate histones near the promoters of specific genes, thus promoting transcription. In contrast, other repressors recruit proteins that deacetylate histones, leading to reduced transcription, a phenomenon referred to as *silencing*. Indeed, recruitment of chromatin-modifying proteins seems to be the most common mechanism of repression in eukaryotes.

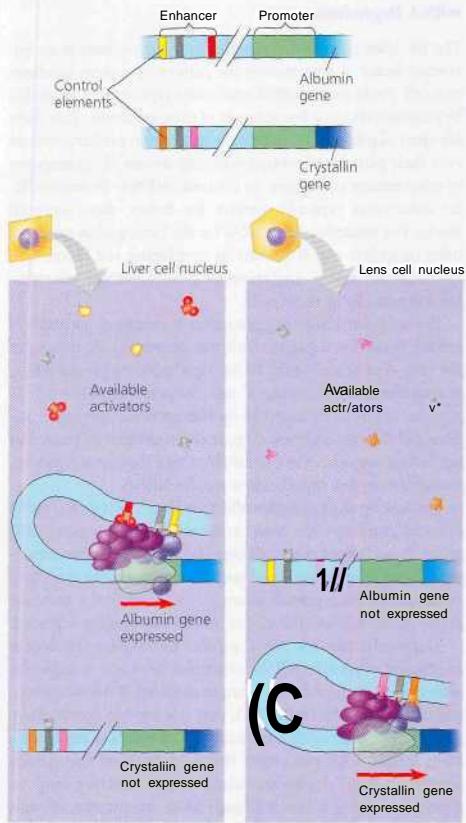

A Figure 19.6 A model for the action of enhancers and transcription activators.

Bending of the DNA by a protein enables enhancers to influence a promoter hundreds or even thousands of nucleotides away. Specific transcription factors called activators bind to the enhancer DNA sequences and then to a group of mediator proteins, which in turn bind to general transcription factors assembling the transcription initiation complex. These protein-protein interactions facilitate the correct positioning of the complex on the promoter and the initiation of RNA synthesis. Only one enhancer is shown in this figure, but a gene may have several that act at different times or in different cell types.

Combinatorial Control of Gene Activation. In eukaryotes, the precise control of transcription depends largely on the binding of activators to DNA control elements. Considering the very large number of genes that must be regulated in a typical animal or plant cell, the number of completely different nucleotide sequences found in control elements is surprisingly small. A dozen or so short nucleotide sequences appear again and again in the control elements for different genes. On average, each enhancer is composed of about ten control elements, each of which can bind only one or two specific transcription factors. The particular combination of control elements in an enhancer associated

with a gene turns out to be more important than the presence of a single unique control element in regulating transcription of the gene.

Even with only a dozen control element sequences available, a large number of combinations are possible. A particular combination of control elements will be able to activate transcription only when the appropriate activator proteins are present, such as at a precise time during development or in a particular cell type. The example in **Figure 19.7** illustrates how the use of different combinations of control elements to activate transcription allows exquisite regulation of transcription with a small set of control elements.

(a) Liver cell. The albumin gene is expressed, and the crystallin gene is not.

(b) Lens cell. The crystallin gene is expressed, and the albumin gene is not.

A Figure 19.7 Cell type-specific transcription. Both liver cells and lens cells have the genes for making the proteins albumin and crystallin, but only liver cells make albumin (a blood protein) and only lens cells make crystallin (the main component of the lens of the eye). The specific transcription factors (activators and repressors) made in a particular type of cell determine which genes are expressed. In this example, the genes for albumin and crystallin are shown at the top, each with an enhancer made up of three different control elements. Although the enhancers for the two genes share one control element, each enhancer has a unique combination of elements. All the activators required for high-level expression of the albumin gene are present only in liver cells (a), whereas the activators needed for expression of the crystallin gene are present only in lens cells (b). For simplicity, we consider only the role of activators here, although the presence or absence of repressors may also influence transcription in certain cell types.

Coordinately Controlled Genes

How does the eukaryotic cell deal with genes of related function that need LO be turned on or off at the same time? In Chapter 18, you learned that in prokaryotes, such coordinately controlled genes are often clustered into an operon, which is regulated by a single promoter and transcribed into a single mRNA molecule. Thus, the genes are expressed together, and the encoded proteins are produced concurrently. With rare exceptions, operons that work in this way have not been found in eukaryotic cells.

Recent studies of the genomes of several eukaryotic species have found that some co-expressed genes are clustered near one another on the same chromosome. Examples include certain genes in the testis of the fruit fly and muscle-related genes in a small worm called a nematode. Unlike genes in prokaryotic operons, however, each eukaryotic gene in these clusters has its own promoter and is individually transcribed. The coordinate regulation of clustered genes in eukaryotic cells is thought to involve changes in the chromatin structure that make the entire group of genes either available or unavailable for transcription.

More commonly, co-expressed eukaryotic genes, such as genes coding for the enzymes of a metabolic pathway, are found scattered over different chromosomes. In these cases, coordinate gene expression seems to depend on the association of a specific control element or combination of elements with every gene of a dispersed group. Copies of the activators that recognize these control elements bind to them, promoting simultaneous transcription of the genes, no matter where they are in the genome.

Coordinate control of dispersed genes in a eukaryotic cell often occurs in response to external chemical signals. A steroid hormone, for example, enters a cell and binds to a specific intracellular receptor protein, forming a hormone-receptor complex that serves as a transcription activator (see Figure 11.6). Every gene whose transcription is stimulated by a particular steroid hormone, regardless of its chromosomal location, has a control element recognized by that hormone-receptor complex.

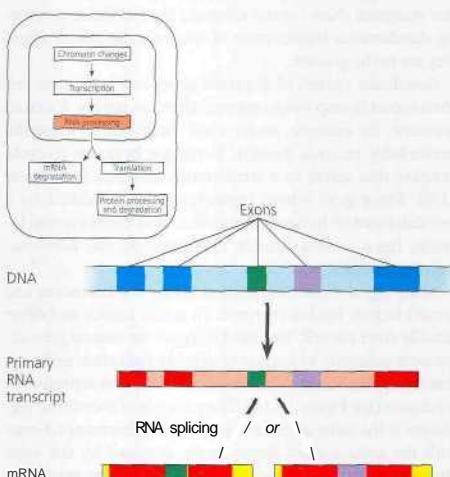

Many signal molecules, such as nonsteroid hormones and growth factors, bind to receptors on a cell's surface and never actually enter the cell. This kind of signal can control gene expression indirectly by triggering signal transduction pathways that lead to activation of particular transcription activators or repressors (see Figure 11.14). The principle of coordinate regulation is the same as in the case of steroid hormones: Genes with the same control elements are activated by the same chemical signals. Systems for coordinating gene regulation probably arose early in evolutionary history and evolved by the duplication and distribution of control elements within the genome.

Mechanisms of Post-Transcriptional Regulation

Transcription alone does not constitute gene expression. The expression of a protein-coding gene is ultimately measured by the amount of functional protein a cell makes, and much happens between the synthesis of the RNA transcript and the activity of the protein in the cell. An increasing number of examples are being found of regulator¹ mechanisms that operate at various stages after transcription (see Figure 19.3). These mechanisms allow a cell to fine-tune gene expression rapidly in response to environmental changes without altering its transcription patterns. Here we discuss how cells can regulate gene expression once a gene has been transcribed.

RNA Processing

RNA processing in the nucleus and the export of mature RNA to the cytoplasm provide several opportunities for regulating gene expression that are not available in prokaryotes. One example of regulation at the RNA-processing level is alternative RNA splicing, in which different mRNA molecules are produced from the same primary transcript, depending on which RNA segments are treated as exons and which as introns (Figure 19.8). Regulatory proteins specific to a cell type control intron-exon choices by binding to regulatory sequences within the primary transcript.

A Figure 19.8 Alternative RNA splicing. The primary transcripts of some genes can be spliced in more than one way, generating different mRNA molecules. Notice in this example that one mRNA molecule has ended up with the green exon and the other with the purple exon. With alternative splicing, an organism can produce more than one type of polypeptide from a single gene.

mRNA Degradation

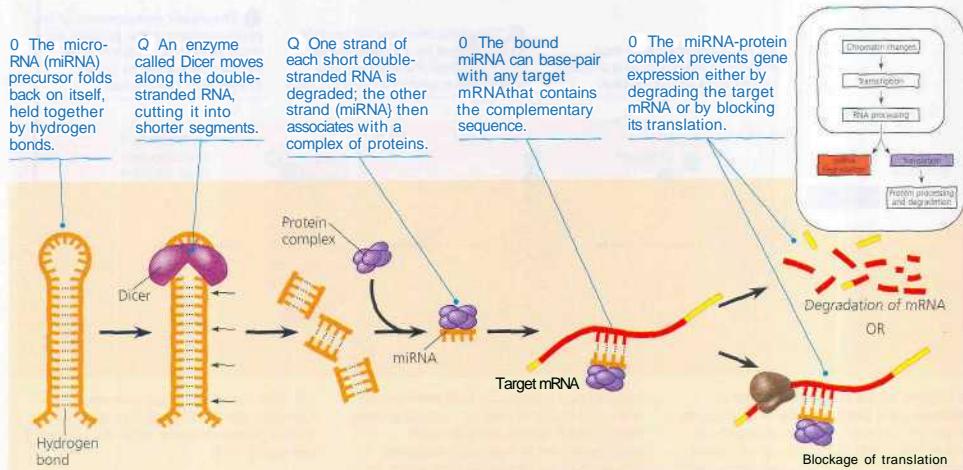

The life span of mRNA molecules in the cytoplasm is an important factor in determining the pattern of protein synthesis in a cell. Prokaryotic mRNA molecules typically are degraded by enzymes within a few minutes of their synthesis. This short life span of prokaryotic mRNAs is one reason prokaryotes can vary their patterns of protein synthesis so quickly in response to environmental changes. In contrast, mRNAs in multicellular eukaryotes typically survive for hours, days, or even weeks. For instance, the mRNAs for the hemoglobin polypeptides (α -globin and β -globin) in developing red blood cells are unusually stable, and these long-lived mRNAs are translated repeatedly in these cells.

Research on yeasts suggests that a common pathway of mRNA breakdown begins with the enzymatic shortening of the poly-A tail (see Figure 19.5). This helps trigger the action of enzymes that remove the 5' cap (the two ends of the mRNA may be briefly held together by the proteins involved). Removal of the cap, a critical step, is also regulated by particular nucleotide sequences in the mRNA. Once the cap is removed, nuclelease enzymes rapidly chew up the mRNA.

Nucleotide sequences that affect the length of time an mRNA remains intact are often found in the untranslated region 5'UTR) at the 5' end of the molecule (see Figure 19.5). In one experiment, researchers transferred such a sequence from the short-lived mRNA for a growth factor to the 5' end of a normally stable globin mRNA. The globin mRNA was quickly degraded.

During the past few years, another mechanism that blocks expression of specific mRNA molecules has come to light. Researchers have found small single-stranded RNA molecules, called microRNAs (miRNAs), that can bind to complementary sequences in mRNA molecules. The miRNAs are formed from longer RNA precursors that fold back on themselves, forming a long, double-stranded hairpin structure held together by hydrogen bonds (Figure 19.9). An enzyme, fittingly called Dicer, then cuts the double-stranded RNA molecule into short fragments. One of the two strands is degraded, and the other strand (miRNA) associates with a large protein complex and acts as a homing device, directing the complex to any mRNA molecules that have the complementary sequence. Depending on various factors, the miRNA-protein complex then either degrades the target mRNA or blocks its translation.

Inhibition of gene expression by RNA molecules was first observed by biologists who noticed that injecting double-stranded RNA molecules into a cell somehow turned off a gene with the same sequence. They called this experimental phenomenon RNA interference (or RNAi). It was later shown to be due to small interfering RNAs (siRNAs), RNAs of similar size and function as miRNAs. In fact, subsequent research showed that the cellular machinery that generates siRNAs is the very same as that responsible for producing miRNAs naturally in the cell. The mechanisms by which these small RNAs function appear to be similar as well.

k Figure 19.9 Regulation of gene expression by microRNAs (miRNAs). RNA transcripts from miRNA-encoding genes are processed into miRNAs, which prevent expression of complementary mRNAs (siRNAs are believed to be generated and to function in a similar way).

Because the cellular RNAi pathway can lead to the destruction of RNAs with sequences complementary to those found in double-stranded RNA molecules, it is commonly believed to have originated as a natural defense against infection by RNA viruses. However, the fact that the RNAi pathway can affect expression of cellular genes also supports alternative models. In any case, it is clear that RNAi plays an important role in regulating gene expression in the cell.

Initiation of Translation

Translation presents another opportunity for regulating gene expression; such regulation occurs most commonly at the initiation stage (see Figure 17.17). The initiation of translation of selected mRNAs can be blocked by regulatory proteins that bind to specific sequences or structures within the untranslated region at the 5' end (5' UTR) of the mRNA, preventing the attachment of ribosomes. A different mechanism for blocking translation is seen in a variety of mRNAs present in the egg cells of many organisms: These stored mRNAs lack poly-A tails of sufficient size to allow translation initiation. At the appropriate time during embryonic development, a cytoplasmic enzyme adds more A residues, allowing translation to begin.

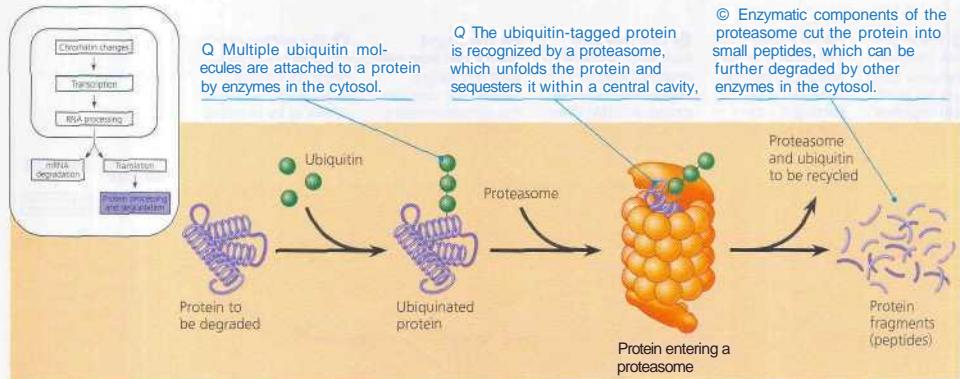

Alternatively, translation of all the mRNAs in a cell may be regulated simultaneously. In a eukaryotic cell, such "global" control usually involves the activation or inactivation of one or more of the protein factors required to initiate translation. This mechanism also plays a role in starting translation of mRNAs that are stored in egg cells. Just after fertilization,

translation is triggered by the sudden activation of translation initiation factors. The response is a burst of synthesis of the proteins encoded by the stored mRNAs. Some plants and algae store mRNAs during periods of darkness; light then triggers the reactivation of the translational apparatus.

Protein Processing and Degradation

The final opportunities for controlling gene expression occur after translation. Often, eukaryotic polypeptides must be processed to yield functional protein molecules. For instance, cleavage of the initial insulin polypeptide (pro-insulin) forms the active hormone. In addition, many proteins undergo chemical modifications that make them functional. Regulatory proteins are commonly activated or inactivated by the reversible addition of phosphate groups, and proteins destined for the surface of animal cells acquire sugars. Cell-surface proteins and many others must also be transported to target destinations in the cell in order to function. Regulation might occur at any of the steps involved in modifying or transporting a protein.

Finally, the length of time each protein functions in the cell is strictly regulated by means of selective degradation. Many proteins, such as the cyclins involved in regulating the cell cycle, must be relatively short-lived if the cell is to function appropriately (see Figure 12.16). To mark a particular protein for destruction, the cell commonly attaches molecules of a small protein called ubiquitin to the protein. Giant protein complexes called proteasomes then recognize the ubiquitin-tagged

A Figure 19.10 Degradation of a protein by a proteasome. A proteasome, an enormous protein complex with a shape suggesting a trash can, chops up unneeded proteins in the cell. In most cases, the proteins

attacked by a proteasome have been tagged with short chains of ubiquitin, a small protein. Steps 1 and 3 require ATP. Eukaryotic proteasomes are as massive as ribosomal subunits and are distributed throughout the

cell. Their barrel-like shape somewhat resembles that of chaperone proteins, which protect protein structure rather than destroy it (see Figure 5.23).

protein molecules and degrade them (**Figure 19.10**). The importance of proteasomes is underscored by the finding that mutations making cell cycle proteins impervious to proteasome degradation can lead to cancer.

Concept Check 19.2

- In general, what is the effect of histone acetylation and DNA methylation on gene expression?
- Compare the roles of general and specific transcription factors in regulating gene expression.
- If you compared the nucleotide sequences of the distal control elements in the enhancers of three coordinately regulated genes, what would you expect to find? Why?
- Once mRNA encoding a particular protein reaches the cytoplasm, what are four mechanisms that can regulate the amount of the active protein in the cell?

For suggested answers, see Appendix A.

Concept 19.3

Cancer results from genetic changes that affect cell cycle control

In Chapter 12, we considered cancer as a set of diseases in which cells escape from the control mechanisms normally limiting their growth. Now that we have discussed the molecular

basis of gene expression and its regulation, we are ready to look at cancer more closely. The gene regulation systems that go wrong during cancer turn out to be the very same systems that play important roles in embryonic development, the immune response, and many other biological processes. Thus, research into the molecular basis of cancer has both benefited from and informed many other fields of biology.

Types of Genes Associated with Cancer

The genes that normally regulate cell growth and division during the cell cycle include genes for growth factors, their receptors, and the intracellular molecules of signaling pathways. (To review the cell cycle, see Chapter 12.) Mutations that alter any of these genes in somatic cells can lead to cancer. The agent of such change can be random spontaneous mutation. However, it is likely that many cancer-causing mutations result from environmental influences, such as chemical carcinogens, X-rays, and certain viruses.

An early breakthrough in understanding cancer came in 1911, when Peyton Rous discovered a virus that causes cancer in chickens. Since then, scientists have recognized a number of *tumor viruses* that cause cancer in various animals, including humans (see Table 18.1). The Epstein-Barr virus, a herpesvirus that causes infectious mononucleosis, has been linked to several types of cancer, notably Burkitt's lymphoma. Papilloma viruses (of the papovavirus group) are associated with cancer of the cervix. Among the retroviruses, one called HTLV-1 causes a type of adult leukemia. All tumor viruses transform cells into cancer cells through the integration of viral nucleic acid into host cell DNA.

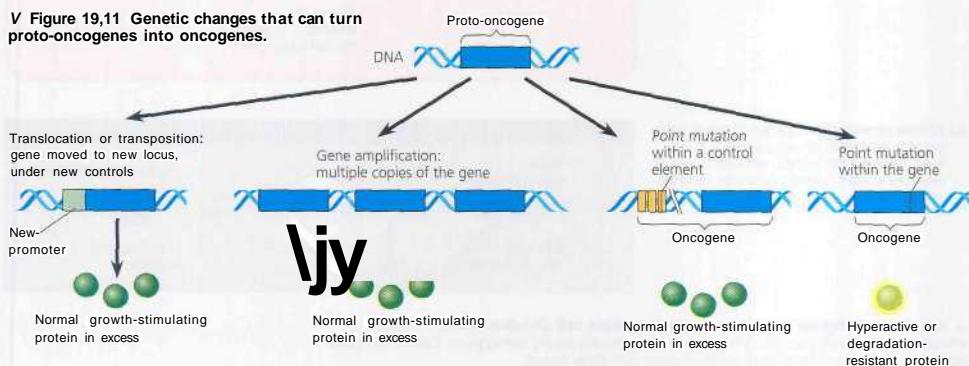

Ontogenes and Proto-Oncogenes

Research on tumor viruses led to the discovery of cancer-causing genes called oncogenes (from the Greek *onco*, tumor) in certain retroviruses. Subsequently, close counterparts of these oncogenes were found in the genomes of humans and other animals. The normal cellular genes, called proto-oncogenes, code for proteins that stimulate normal cell growth and division.

How might a proto-oncogene—a gene that has an essential function in normal cells—become an oncogene, a cancer-causing gene? In general, an oncogene arises from a genetic change that leads to an increase either in the amount of the proto-oncogenes protein product or in the intrinsic activity of each protein molecule. The genetic changes that convert proto-oncogenes to oncogenes fall into three main categories: movement of DNA within the genome, amplification of a proto-oncogene, and point mutations in a control element or in the proto-oncogene itself (**Figure 19.11**).

Cancer cells are frequently found to contain chromosomes that have broken and rejoined incorrectly, translocating fragments from one chromosome to another (see Figure 15.14). If a translocated proto-oncogene ends up near an especially active promoter (or other control element), its transcription may increase, making it an oncogene. Movement of transposable elements also may place a more active promoter near a proto-oncogene, increasing its expression. (Eukaryotic transposable elements are described later in the chapter.) The second main type of genetic change, amplification, increases the number of copies of the proto-oncogene in the cell. The third possibility is a point mutation either (1) in the promoter or an enhancer that controls a proto-oncogene, causing an increase in its expression, or (2) in the coding sequence, changing the gene's product to a protein that is more active or more resistant to degradation than the normal protein. All these mechanisms can lead to abnormal stimulation of the cell cycle and put the cell on the path to malignancy.

V **Figure 19.11** Genetic changes that can turn proto-oncogenes into oncogenes.

Tumor-Suppressor Genes

In addition to genes whose products normally promote cell division, cells contain genes whose normal products *inhibit* cell division. Such genes are called tumor-suppressor genes because the proteins they encode help prevent uncontrolled cell growth. Any mutation that decreases the normal activity of a tumor-suppressor protein may contribute to the onset of cancer, in effect stimulating growth through the absence of suppression.

The protein products of tumor-suppressor genes have various functions. Some tumor-suppressor proteins normally repair damaged DNA, a function that prevents the cell from accumulating cancer-causing mutations. Other tumor-suppressor proteins control the adhesion of cells to each other or to the extracellular matrix; proper cell anchorage is crucial in normal tissues—and often absent in cancers. Still other tumor-suppressor proteins are components of cell-signaling pathways that inhibit the cell cycle.

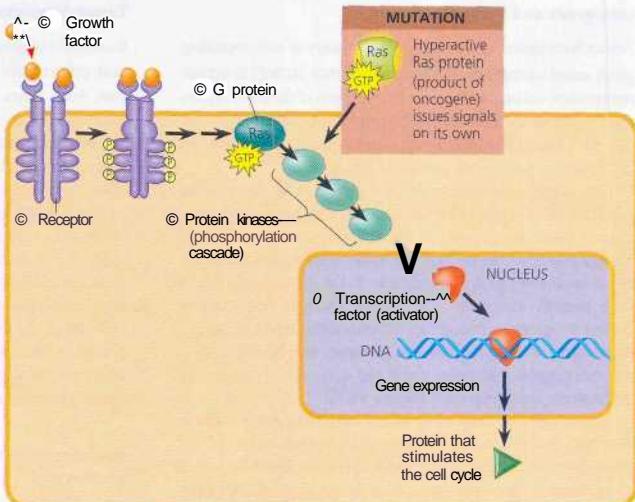

Interference with Normal Cell-Signaling Pathways

The proteins encoded by many proto-oncogenes and tumor-suppressor genes are components of cell-signaling pathways. Let's take a closer look at how such proteins function in normal cells and what goes wrong with their function in cancer cells. We will focus on the products of two key genes, the *ras* proto-oncogene and the *p53* tumor-suppressor gene. Mutations in *ras* occur in about 30% of human cancers; mutations in *p53* in more than 50%.

The *Ras* protein, encoded by the *ras* gene, is a G protein that relays a signal from a growth factor receptor on the plasma membrane to a cascade of protein kinases. The cellular response at the end of the pathway is the synthesis of a protein that stimulates the cell cycle (**Figure 19.12a**, on the next page). Normally, such a pathway will not operate unless triggered by

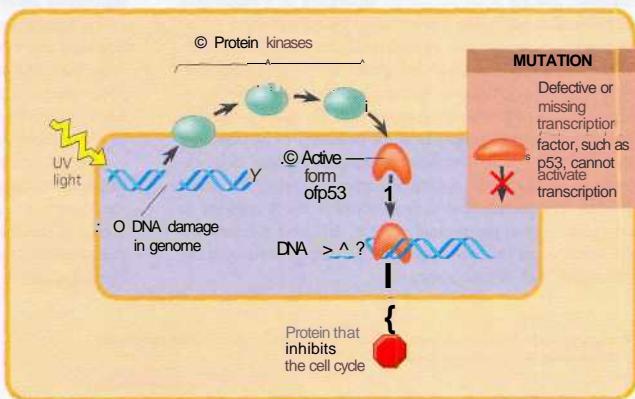

(a) Cell cycle-stimulating pathway.

This pathway is triggered by a growth factor that binds to its receptor in the plasma membrane. The signal is relayed to a G protein called Ras. Like all G proteins, Ras is active when GTP is bound to it. Ras passes the signal to a series of protein kinases. The last kinase activates a transcription activator that turns on one or more genes for proteins that stimulate the cell cycle. If a mutation makes Ras or any other pathway component abnormally active, excessive cell division and cancer may result.

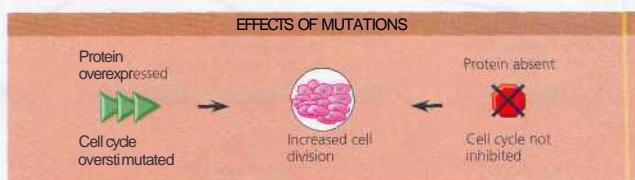

(b) Cell cycle-inhibiting pathway.

In this pathway, DNA damage is an intracellular signal that is passed via protein kinases and leads to activation of p53. Activated p53 promotes transcription of the gene for a protein that inhibits the cell cycle. The resulting suppression of cell division ensures that the damaged DNA is not replicated. Mutations causing deficiencies in any pathway component can contribute to the development of cancer.

(c) Effects of mutations. Increased cell division, possibly leading to cancer, can result if the cell cycle is overstimulated, as in (a), or not inhibited when it normally would be, as in (b).

A Figure 19.12 Signaling pathways that regulate cell division. Both stimulatory and inhibitory pathways regulate the cell cycle, commonly by influencing transcription. Cancer can result from aberrations in such pathways, in combination with other factors.

the appropriate growth factor. But certain mutations in the ras gene can lead to production of a hyperactive Ras protein that triggers the kinase cascade, resulting in increased cell division even in the absence of growth factor. In fact, hyperactive versions or excess amounts of any of the pathway's components can have the same outcome: excessive cell division.

Figure 19.12b shows a pathway in which a signal leads to the synthesis of a protein that suppresses the cell cycle. In this case, the signal is damage to the cell's DNA, perhaps as the result of exposure to ultraviolet light. Operation of this signaling pathway blocks the cell cycle until the damage has been repaired. Otherwise, the damage might contribute to tumor formation by causing mutations or chromosomal abnormalities. Thus, the genes for the components of the pathway act as tumor-suppressor genes. The tumor-suppressor protein encoded by the wild-type *p53* gene is a specific transcription factor that promotes the synthesis of cell cycle-inhibiting proteins. That is why a mutation knocking out the *p53* gene, like a mutation that leads to a hyperactive Ras protein, can lead to excessive cell growth and cancer (**Figure 19.12c**).

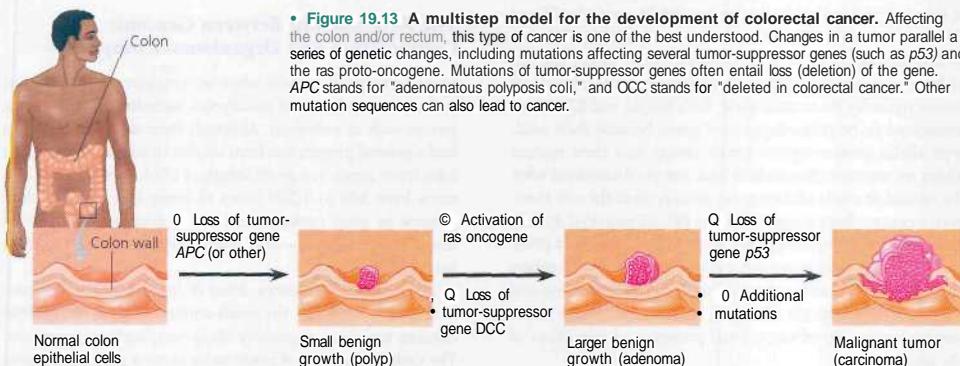

The *p53* gene, named for the 53,000-dalton molecular weight of its protein product, has been called the "guardian angel of the genome." Once activated, for example by DNA damage, the *p53* protein functions as an activator for several genes. Often it activates a gene called *p21*, whose product halts the cell cycle by binding to cyclin-dependent kinases, allowing time for the cell to repair the DNA; the *p53* protein can also turn on genes directly involved in DNA repair. When DNA damage is irreparable, *p53* activates "suicide" genes, whose protein products cause cell death by a process called apoptosis (see Figure 21.18). Thus, in at least three ways, *p53* prevents a cell from passing on mutations due to DNA damage. If mutations do accumulate and the cell survives through many divisions—as is more likely if the *p53* tumor-suppressor gene is defective or missing—cancer may ensue.

The Multistep Model of Cancer Development

More than one somatic mutation is generally needed to produce all the changes characteristic of a full-fledged cancer cell. This may help explain why the incidence of cancer increases greatly with age. If cancer results from an accumulation of mutations and if mutations occur throughout life, then the longer we live, the more likely we are to develop cancer.

The model of a multistep path to cancer is well supported by studies of one of the best understood types of human cancer, colorectal cancer. About 135,000 new cases of colorectal cancer are diagnosed each year in the United States, and the disease causes 60,000 deaths per year. Like most cancers, colorectal cancer develops gradually (**Figure 19.13**). The first sign is often a polyp, a small, benign growth in the colon lining. The cells of the polyp look normal, although they divide unusually frequently. The tumor grows and may eventually become malignant, invading other tissues. The development of a malignant tumor is paralleled by a gradual accumulation of mutations that convert proto-oncogenes to oncogenes and knock out tumor-suppressor genes. A ras oncogene and a mutated *p53* tumor-suppressor gene are often involved.

About a half dozen changes must occur at the DNA level for a cell to become fully cancerous. These usually include the appearance of at least one active oncogene and the mutation or loss of several tumor-suppressor genes. Furthermore, since mutant tumor-suppressor alleles are usually recessive, in most cases mutations must knock out *both* alleles in a cell's genome to block tumor suppression. (Most oncogenes, on the other hand, behave as dominant alleles.) Finally, in many malignant tumors, the gene for telomerase is activated. This enzyme prevents the shortening of chromosome ends during DNA replication (see Figure 16.19). Production of telomerase in cancer cells removes a natural limit on the number of times the cells can divide.

Viruses seem to play a role in about 15% of human cancer cases worldwide. Viruses contribute to cancer development by integrating their genetic material into the DNA of infected cells. By this process, a retrovirus may donate an oncogene to the cell. Alternatively, integrated viral DNA may disrupt a tumor-suppressor gene or convert a proto-oncogene to an oncogene. Finally, some viruses produce proteins that inactivate p53 and other tumor-suppressor proteins, thus making the cell more prone to becoming cancerous.

Inherited Predisposition to Cancer

The fact that multiple genetic changes are required to produce a cancer cell helps explain the observation that certain cancers run in some families. An individual inheriting an oncogene or a mutant allele of a tumor-suppressor gene is one step closer to accumulating the necessary mutations for cancer to develop than is an individual without any such mutations.

Geneticists are devoting much effort to identifying inherited cancer alleles so that predisposition to certain cancers can be detected early in life. About 15% of colorectal cancers, for example, involve inherited mutations. Many of these affect the tumor-suppressor gene called *adenomatous polyposis coli*, or *APC* (see Figure 19.13). This gene has multiple functions in the cell, including regulation of cell migration and adhesion. Even in patients with no family history of the disease, the *APC* gene is mutated in 60% of colorectal cancers. In these individuals, new mutations must occur in both *APC* alleles before the gene's function is lost. Since only 15% of colorectal cancers are associated with known inherited mutations, researchers continue in their efforts to identify "markers" that could predict the risk of developing this type of cancer.

There is evidence of a strong inherited predisposition in 5–10% of patients with breast cancer. This is the second most common type of cancer in the United States, striking over 180,000 women (and some men) annually and killing 40,000 each year. Mutations in the *BRCA1* or *BRCA2* gene are found in at least half of inherited breast cancers (*BRCA* stands for BReast CAncer). A woman who inherits one mutant *BRCA1* allele has a 60% probability of developing breast cancer before the age of 50, compared with only a 2% probability for an individual homozygous for the normal allele. Both *BRCA1* and *BRCA2* are considered to be tumor-suppressor genes because their wild-type alleles protect against breast cancer and their mutant alleles are recessive. Researchers have not yet determined what the normal products of these genes actually do in the cell. However, recent evidence suggests that the *BRCA2* protein is directly involved in repairing breaks that occur in both strands of DNA.

The study of these and other genes associated with inherited cancer may lead to new methods for early diagnosis and treatment of all cancers. Studying these genes also increases our understanding of the normal processes of regulation of the genome.

Concept Check 19.3

1. Compare the usual functions of proteins encoded by proto-oncogenes with those encoded by tumor-suppressor genes.
2. Explain how the types of mutations that lead to cancer are different for a proto-oncogene and a tumor-suppressor gene.
3. Under what circumstances do we consider cancer to have a hereditary component?

For suggested answers, see Appendix A.

Concept 19.4

Eukaryotic genomes can have many noncoding DNA sequences in addition to genes

We have spent most of this chapter, and indeed this unit, focusing on genes that code for proteins. Yet the coding regions of these genes and the genes for RNA products such as rRNA and tRNA make up only a tiny portion of the genomes of most multicellular eukaryotes. The bulk of most eukaryotic genomes consists of noncoding DNA sequences, often described in the past as "junk DNA." However, much evidence is accumulating that noncoding DNA plays important roles in the cell, an idea supported by its persistence in diverse genomes over many hundreds of generations. In this section, we examine how genes and noncoding DNA sequences are organized within eukaryotic genomes, using the human genome as our prime example. Genome organization tells us much about how genomes have evolved and continue to evolve, the subject of the final section of the chapter.

The Relationship Between Genomic Composition and Organismal Complexity

Several trends are evident when we compare the genomes of prokaryotes and those of eukaryotes, including more complex groups such as mammals. Although there are exceptions, we find a general progression from smaller to larger genomes, but with fewer genes in a given length of DNA. For example, humans have 500 to 1,500 times as many base pairs in their genome as most prokaryotes, but on average only 5 to 15 times as many genes—thus many fewer genes in any given length of DNA.

In prokaryotic genomes, most of the DNA codes for protein, tRNA, or rRNA; the small amount of noncoding DNA consists mainly of regulatory sequences, such as promoters. The coding sequence of nucleotides along a prokaryotic gene

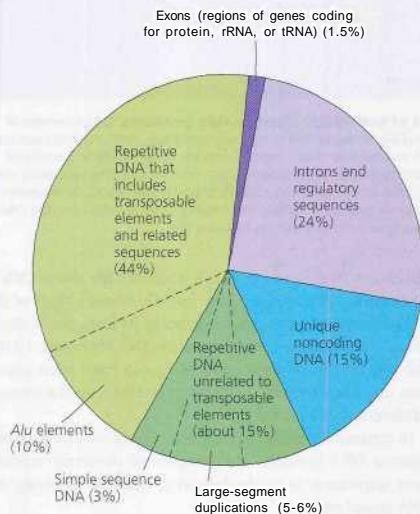

proceeds from start to finish without interruption by noncoding sequences (introns). In eukaryotic genomes, by contrast, most of the DNA does *not* encode protein or RNA, and it includes more complex regulatory sequences. In fact, humans have 10,000 times as much noncoding DNA as prokaryotes. Some of the noncoding DNA in multicellular eukaryotes is present as introns within genes. Indeed, introns account for most of the difference in average length between human genes (27,000 base pairs) and prokaryotic genes (1,000 base pairs).

Now that the complete sequence of the human genome is available, we know what makes up most of the 98.5% that does not code for proteins, rRNAs, or tRNAs (Figure 19.14). Gene-related regulatory sequences and introns account for 24% of the human genome. The remaining sequences, located between functional genes, include some unique noncoding DNA, such as gene fragments and mutated genes that are nonfunctional. Most intergenic DNA, however, is repetitive DNA, sequences that are present in multiple copies in the genome. Somewhat surprisingly, about three-fourths of this

repetitive DNA (44% of the entire human genome) is made up of transposable elements and sequences related to them.

Transposable Elements and Related Sequences

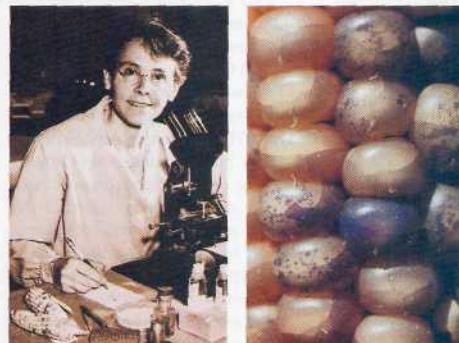

All organisms seem to have stretches of DNA that can move from one location to another within the genome. In Chapter 18, we described transposable elements in prokaryotes, which may have been an evolutionary source of viruses. However, the first evidence for wandering DNA segments did not come from experiments with prokaryotes, but from American geneticist Barbara McClintock's breeding experiments with Indian corn (maize) in the 1940s and 1950s (Figure 19.15). McClintock identified changes in the color of corn kernels that made sense only if she postulated the existence of genetic elements capable of moving from other locations in the genome into the genes for kernel color. McClintock's discovery received little attention until transposable elements were discovered in bacteria many years later and microbial geneticists learned more about the molecular basis of transposition.

A. Figure 19.14 Types of DNA sequences in the human genome. The coding sequences in genes (dark purple) make up only about 1.5% of the human genome, while introns and regulatory sequences associated with genes (light purple) make up about a quarter. The vast majority of the human genome does not code for human proteins or RNAs, and much of it is repetitive DNA (dark and light green). Because repetitive DNA is the most difficult to sequence and analyze, classification of some portions is tentative, and the percentages given here may shift slightly as genome analysis continues.

Movement of Transposons and Retrotransposons

Eukaryotic transposable elements are of two types: transposons, which move within a genome by means of a DNA intermediate, and retrotransposons, which move by means of an RNA intermediate, a transcript of the retrotransposon DNA. Transposons can move by a "cut-and-paste" mechanism, which removes the element from the original site, or by

A. Figure 19.15 The effect of transposable elements on corn kernel color. Barbara McClintock first proposed the idea of mobile genetic elements after observing variegations in corn kernel color. Although her idea was met with skepticism when she proposed it in the 1940s, it was later validated. She received the Nobel Prize in 1983, at the age of 81, for her pioneering research.

a "copy-and-paste" mechanism, which leaves a copy behind (**Figure 19.16a**).

Retrotransposons always leave a copy at the original site during transposition, since they are initially transcribed into an RNA intermediate (**Figure 19.16b**). To insert at another site, the RNA intermediate is first converted back to DNA by reverse transcriptase, an enzyme encoded in the retrotransposon itself. Thus, reverse transcriptase can be present in cells not infected with retroviruses. (In fact, retroviruses may have evolved from retrotransposons.) A cellular enzyme catalyzes insertion of the reverse-transcribed DNA at a new site. Most transposable elements in eukaryotic genomes are retrotransposons.

Sequences Related to Transposable Elements

Multiple copies of transposable elements and sequences related to them are scattered throughout eukaryotic genomes. A single unit is usually hundreds to thousands of base pairs long, and the dispersed "copies" are similar but usually not identical to each other. Some of these are transposable elements that move using enzymes encoded either by themselves or by other transposable elements

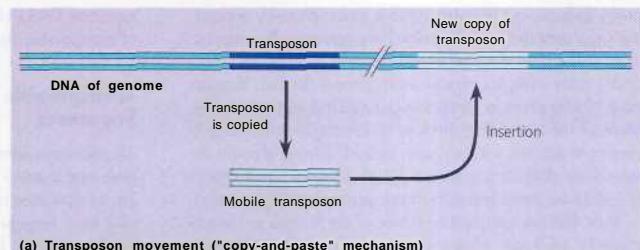

and some are related sequences that have lost the ability to move altogether. Transposable elements and related sequences make up 25–50% of most mammalian genomes and even higher percentages in amphibians and higher plants (see Figure 19.14).

In humans and other primates, a large portion of transposable element-related DNA consists of a family of similar sequences called *Alu elements*. These sequences alone account for approximately 10% of the human genome. *Alu* elements are about 300 nucleotides long, much shorter than most functional transposable elements, and they do not code for any protein. However, many *Alu* elements are transcribed into RNA molecules; their cellular function, if any, is unknown.

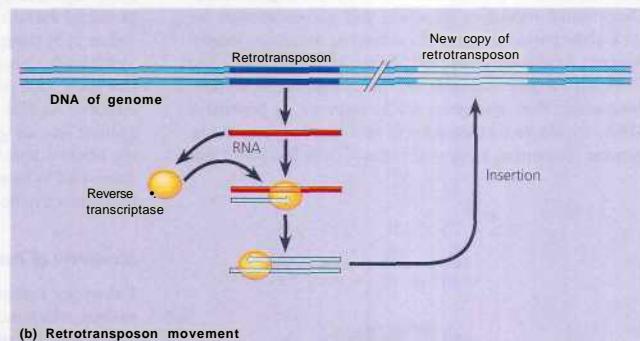

Although many transposable elements encode proteins, these proteins do not carry out normal cellular functions. Thus, these elements often are described as "noncoding" DNA, along with other repetitive sequences.

Other Repetitive DNA, Including Simple Sequence DNA

Repetitive DNA that is not related to transposable elements probably arose by mistakes that occurred during DNA

(a) Transposon movement ("copy-and-paste" mechanism)

(b) Retrotransposon movement

A Figure 19.16 Movement of eukaryotic transposable elements. (a) Movement of transposons by either the cut-and-paste mechanism or the copy-and-paste mechanism (shown here) involves a double-stranded DNA intermediate that is inserted into the genome. (b) Movement of retrotransposons begins with formation of a single-stranded RNA intermediate. The remaining steps are essentially identical to part of the retrovirus reproductive cycle (see Figure 18.10). In movement of transposons by the copy-and-paste mechanism and in movement of retrotransposons, the DNA sequence remains in the original site as well as appearing in a new site,

replication or recombination. It accounts for about 15% of the human genome (see Figure 19.14). About a third of this (5% of the human genome) consists of large-segment duplications, in which a long stretch of DNA, between 10,000 and 300,000 nucleotide pairs, seems to have been copied from one chromosomal location to another, on the same or a different chromosome.

In contrast to single duplications of long sequences, *simple sequence DNA* contains many copies of tandemly repeated short sequences, as in the following example (showing one DNA strand only):

...GTTACGTACGTACGTACGTACGTAC...

In this case, the repeated unit consists of five nucleotides (GTTAC). Repeated units often contain fewer than 15 nucleotides, but they may include as many as 500 nucleotides. The number of repeated units at a particular site in the genome varies as well. For example, there could be as many as several hundred thousand repetitions of the GTTAC unit at

one site. Altogether, simple sequence DNA makes up 3% of the human genome.

The nucleotide composition of simple sequence DNA is often different enough from the rest of the cell's DNA to have an intrinsically different density. If genomic DNA is cut into pieces and centrifuged at high speed, segments of different density migrate to different positions in the centrifuge tube. Repetitive DNA isolated in this way was originally called *satellite* DNA because it appeared as a "satellite" band in the centrifuge tube, separate from the rest of the DNA. Now the term is often used interchangeably with *simple sequence DNA*.

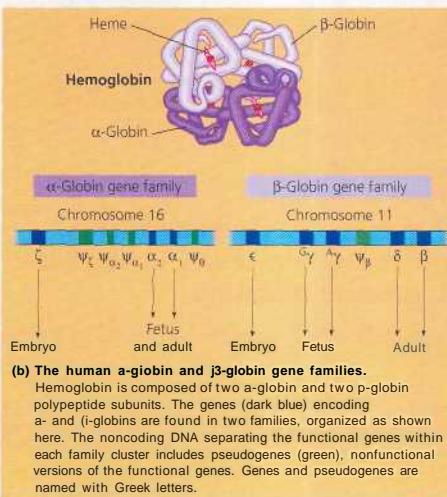

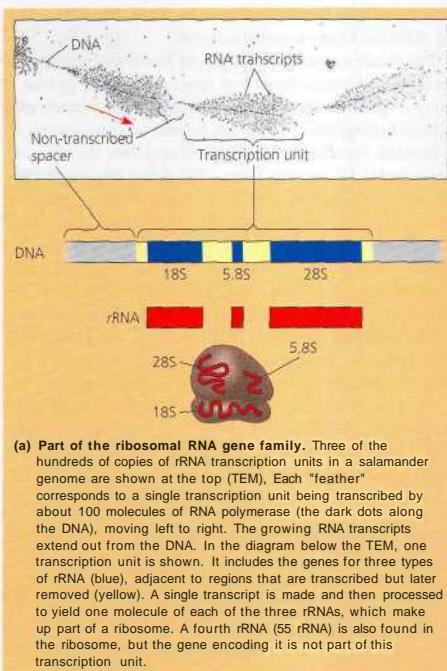

Much of a genome's simple sequence DNA is located at chromosomal telomeres and centromeres, suggesting that this DNA plays a structural role for chromosomes. The DNA at centromeres is essential for the separation of chromatids in cell division (see Chapter 12). Centromeric DNA, along with simple sequence DNA located elsewhere, also may help organize the chromatin within the interphase nucleus. The simple sequence DNA located at telomeres, at the tips of chromosomes, prevents genes from being lost as the DNA shortens with each round of replication (see Chapter 16). Telomeric DNA also binds proteins that protect the ends of a chromosome from degradation and from joining to other chromosomes.

Genes and Multigene Families

We finish our discussion of the various types of DNA sequences in eukaryotic genomes with a closer look at genes. Recall that sequences coding for proteins and structural RNAs compose a mere 1.5% of the human genome (see Figure 19-14). If we include introns and regulatory sequences associated with genes, the total amount of gene-related DNA—coding and noncoding—constitutes about 25% of the human genome.

As in prokaryotes, most eukaryotic genes are present as unique sequences, with only one copy per haploid set of chromosomes. But in the human genome, such solitary genes make up only about half of the total coding DNA. The rest occurs in **multigene families**, collections of identical or very similar genes.

Some multigene families consist of *identical* DNA sequences, usually clustered tandemly. With the notable exception of the genes for histone proteins, multigene families of identical genes code for RNA products. An example is the family of identical sequences encoding the three largest ribosomal RNA (rRNA) molecules (Figure 19.17a). These rRNA molecules are encoded in a single transcription unit that is repeated tandemly hundreds to thousands of times in one or several clusters in the genome of a multicellular eukaryote. The many copies of this rRNA transcription unit help cells to quickly make the millions of ribosomes needed for active protein synthesis. The primary transcript is cleaved to yield the three rRNA molecules. These are then

A Figure 19.17 Gene families.

combined with proteins and one other kind of rRNA (5S rRNA) to form ribosomal subunits.

The classic examples of multigene families of *nonidentical* genes are two related families of genes that encode globins, a group of proteins that include the α and β polypeptide subunits of hemoglobin. One family, located on chromosome 16 in humans, encodes various forms of α-globin; the other, on chromosome 11, encodes forms of β-globin (Figure 19.17b). The different forms of each globin subunit are expressed at different times in development, allowing hemoglobin to function effectively in the changing environment of the developing animal. In humans, for example, the embryonic and fetal forms of hemoglobin have a higher affinity for oxygen than the adult forms, ensuring the efficient transfer of oxygen from mother to developing fetus. Also found in the globin gene family clusters are several pseudogenes, nonfunctional nucleotide sequences quite similar to the functional genes.

The arrangement of the genes in gene families has provided insight into the evolution of genomes. We will consider some of the processes that have shaped the genomes of different species over evolutionary time in the next section.

Concept Check 19.4

1. Discuss the characteristics that make mammalian genomes larger than prokaryotic genomes.
2. How do introns, transposable elements, and simple sequence DNA differ in their distribution in the genome?
3. Discuss the differences in the organization of the rRNA gene family and the globin gene families. How do these gene families benefit the organism?

For suggested answers, see Appendix A.

Concept 19.5

Duplications, rearrangements, and mutations of DNA contribute to genome evolution

The basis of change at the genomic level is mutation, which underlies much of genome evolution. It seems likely that the earliest forms of life had a minimal number of genes—those necessary for survival and reproduction. If this was indeed the case, one aspect of evolution must have been an increase in the size of the genome, with the extra genetic material providing the raw material for gene diversification. In this section, we will first describe how extra copies of all or part of a genome can arise and then consider subsequent processes that

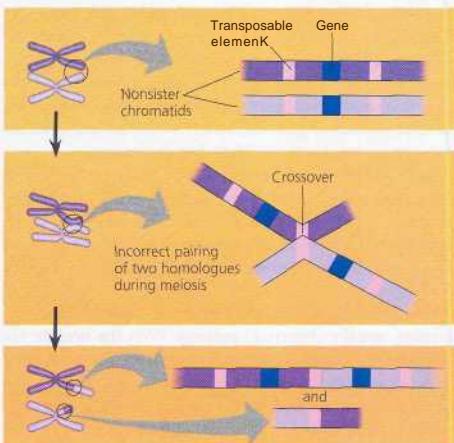

can lead to the evolution of proteins (or RNA products) with related or entirely new functions.

Duplication of Chromosome Sets

An accident in meiosis can result in one or more extra sets of chromosomes, a condition known as polyploidy. In a polyploid organism, one complete set of genes can provide essential functions for the organism. The genes in the one or more extra sets can diverge by accumulating mutations; these variations may persist if the organism carrying them survives and reproduces. In this way, genes with novel functions can evolve. As long as one copy of a crucial gene is expressed, the divergence of another copy can lead to its encoded protein acting in a novel way, thereby changing the organism's phenotype. The accumulation of mutations in many (or even a few) genes may lead to the branching off of a new species, as happens often in plants (see Chapter 24). Although polyploid animals exist, they are rare.

Duplication and Divergence of DNA Segments

Errors during meiosis can also lead to the duplication of individual genes. Unequal crossing over during prophase I of meiosis, for instance, can result in one chromosome with a deletion and another with a duplication of a particular region. As illustrated in Figure 19.18, transposable elements in the

A Figure 19.18 Gene duplication due to unequal crossing over. One mechanism by which a gene (or other DNA segment) can be duplicated is recombination during meiosis between copies of a transposable element flanking the gene. Such recombination between misaligned nonsister chromatids of homologous chromosomes produces one chromatid with two copies of the gene and one chromatid with no copy.

genome can provide sites where nonsister chromatids can cross over, even when their homologous gene sequences are not correctly aligned.

Also, slippage can occur during DNA replication, such that the template shifts with respect to the new complementary strand, and one region of the template strand is either not copied or copied twice. As a result, a region of DNA is deleted or duplicated. It is easy to imagine how such errors could occur in regions of repeats, such as the simple sequence DNA described previously. The variability in numbers of repeated units of simple sequence DNA at the same site is probably due to errors like these. Evidence that molecular events such as unequal crossing over and slippage lead to duplication of genes is found in the existence of multigene families.

Evolution of Genes with Related Functions: The Human Globin Genes

Duplication events can lead to the evolution of genes with related functions, such as those of the α -globin and β -globin gene families (see Figure 19.17b). A comparison of gene sequences within a multigene family can suggest the order in which the genes arose. This approach to re-creating the evolutionary history of the various globin genes indicates that they all evolved from one common ancestral globin gene, which was duplicated and diverged into α -globin and β -globin ancestral genes about 450–500 million years ago (Figure 19.19). Each of these genes was later duplicated several times, and the copies then diverged from each other in sequence, yielding the current family members. In fact, the common ancestral globin gene also gave rise to the oxygen-binding muscle protein myoglobin and to the plant protein leghemoglobin. The latter two proteins function as monomers, and their genes are included in a "globin superfamily."

After the duplication events, the differences between the genes in the globin families undoubtedly arose from mutations that accumulated in the gene copies over many generations. The current model is that the necessary function provided by an α -globin protein, for example, was fulfilled by one gene, while other copies of the α -globin gene accumulated random mutations. Some mutations may have had an adverse effect on the organ-

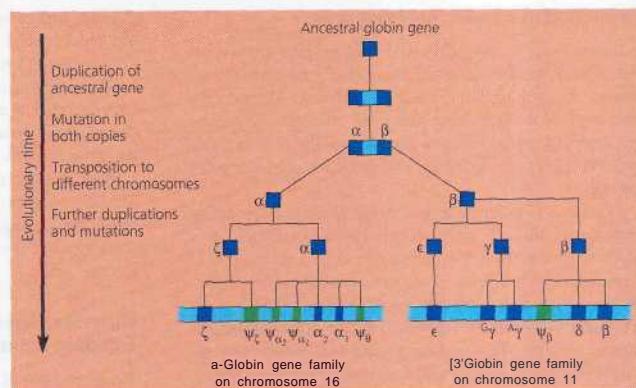

Figure 19.19 Evolution of the human α -globin and β -globin gene families.
Shown here is a model for evolution of the modern α -globin and β -globin gene families from a single ancestral globin gene,

ism and some may have had no effect, but some mutations may have altered the function of the protein product in a way that was advantageous to the organism at a particular life stage without substantially changing its oxygen-carrying function. Presumably, natural selection acted on these altered genes to maintain them in the population, leading to production of alternative forms of α -globin protein.

The similarity in the amino acid sequences of the various α -globin and β -globin proteins supports this model of gene duplication and mutation (Table 19.1). The amino acid sequences of the β -globins, for instance, are much more similar to each other than to the α -globin sequences. The existence of several pseudogenes among the functional globin genes provides additional evidence for this model (see Figure 19.17b). That is, random mutations in these "genes" over evolutionary time have destroyed their function.

Table 19.1 Percentage of Similarity in Amino Acid Sequence Between Human Globin Proteins

| | u-Globins | | p-Globins | | |
|------------------|-----------|---------|-----------|----------|------------|
| | α | ζ | β | γ | ϵ |
| a-Globins | 100 | 58 | 42 | 39 | 37 |
| | 58 | 100 | 34 | 38 | 37 |
| β -Globins | 42 | 34 | 100 | 73 | 75 |
| | 39 | 38 | 73 | 100 | 80 |
| (3-Globins) | 37 | 37 | 75 | 80 | 100 |
| | | | | | |

Evolution of Genes with Novel Functions

In the evolution of the globin gene families, gene duplication and subsequent divergence produced family members whose protein products performed related functions. Alternatively, one copy of a duplicated gene can undergo alterations that lead to a completely new function for the protein product. The genes for lysozyme and α -lactalbumin are good examples.

Lysozyme is an enzyme that helps prevent infection by hydrolyzing the cell walls of bacteria; α -lactalbumin is a nonenzymatic protein that plays a role in milk production in mammals. The two proteins are quite similar in their amino acid sequences and three-dimensional structures. Both genes are found in mammals, whereas only the lysozyme gene is present in birds. These findings suggest that at some time after the lineages leading to mammals and birds had separated, the lysozyme gene underwent a duplication event in the mammalian lineage but not in the avian lineage. Subsequently, one copy of the duplicated lysozyme gene evolved into a gene encoding α -lactalbumin, a protein with a completely different function.

Rearrangements of Parts of Genes: Exon Duplication and Exon Shuffling

Rearrangement of existing DNA sequences has also contributed to genome evolution. The presence of introns in most eukaryotic genes may have promoted the evolution of new and potentially useful proteins by facilitating the duplication or repositioning of exons in the genome. Recall from Chapter 17 that an exon often codes for a domain, a distinct structural or functional region of a protein.

We've already seen that unequal crossing over during meiosis can lead to duplication of a gene on one chromosome and its loss from the homologous chromosome (see Figure 19.18). By a similar process, a particular exon within a gene could be duplicated on one chromosome and deleted from the homologous chromosome. The gene with the duplicated exon would code for a protein containing a second copy of the encoded domain. This change in the protein's structure could augment its function by increasing its stability, enhancing its ability to bind a particular ligand, or altering some other property. Quite a few protein-coding genes have multiple copies of related exons, which presumably arose by duplication and then diverged. The gene encoding the extracellular matrix protein collagen is a good example. Collagen is a structural protein with a highly repetitive amino acid sequence, which is reflected in the repetitive pattern of exons in the collagen gene.

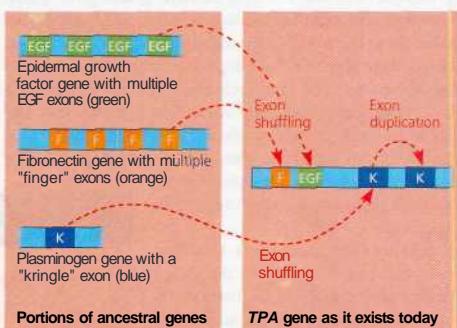

Alternatively, we can imagine the occasional mixing and matching of different exons either within a gene or between two nonallelic genes owing to errors in meiotic recombination. This process, termed *exon shuffling*, could lead to new

proteins with novel combinations of functions. As an example, let's consider the gene for tissue plasminogen activator (TPA). The TPA protein is an extracellular protein involved in limiting blood clotting. It has four domains of three types, each encoded by an exon; one exon is present in two copies. Because each type of exon is also found in other proteins, the gene for TPA is believed to have arisen by several instances of exon shuffling and duplication (Figure 19.2D). The TPA protein slows the clotting reaction and therefore limits the damage that can result from heart attacks and some types of stroke, as long as it is administered immediately to victims.

How Transposable Elements Contribute to Genome Evolution

The persistence of transposable elements as a large fraction of some eukaryotic genomes is consistent with the idea that they can play an important role in shaping a genome over evolutionary time. These elements can contribute to the evolution of the genome in several ways. They can promote recombination, disrupt cellular genes or control elements, and carry entire genes or individual exons to new locations.

The presence of homologous transposable element sequences scattered throughout the genome allows recombination to take place between different chromosomes. Most such alterations are probably detrimental, causing chromosomal translocations and other changes in the genome that may be lethal to the organism. But over the course of evolutionary time, an occasional recombination like this may be advantageous to the organism.

A Figure 19.20 Evolution of a new gene by exon shuffling. Exon shuffling could have moved exons from ancestral forms of the genes for epidermal growth factor, fibronectin, and plasminogen (left) into the evolving gene for tissue plasminogen activator, TPA (right). The order in which these events might have occurred is unknown. Duplication of the "kringle" exon from plasminogen after its movement could account for the two copies of this exon in the TPA gene. Each type of exon encodes a particular domain in the TPA protein.

The movement of transposable elements around the genome can have several direct consequences. For instance, if a transposable element "jumps" into the middle of a coding sequence of a protein-coding gene, it prevents the normal functioning of the interrupted gene. If a transposable element inserts within a regulatory sequence, the transposition may lead to increased or decreased production of one or more proteins. Transposition caused both types of effects on the genes coding for pigment-synthesizing enzymes in McClintock's corn kernels. Again, while such changes may usually be harmful, in the long run some may prove beneficial.

During transposition, a transposable element may carry along a gene or group of genes to a new position in the genome. This mechanism probably accounts for the location of the α -globin and β -globin gene families on different human chromosomes, as well as the dispersion of the genes of certain other gene families. By a similar tag-along process, an exon from one gene may be inserted into another gene in a mechanism similar to that of exon shuffling during recombination. For example, an exon may be inserted by transposition into the intron of a protein-coding gene. If the inserted exon is retained in the RNA transcript during RNA splicing, the protein that is synthesized will have an additional domain, which may confer a new function on the protein.

Recent research reveals yet another way that transposable elements can lead to new coding sequences. This work shows that an Alu element may hop into introns in a way that creates a weak alternative splice site in the RNA transcript. During processing of the transcript, the regular splice sites are used

more often, so that the original protein is made. On occasion, however, splicing occurs at the new weak site, with the result that some of the Alu element ends up in the mRNA, coding for a new portion of the protein. In this way, alternative genetic combinations can be "tried out" while the function of the original gene product is retained.

Clearly, these processes produce either no effect or harmful effects in most individual cases. However, over long periods of time, the generation of genetic diversity provides more raw material for natural selection to work on during evolution. Recent advances in DNA technology have allowed researchers to sequence and compare the genomes of many different species, increasing our understanding of how genomes evolve. You will learn more about these topics in the next chapter.

Concept Check 19.5

1. Describe three examples of errors in cellular processes that lead to DNA duplications.
2. What processes are thought to have led to the evolution of the globin gene families?
3. Look at the portions of the fibronectin and EGF genes shown in Figure 19.20 (left). How might they have arisen?
4. What are three ways transposable elements are thought to contribute to the evolution of the genome?

For suggested answers, see Appendix A.

Chapter 19 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 19.1

Chromatin structure is based on successive levels of DNA packing

- **Nucleosomes, or "Beads on a String"** (pp. 360–361)
Eukaryotic chromatin is composed mostly of DNA and histone proteins that bind to each other and to the DNA to form nucleosomes, the most basic units of DNA packing. Histone tails extend outward from each bead-like nucleosome core.
- > **Higher Levels of DNA Packing (pp. 360–361)** Additional folding leads ultimately to highly compacted heterochromatin, the form of chromatin in a metaphase chromosome. In interphase cells, most chromatin is in the highly extended form called euchromatin.

Activity DNA Packing

Concept 19.2

Gene expression can be regulated at any stage, but the key step is transcription

- **Differential Gene Expression** (pp. 362–363) Each cell of a multicellular eukaryote expresses only a fraction of its genes. In each type of differentiated cell, a unique subset of genes is expressed. Key stages at which gene expression may be regulated include changes in chromatin structure, initiation of transcription, RNA processing, mRNA degradation, translation, and protein processing and degradation.

Activity Overview: Control of Gene Expression

- **Regulation of Chromatin Structure** (pp. 363–364) Genes in highly compacted chromatin are generally not transcribed. Chemical modification of histone tails can affect the configuration of chromatin and thus gene expression. Histone acetylation seems to loosen chromatin structure and thereby enhance transcription. DNA methylation is associated with reduced transcription.
- **Regulation of Transcription Initiation** (pp. 364–367) Multiple DNA control elements distant from the promoter (in one or more enhancers) bind specific transcription factors

(activators or repressors) that regulate transcription initiation for specific genes within the genome. Bending of DNA enables activators bound to enhancers to contact proteins at the promoter. Unlike the genes of a prokaryotic operon, coordinately controlled eukaryotic genes each have a promoter and control elements. The same regulatory sequences are common to all the genes of a group, enabling recognition by the same specific transcription factors.

Activity *Control of Transcription*

Investigation How Do You Design a Gene Expression System?

• Mechanisms of Post-Transcriptional Regulation

(pp. 368–370) Regulation at the RNA-processing level is exemplified by alternative RNA splicing. Also, each mRNA has a characteristic life span, determined in part by sequences in the leader and trailer regions. RNA interference by single-stranded micro-RNAs can lead to degradation of an mRNA or block its translation. The initiation of translation can be controlled via regulation of initiation factors. After translation, various types of protein processing (such as cleavage and the addition of chemical groups) are subject to control, as is the degradation of proteins by proteasomes.

Activity *Post-Transcriptional Control Mechanisms*

Activity Review: *Control of Gene Expression*

Concept 19.3

Cancer results from genetic changes that affect cell cycle control

• Types of Genes Associated with Cancer (pp. 370–371)

The products of proto-oncogenes and tumor-suppressor genes control cell division. A DNA change that makes a proto-oncogene excessively active converts it to an oncogene, which may promote excessive cell division and cancer. A tumor-suppressor gene encodes a protein that inhibits abnormal cell division. A mutation in such a gene that reduces the activity of its protein product may also lead to excessive cell division and possibly to cancer.

• Interference with Normal Cell-Signaling Pathways

(pp. 371–373) Many proto-oncogenes and tumor-suppressor genes encode components of growth-stimulating and growth-inhibiting signaling pathways, respectively. A hyperactive version of a protein in a stimulatory pathway, such as Ras (a G protein), functions as an oncogenic protein. A defective version of a protein in an inhibitory pathway, such as p53 (a transcription activator), fails to function as a tumor suppressor.

• The Multistep Model of Cancer Development

(pp. 373–374) Normal cells are converted to cancer cells by the accumulation of multiple mutations affecting proto-oncogenes and tumor-suppressor genes. Certain viruses promote cancer by integration of viral DNA into a cell's genome.

• Inherited Predisposition to Cancer (p. 374) Individuals who inherit a mutant oncogene or tumor-suppressor allele have an increased risk of developing certain types of cancer.

Activity *Causes of Cancer*

Concept 19.4

Eukaryotic genomes can have many nonecoding DNA sequences in addition to genes

• The Relationship Between Genomic Composition and Organisational Complexity (pp. 374–375) Compared with prokaryotic genomes, the genomes of eukaryotes generally are larger, have longer genes, and contain a much greater amount of nonecoding DNA both associated with genes (introns, regulatory sequences) and between genes (much of it repetitive sequences).

• Transposable Elements and Related Sequences

(pp. 375–376) The most abundant type of repetitive DNA in higher eukaryotes consists of transposable elements and related sequences. Two types of transposable elements occur in eukaryotes: transposons, which move via a DNA intermediate, and retrotransposons, which are the most prevalent and move via mRNA intermediate. Each element may be hundreds or thousands of base pairs long, and similar but usually not identical copies are dispersed throughout the genome.

• Other Repetitive DNA, Including Simple Sequence DNA

(pp. 376–377) Short, nonecoding sequences that are tandemly repeated thousands of times (simple sequence DNA) are especially prominent in centromeres and telomeres, where they probably play structural roles in the chromosome.

• Genes and Multigene Families

(pp. 377–378) Most eukaryotic genes are present in one copy per haploid set of chromosomes. However, the transcription unit encoding the three largest rRNAs is tandemly repeated hundreds to thousands of times at one or several chromosomal sites, enabling the cell to make the rRNA for millions of ribosomes quickly. The multiple, slightly different genes in the two globin gene families encode polypeptides used at different developmental stages of an animal.

Concept 19.5

Duplications, rearrangements, and mutations of DNA contribute to genome evolution

• Duplication of Chromosome Sets (p. 378) Accidents in cell division can lead to extra copies of all or part of a genome, which may then diverge if one set accumulates sequence changes.

• Duplication and Divergence of DNA Segments

(pp. 378–380) The genes encoding the various globin proteins evolved from one common ancestral globin gene, which duplicated and diverged into α-globin and β-globin ancestral genes. Subsequent duplications of these genes and random mutations gave rise to the present globin genes, all of which code for oxygen-binding proteins. The copies of some duplicated genes have diverged so much during evolutionary time that the functions of their encoded proteins are now substantially different.

• Rearrangements of Parts of Genes: Exon Duplication and Exon Shuffling (p. 380) Rearrangement of exons within and between genes during evolution has led to genes containing multiple copies of similar exons and/or several different exons derived from other genes.

• How Transposable Elements Contribute to Genome Evolution (pp. 380–381) Movement of transposable elements or recombination between copies of the same element occasionally generates new sequence combinations that are beneficial to the organism. Such mechanisms can alter the functions of genes or their patterns of expression and regulation.

TESTING YOUR KNOWLEDGE

Evolution Connection

One of the revelations of the human genome sequence was the presence of relict prokaryotic sequences—genes of prokaryotes incorporated into our genome but now defunct molecular fossils. What may have occurred to maroon prokaryotic genes in our genome?

Scientific Inquiry

Prostate cells usually require testosterone and other androgens to survive. But some prostate cancer cells thrive despite treatments that eliminate androgens. One hypothesis is that estrogen, often considered a female hormone, may be activating genes normally controlled by an androgen in these cancer cells. Describe one or more experiments to test this hypothesis. (See Figure 11.6 to review the action of these steroid hormones.)

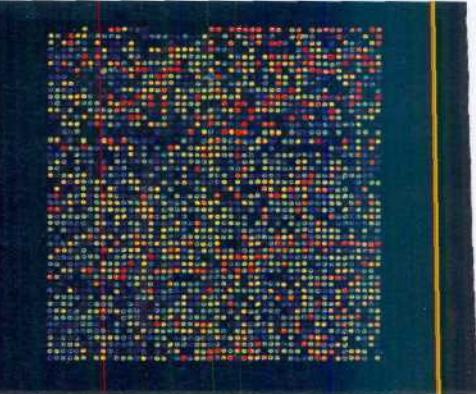

Investigation *How Do You Design a Gene Expression System?*

Science, Technology, and Society

Traces amounts of dioxin were present in Agent Orange, a defoliant sprayed on vegetation during the Vietnam War. Animal tests suggest that dioxin can cause birth defects, cancer, liver and thymus damage, and immune system suppression, sometimes leading to death. But the animal tests are equivocal; a hamster is not affected *by* a dose that can kill a guinea pig. Dioxin acts somewhat like a steroid hormone, entering a cell and binding to a receptor protein that then attaches to the cell's DNA. How might this mechanism help explain the variety of dioxin's effects on different body systems and in different animals? How might you determine whether a type of illness is related to dioxin exposure? How might you determine whether a particular individual became ill as a result of exposure to dioxin? Which would be more difficult to demonstrate? Why?

Key Concepts

- 20.1 DNA cloning permits production of multiple copies of a specific gene or other DNA segment
- 20.2 Restriction fragment analysis detects DNA differences that affect restriction sites
- 20.3 Entire genomes can be mapped at the DNA level
- 20.4 Genome sequences provide clues to important biological questions
- 20.5 The practical applications of DNA technology affect our lives in many ways

Overview

Understanding and Manipulating Genomes

One of the great achievements of modern science has been the sequencing of the human genome, which was largely completed by 2003. The sequencing of the first complete genome, that of a bacterium, had been carried out a mere eight years previously. During the intervening years, researchers accelerated the pace of DNA sequencing, while working on other genomes, aided by the development of faster and faster sequencing machines. These sequencing accomplishments have all depended on advances in DNA technology, starting with the invention of methods for making **recombinant DNA**. This is DNA in which nucleotide sequences from two different sources—often different species—are combined *in vitro* into the same DNA molecule.

The methods for making recombinant DNA are central to **genetic engineering**, the direct manipulation of genes for practical purposes. Applications of genetic engineering include

the manufacture of hundreds of protein products, such as hormones and blood-clotting factors. Using DNA technology, scientists can make recombinant DNA and then introduce it into cultured cells that replicate the DNA and express its genes, yielding a desired protein.

DNA technology has launched a revolution in the area of biotechnology, the manipulation of organisms or their components to make useful products. Practices that go back centuries are forms of biotechnology: for example, the use of microbes to make wine and cheese and the selective breeding of livestock, which exploits naturally occurring mutations and genetic recombination. Modern biotechnology based on the manipulation of DNA *in vitro* differs from earlier practices by enabling scientists to modify specific genes and move them between organisms as distinct as bacteria, plants, and animals.

DNA technology is now applied in areas ranging from agriculture to criminal law. More important, its use allows researchers in virtually all fields of biology to tackle age-old questions in a more comprehensive way. For instance, the level of expression of thousands of different genes can now be measured at the same time, as shown in the DNA microarray in **Figure 20.1**. In the photograph, the color of each spot represents the relative expression of one of 2,400 human genes in a particular tissue. With this technique, researchers can compare gene expression in particular tissues or under different conditions. The knowledge gained from such global expression studies was largely inaccessible only a few decades ago.

In this chapter, we first describe the main techniques for manipulating DNA and then discuss how genomes are analyzed and compared at the DNA level. In the last section, we survey the practical applications of DNA technology, concluding the chapter by considering some of the social and ethical issues that arise as DNA technology becomes more pervasive in our lives.

Concept 20.1

DNA cloning permits production of multiple copies of a specific gene or other DNA segment

The molecular biologist studying a particular gene faces a challenge. Naturally occurring DNA molecules are very long, and a single molecule usually carries many genes. Moreover, genes may occupy only a small proportion of the chromosomal DNA, the rest being noncoding nucleotide sequences. A single human gene, for example, might constitute only 1% of a chromosomal DNA molecule. As a further complication, the distinctions between a gene and the surrounding DNA are subtle, consisting only of differences in nucleotide sequence. To work directly with specific genes, scientists have developed methods for preparing well-defined, gene-sized pieces of DNA in multiple identical copies, a process called gene cloning.

DNA Cloning and Its Applications: A Preview

Most methods for cloning pieces of DNA in the laboratory share certain general features. One common approach uses bacteria (most often, *Escherichia coli*) and their plasmids. Recall from Chapter 18 that bacterial plasmids are relatively small, circular DNA molecules that replicate separate from a bacterial chromosome. For cloning genes or other pieces of DNA in the laboratory, a plasmid is first isolated from a bacterial cell, and then the foreign DNA is inserted into it (**Figure 20.2**). The resulting plasmid is now a recombinant DNA molecule, combining DNA from two sources. The plasmid is returned to a bacterial cell, producing a recombinant bacterium, which reproduces to form a clone of identical cells. Because the dividing bacteria replicate the recombinant plasmid and pass it on to their descendants, the foreign gene is "cloned" at the same time; that is, the clone of cells contains multiple copies of the gene.

Cloned genes are useful for two basic purposes: to make many copies of a particular gene and to produce a protein product. Researchers can isolate copies of a cloned gene from bacteria for use in basic research or to endow an organism with a new metabolic capability, such as pest resistance. For example, a resistance gene present in one crop species might be cloned and transferred into plants of another species. Alternatively, a protein with medical uses, such as human growth hormone, can be harvested in large quantities from bacterial cultures carrying the cloned gene for the protein.

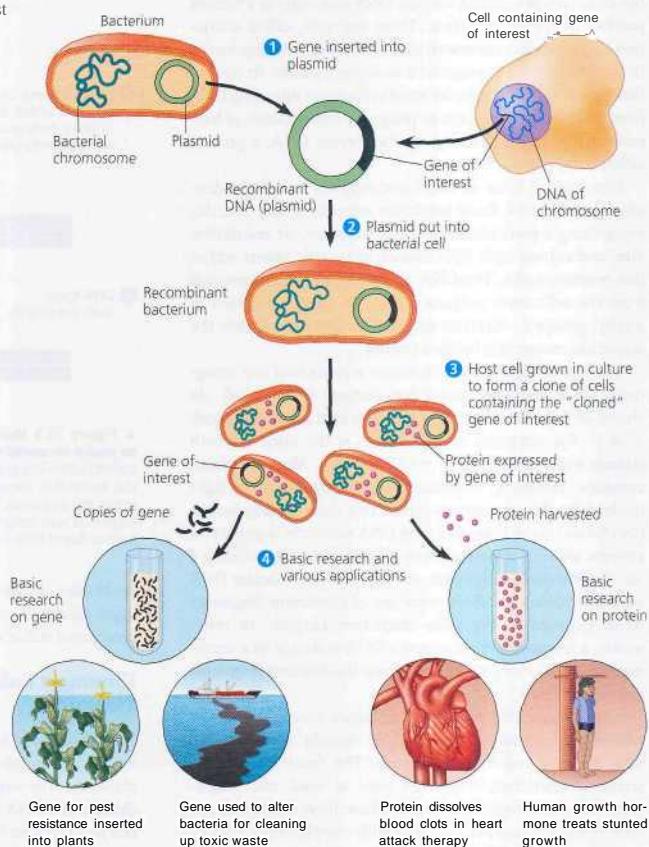

Figure 20.2 Overview of gene cloning with a bacterial plasmid, showing various uses of cloned genes. In this simplified diagram of gene cloning in the laboratory, we start with a plasmid isolated from a bacterial cell and a gene of interest from another organism. Only one copy of the plasmid and one copy of the gene of interest are shown at the top of the figure, but the starting materials would include many copies of each.

Most protein-coding genes exist in only one copy per genome—something on the order of *one* part per million of DNA—so the ability to clone such rare DNA fragments is extremely valuable. In the remainder of this chapter, you will learn more about the techniques outlined in Figure 20.2 and related methods.

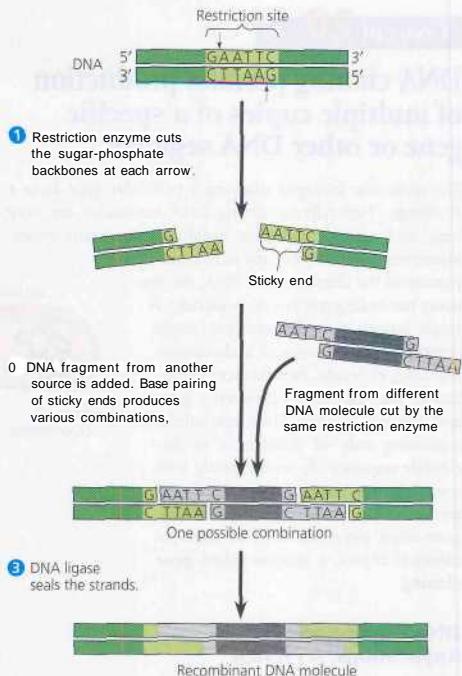

Using Restriction Enzymes to Make Recombinant DNA

Gene cloning and genetic engineering were made possible by the discovery of enzymes that cut DNA molecules at a limited number of specific locations. These enzymes, called restriction endonucleases, or **restriction enzymes**, were discovered in the late 1960s by researchers studying bacteria. In nature, these enzymes protect the bacterial cell against intruding DNA from other organisms, such as phages or other species of bacteria. They work by cutting up the foreign DNA, a process called *restriction*.

Hundreds of different restriction enzymes have been identified and isolated. Each restriction enzyme is very specific, recognizing a particular short DNA sequence, or **restriction site**, and cutting both DNA strands at specific points within this restriction site. The DNA of a bacterial cell is protected from the cell's own restriction enzymes by the addition of methyl groups ($-CH_3$) to adenines or cytosines within the sequences recognized by the enzymes.

The top of **Figure 20.3** illustrates a restriction site recognized by a particular restriction enzyme from *E. coli*. As shown in this example, most restriction sites are symmetrical: That is, the sequence of nucleotides is the same on both strands when read in the 5' → 3' direction. Most restriction enzymes recognize sequences containing four to eight nucleotides. Because any sequence this short usually occurs (by chance) many times in a long DNA molecule, a restriction enzyme will make many cuts in a DNA molecule, yielding a set of **restriction fragments**. All copies of a particular DNA molecule always yield the same set of restriction fragments when exposed to the same restriction enzyme. In other words, a restriction enzyme cuts a DNA molecule in a reproducible way. (Later you will learn how the different fragments can be separated.)

The most useful restriction enzymes cleave the sugar-phosphate backbones in both DNA strands in a staggered way, as indicated in Figure 20.3. The resulting double-stranded restriction fragments have at least one single-stranded end, called a **sticky end**. These short extensions can form hydrogen-bonded base pairs with complementary sticky ends on any other DNA molecules cut with the same enzyme. The associations formed in this way are only temporary, but the associations between fragments can be made permanent by the enzyme **DNA ligase**. This enzyme catalyzes the formation of covalent bonds that close up the sugar-phosphate

▲ Figure 20.3 Using a restriction enzyme and DNA ligase to make recombinant DNA. The restriction enzyme in this example (called *Kpn*I) recognizes a specific nucleotide sequence, the restriction site, and makes staggered cuts in the sugar-phosphate backbones within this sequence, producing fragments with sticky ends. Any fragments with complementary sticky ends can base-pair; if they come from different DNA molecules, recombinant DNA is the product.

backbones. As you can see at the bottom of Figure 20.3, the ligase-catalyzed joining of DNA from two different sources produces a stable recombinant DNA molecule.

Cloning a Eukaryotic Gene in a Bacterial Plasmid

Now that you've learned about restriction enzymes and DNA ligase, we can take a closer look at how genes are cloned in plasmids. The original plasmid is called a **cloning vector**, defined as a DNA molecule that can carry⁷ foreign DNA into a cell and replicate there. Bacterial plasmids are widely used as cloning vectors for several reasons. They can be easily isolated from bacteria, manipulated to form recombinant plasmids by insertion of foreign DNA *in vitro*, and then reintroduced into bacterial cells. Moreover, bacterial cells reproduce rapidly and in the process multiply any foreign DNA they carry.

Producing Clones of Cells

Figure 20.4 details one method for cloning a particular gene from humans or other eukaryotic species using a bacterial plasmid as the cloning vector. The step numbers in the text that follows correspond to those in the figure.

O We begin by isolating the bacterial plasmid from *E. coli* cells and DNA containing the gene of interest from human cells grown in laboratory culture. The plasmid has been engineered to carry two genes that will later prove useful: *amp^R*, which makes *E. coli* cells resistant to the antibiotic ampicillin, and *lacZ*, which encodes (S)-galactosidase. This enzyme hydrolyzes the sugar lactose, as well as a synthetic molecular mimic called X-gal. Within the *lacZ* gene is a single copy of the restriction site recognized by the restriction enzyme used in the next step.

O Both the plasmid and the human DNA are digested with the same restriction enzyme, one that produces sticky ends. The enzyme cuts the plasmid DNA at its single restriction site within the *lacZ* gene, but cuts the human DNA at multiple sites, generating many thousands of fragments. One of the human DNA fragments carries the gene of interest.

<Next we mix the human DNA fragments with the cut plasmids, allowing base pairing between their complementary sticky ends. We then add DNA ligase, which permanently joins each base-paired plasmid and human DNA fragment. Some of the resulting recombinant plasmids contain human DNA fragments like the three shown in Figure 20.4. This step may also generate other products, such as a plasmid containing several human DNA fragments, a combination of two plasmids, or a rejoined, nonrecombinant version of the original plasmid.

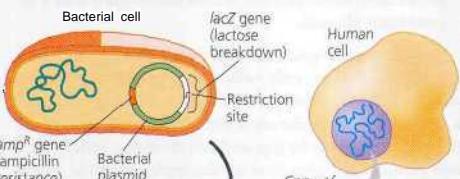

Q The DNA prepared in step 3 is mixed with bacteria that have a mutation in their own *lacZ* gene, making them unable to hydrolyze lactose. Under

Figure 20.4 **Cloning a Human Gene in a Bacterial Plasmid**

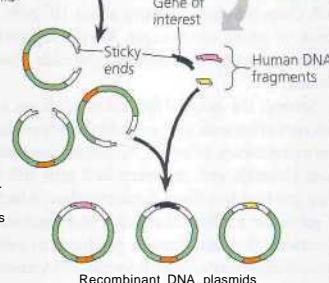

APPLICATION Cloning is used to prepare many copies of a gene of interest for use in sequencing the gene, in producing its encoded protein, in gene therapy, or in basic research.

TECHNIQUE In this example, a human gene is inserted into a plasmid from *B. coli*. The plasmid contains the *amp^R* gene, which makes *E. coli* cells resistant to the antibiotic ampicillin. It also contains the *lacZ* gene, which encodes (S)-galactosidase. This enzyme hydrolyzes a molecular mimic of lactose (X-gal) to form a blue product. Only three plasmids and three human DNA fragments are shown, but millions of copies of the plasmid and a mixture of millions of different human DNA fragments would be present in the samples.

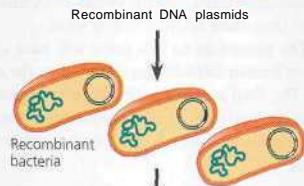

- 0 Isolate plasmid DNA from bacterial cells and DNA from human cells containing the gene of interest.

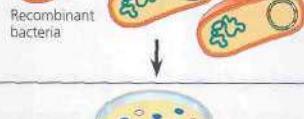

- 1 Cut both DNA samples with the same restriction enzyme, one that makes a single cut within the *lacZ* gene and many cuts within the human DNA.

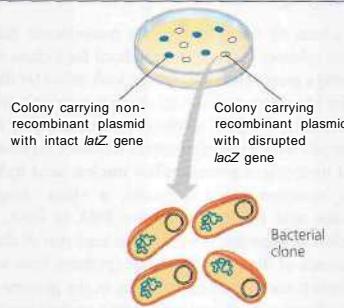

- 2 Mix the cut plasmids and DNA fragments. Some join by base pairing; add DNA ligase to seal them together. The products are recombinant plasmids (shown here) and many nonrecombinant plasmids.

- 3 Introduce the DNA into bacterial cells that have a mutation in their own *lacZ* gene. Under suitable conditions, some cells will take up a recombinant plasmid or other DNA molecule by transformation.

- 4 Plate the bacteria on agar containing ampicillin and X-gal. Incubate until colonies grow.

RESULTS Only a cell that took up a plasmid, which has the *amp^R* gene, will reproduce and form a colony. Colonies with nonrecombinant plasmids will be white, because they can hydrolyze X-gal. Colonies with recombinant plasmids, in which *lacZ* is disrupted, will be blue, because they cannot hydrolyze X-gal. By screening the white colonies with a nucleic acid probe (see Figure 20.5), researchers can identify clones of bacterial cells carrying the gene of interest.

suitable experimental conditions, the cells take up foreign DNA by transformation (see p. 348). Some cells acquire a recombinant plasmid carrying the gene of interest. Many other cells, however, take up a recombinant plasmid carrying a different gene, a nonrecombinant plasmid, or a human DNA fragment. These different possibilities will be sorted out later.

- © In the actual cloning step, the bacteria are plated out on solid nutrient medium (agar) containing ampicillin and X-gal, the molecular mimic of lactose. Use of this medium allows us to identify clones of cells transformed with a recombinant plasmid.

How do we recognize the cell clones carrying recombinant plasmids? First, only cells with a plasmid will reproduce, for only they have the *amp^R* gene conferring resistance to the ampicillin in the medium. Each reproducing bacterium forms a clone by repeated cell divisions, generating a large group of cells that have all descended from the parent cell. Once the clone contains about 10^5 cells, it is visible as a mass, or *colony*, on the agar. As cells reproduce, any foreign genes carried by recombinant plasmids also are copied, or cloned.

Second, the color of the colonies allows us to distinguish colonies of bacteria with recombinant plasmids from those with nonrecombinant plasmids. Colonies containing nonrecombinant plasmids with the intact *lacZ* gene will be blue because they produce functional p-galactosidase, which hydrolyzes the X-gal in the medium, forming a blue product. In contrast, *no* functional (3-galactosidase is produced in colonies containing recombinant plasmids with foreign DNA inserted into the *lacZ* gene; thus, these colonies will be white.

The procedure to this point will have cloned many different human DNA fragments, not just the one that interests us. The final and most difficult part of cloning a particular gene is identifying a colony containing that gene among the many thousands of colonies carrying other pieces of human DNA.

Identifying Clones Carrying a Gene of Interest

To screen all the colonies with recombinant plasmids (the white colonies in the above method) for a clone of cells containing a gene of interest, we can look either for the gene itself or for its protein product. In the first approach, which we describe here, the DNA of the gene is detected by its ability to base-pair with a complementary sequence on another nucleic acid molecule, a process called **nucleic acid hybridization**. The complementary molecule, a short, single-stranded nucleic acid that can be either RNA or DNA, is called a **nucleic acid probe**. If we know at least part of the nucleotide sequence of the gene of interest (perhaps from knowing the protein it encodes or its sequence in the genome of a closely related species), we can synthesize a probe complementary to

it. For example, if part of the sequence on one strand of the desired gene is

then we would synthesize this probe:

Each probe molecule, which will hydrogen-bond specifically to a complementary strand in the desired gene, is labeled with a radioactive isotope or a fluorescent tag so we can track it.

For example, we could transfer a few cells from each white colony in Figure 20.4 (step 5) to a spot on a new agar plate and allow each to grow into a new colony. Figure 20.5 shows how a number of such bacterial clones can be simultaneously screened for the presence of DNA complementary to a DNA probe. An essential step in this method is the **denaturation** of the cells' DNA—that is, the separation of its two strands. As with protein denaturation, DNA denaturation is routinely accomplished "with chemicals or heat.

Once we've identified the location of a colony **carrying the** desired gene, we can grow some cells from that colony in liquid culture in a large tank and then easily isolate large amounts of the gene. Also, we can use the cloned gene **itself** as a probe to identify similar or identical genes in DNA from other sources, such as DNA from other species.

Storing Cloned Genes in DNA Libraries

The cloning procedure in Figure 20.4, which starts with a mixture of fragments from the entire genome of an organism, is called a "shotgun" approach; no single gene is targeted for cloning. Thousands of different recombinant plasmids are produced in step 3, and a clone of each ends up as a (white) colony instead. The complete set of plasmid clones, each carrying copies of a particular segment from the initial genome, is referred to as a **genomic library** (Figure 20.6a). Scientists often obtain such libraries (or even particular cloned genes) from another researcher or a commercial source (sometimes referred to as "cloning by phone"!).

Certain bacteriophages are also common cloning vectors for making genomic libraries. Fragments of foreign DNA can be spliced into a phage genome, as into a plasmid, by using a restriction enzyme and DNA ligase. An advantage of using phages as vectors is that a phage can carry a larger DNA insert than a bacterial plasmid. The recombinant phage DNA is packaged into capsids *in vitro* and introduced into a bacterial cell through the normal infection process. Inside the cell, the phage DNA replicates and produces new phage particles, each carrying the foreign DNA. A genomic library made using phage is stored as a collection of phage clones (Figure 20.6b). Since restriction enzymes do not recognize gene boundaries,

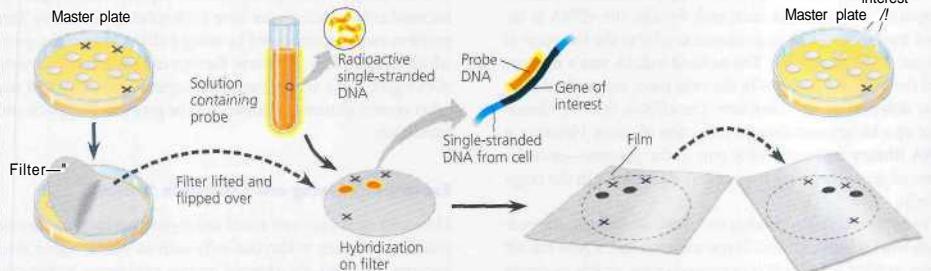

Figure 20.5

Nucleic Acid Probe Hybridization**APPLICATION**

Hybridization with a complementary nucleic acid probe detects a specific DNA within a mixture of DNA molecules. In this example, a collection of bacterial clones (colonies) are screened to identify those carrying a plasmid with a gene of interest.

TECHNIQUE

Cells from each colony known to contain recombinant plasmids (white colonies in Figure 20.4) are transferred to separate locations on a new agar plate and allowed to grow into visible colonies. This collection of bacterial colonies is the master plate.

(f) A special filter paper is pressed against the master plate, transferring cells to the bottom side of the filter. Marks (Xs) are placed on the filter paper and agar to establish the position of each individual colony in reference to the marks.

(g) The filter is treated to break open the cells and denature their DNA; the resulting single-stranded DNA molecules are treated so that they stick to the filter. Radioactive probe molecules complementary to part of the gene of interest are incubated with the filter. The single-stranded probe base-pairs with any complementary DNA on the filter; excess DNA is rinsed off. (Colonies with radioactive probe-DNA hybrids are shown here in orange but would not be visible yet.)

(h) The filter is laid under photographic film, allowing any radioactive areas to expose the film (autoradiography). Black spots on the film correspond to the locations on the filter of DNA that has hybridized to the probe.

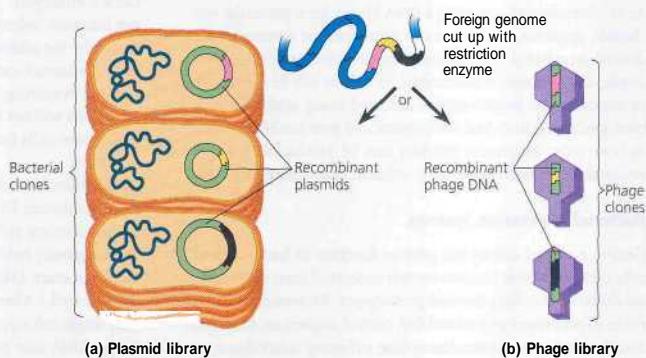

Colonies containing gene of interest

Master plate

RESULTS

Colonies of cells containing the gene of interest have been identified by nucleic acid hybridization. Cells from colonies tagged with the probe can be grown in large tanks of liquid growth medium. Large amounts of the DNA containing the gene of interest can be isolated from these cultures. By using probes with different nucleotide sequences, the collection of bacterial clones can be screened for different genes.

• Figure 20.6 Genomic libraries. A genomic library is a collection of many bacterial or phage clones, each containing copies of a particular DNA segment from a foreign genome. In a complete genomic library, the foreign DNA segments cover the entire genome of an organism. (a) Shown are three of the thousands of "books" in a plasmid library. Each "book" is a clone of bacterial cells, each containing copies of a particular foreign genome fragment (pink, yellow, black segments) in its recombinant plasmid. (b) The same three foreign genome segments are shown in three "books" of a phage library.

some genes in either type of genomic library will be cut and divided up among two or more clones.

Researchers can make another kind of DNA library starting with mRNA extracted from cells. The enzyme reverse transcriptase (obtained from retroviruses) is used *in vitro* to make single-stranded DNA transcripts of the mRNA molecules. Following enzymatic degradation of the mRNA, a second DNA strand, complementary to the first, is synthesized by DNA polymerase. This double-stranded DNA, called complementary DNA (cDNA), is then modified by addition of restriction enzyme recognition sequences at each end. Finally, the cDNA is inserted into vector DNA in a manner similar to the insertion of genomic DNA fragments. The isolated mRNA was a mixture of all the mRNA molecules in the cells used, transcribed from many different genes. Therefore, the cDNAs that are cloned make up a library containing a collection of genes. However, a cDNA library represents only part of the genome—only the subset of genes that were transcribed into mRNA in the original cells.

Genomic and cDNA libraries each have advantages, depending on what is being studied. If you want to clone a gene but are unsure in what cell type it is expressed or are unable to obtain that cell type, a genomic library is almost certain to contain the gene. Also, if you are interested in the regulatory sequences or introns associated with a gene, a genomic library is required because these sequences are absent from the fully processed mRNAs used in making a cDNA library. For this very reason, if you are only interested in the coding sequence of a gene, you can obtain a stripped-down version of the gene from a cDNA library. A cDNA library is also useful for studying genes responsible for the specialized functions of a particular cell type, such as brain or liver cells. Finally, changes in patterns of gene expression during development can be traced by making cDNA from cells of the same type at different times in the life of an organism.

Cloning and Expressing Eukaryotic Genes

As an alternative to screening a DNA library for a particular nucleotide sequence, the clones can sometimes be screened for a desired gene based on detection of its encoded protein. For example, if the protein is an enzyme, its activity can be measured; alternatively, the protein can be detected using antibodies that bind specifically to it. And once a particular gene has been cloned in host cells, its protein product can be produced in larger amounts for research purposes or valuable practical applications.

Bacterial Expression Systems

Getting a cloned eukaryotic gene to function in bacterial host cells can be difficult because certain aspects of gene expression are different in eukaryotes and prokaryotes. To overcome differences in promoters and other DNA control sequences, scientists usually employ an expression vector, a cloning vector that con-

tains a highly active prokaryotic promoter just upstream of a restriction site where the eukaryotic gene can be inserted in the correct reading frame. The bacterial host cell will recognize the promoter and proceed to express the foreign gene now linked to that promoter. Such expression vectors allow the synthesis of many eukaryotic proteins in bacterial cells.

Another problem with expressing cloned eukaryotic genes in bacteria is the presence of noncoding regions (introns) in most eukaryotic genes. Introns can make a eukaryotic gene very long and unwieldy, and they prevent correct expression of the gene by bacterial cells, which do not have RNA-splicing machinery. This problem can be surmounted by using a cDNA form of the gene, which includes only the exons. Bacteria can express a eukaryotic cDNA gene if the vector contains a bacterial promoter and any other control elements necessary for the gene's transcription and translation.

Eukaryotic Cloning and Expression Systems

Molecular biologists can avoid eukaryotic-prokaryotic incompatibility by using eukaryotic cells such as yeasts, rather than bacteria, as hosts for cloning and/or expressing eukaryotic genes of interest. Yeast cells, single-celled fungi, offer two advantages: They are as easy to grow as bacteria, and they have plasmids, a rarity among eukaryotes. Scientists have even constructed recombinant plasmids that combine yeast and bacterial DNA and can replicate in either type of cell. Another useful tool for cloning eukaryotic genes are yeast artificial chromosomes (YACs), which combine the essentials of a eukaryotic chromosome—an origin for DNA replication, a centromere, and two telomeres—with foreign DNA. These chromosome-like vectors behave normally in mitosis, cloning the foreign DNA as the yeast cell divides. Because a YAC can carry a much longer DNA segment than can a plasmid vector, a cloned fragment is more likely to contain an entire gene rather than just a portion of it.

Another reason to use eukaryotic host cells for expressing a cloned eukaryotic gene is that many eukaryotic proteins will not function unless they are modified after translation, for example by the addition of carbohydrate or lipid groups. Bacterial cells cannot carry out these modifications, and if the gene product requiring such processing is from a mammal, even yeast cells will not be able to modify the protein correctly. The use of host cells from an animal cell culture may therefore be necessary.

Scientists have developed a variety of methods for introducing recombinant DNA into eukaryotic cells. In electroporation, a brief electrical pulse applied to a solution containing cells creates temporary holes in their plasma membranes, through which DNA can enter. (This technique is now commonly used for bacteria as well.) Alternatively, scientists can inject DNA directly into single eukaryotic cells using microscopically thin needles. To get DNA into plant cells, the soil bacterium *Agrobacterium*

can be used, as you will learn later. If the introduced DNA is incorporated into a cells genome by genetic recombination, then it may be expressed by the cell.

Amplifying DNA *in Vitro*: The Polymerase Chain Reaction (PCR)

DNA cloning in cells remains the best method for preparing large quantities of a particular gene or other DNA sequence. However, when the source of DNA is scanty or impure, the **polymerase chain reaction**, or **PCR**, is quicker and more selective. In this technique, any specific target segment within one or many DNA molecules can be quickly amplified (copied many times) in a test tube. With automation, PCR can make billions of copies of a target segment of DNA in a few hours, significantly faster than the days it would take to obtain the same number of copies by screening a DNA library for a clone with the desired gene and letting it replicate within host cells.

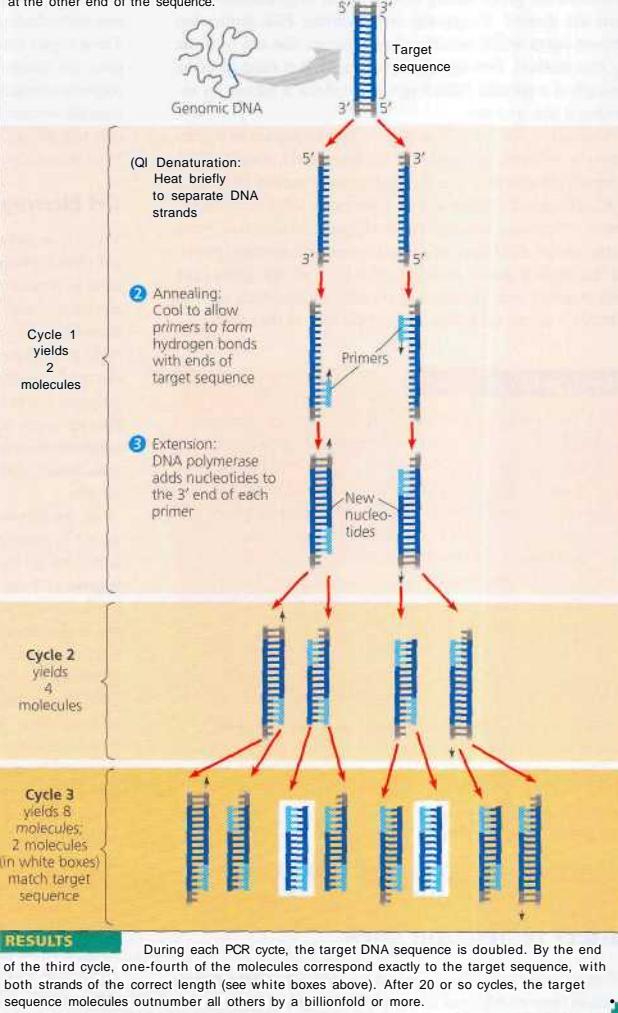

In the PCR procedure (Figure 20.7), a three-step cycle brings about a chain reaction that produces an exponentially growing population of identical DNA molecules. During each cycle, the reaction mixture is heated to denature (separate) the DNA strands and then cooled to allow annealing (hydrogen bonding) of short, single-stranded DNA primers complementary to sequences on opposite strands at each end of the target sequence; finally a heat-stable DNA polymerase extends the primers in the 5' → 3' direction. If a standard DNA polymerase were used, the protein would be denatured along with the DNA during the first heating step and would have to be replaced after each cycle. The key to automating PCR was the discovery of an unusual heat-stable DNA polymerase, first isolated from prokaryotes living in hot springs, that could withstand the heat at the start of each cycle.

Just as impressive as the speed of PCR is its specificity. Only minute amounts of DNA need be present in the starting material, and this DNA can be in a partially degraded state. The key to this high

Figure 20.7
Research Method The Polymerase Chain Reaction (PCR)

APPLICATION With PCR, any specific segment—the target sequence—within a DNA sample can be copied many times (amplified) completely *in vitro*.

TECHNIQUE The starting materials for PCR are double-stranded DNA containing the target nucleotide sequence to be copied, a heat-resistant DNA polymerase, all four nucleotides, and two short, single-stranded DNA molecules that serve as primers. One primer is complementary to one strand at one end of the target sequence; the second is complementary to the other strand at the other end of the sequence.

specificity is the primers, which hydrogen-bond *only* to sequences at opposite ends of the target segment. By the end of the third cycle, one-fourth of the molecules are identical to the target segment, with both strands the appropriate length. With each successive cycle, the number of target segment molecules of the correct length doubles, soon greatly outnumbering all other DNA molecules in the reaction.

Despite its speed and specificity, PCR amplification cannot substitute for gene cloning in cells when large amounts of a gene are desired. Occasional errors during PCR replication impose limits on the number of good copies that can be made by this method. Increasingly, however, PCR is used to make enough of a specific DNA fragment to clone it merely by inserting it into a vector.

Devised in 1985, PCR has had a major impact on biological research and biotechnology. PCR has been used to amplify DNA from a wide variety of sources: fragments of ancient DNA from a 40,000-year-old frozen woolly mammoth; DNA from fingerprints or from tiny amounts of blood, tissue, or semen found at crime scenes; DNA from single embryonic cells for rapid prenatal diagnosis of genetic disorders; and DNA of viral genes from cells infected with viruses that are difficult to detect, such as HIV. We'll return to applications of PCR later in the chapter.

Concept Check 20.1

- If the medium used for plating cells in step 5 of Figure 20.4 did not contain ampicillin, cells containing no plasmid would be able to grow into colonies. What color would those colonies be and why?
- Imagine you want to study human β -globin, a protein present in red blood cells. To obtain sufficient amounts of the protein, you decide to clone the β -globin gene. Would you construct a genomic library or a cDNA library? What material would you use as a source of DNA or RNA?
- What are two potential difficulties in using plasmid vectors and bacterial host cells for production of large quantities of human proteins from cloned genes?

For suggested answers, see Appendix A.

Concept 20.2

Restriction fragment analysis detects DNA differences that affect restriction sites

With techniques available for making homogeneous preparations of large numbers of identical DNA segments, we can begin to tackle interesting questions about specific genes and

their functions. Does a particular gene differ from person to person, and are there certain alkies associated with a hereditary disorder? Where in the body and when is the gene expressed? Where is the gene located within the genome? Is expression of the gene related to expression of other genes? We can also ask how the gene differs from species to species and begin to unravel its evolutionary history.

To answer such questions, we need to know the complete nucleotide sequence of the gene and its counterparts in various individuals and species, as well as its expression pattern. These topics are covered in the next two sections. In this section, we discuss a more indirect approach, called *restriction fragment analysis*, that detects certain differences in the IJ-cleotide sequences of DNA molecules. This type of analysis can rapidly provide useful comparative information about DNA sequences.

Gel Electrophoresis and Southern Blotting

Many approaches for studying DNA molecules make use of gel electrophoresis. This technique uses a gel as a molecular sieve to separate nucleic acids or proteins on the basis of size, electrical charge, and other physical properties (Figure 20.8). Because nucleic acid molecules carry negative charges en their phosphate groups, they all travel toward the positive electrode in an electric field. As they move, the thicket of polymer fibers impedes longer molecules more than it does shorter ones, separating them by length. Thus, gel electrophoresis separates a mixture of linear DNA molecules into bands, each consisting of DNA molecules of the same length.

In restriction fragment analysis, the DNA fragments produced by restriction enzyme digestion of a DNA molecule are sorted by gel electrophoresis. When the mixture of restriction fragments from a particular DNA molecule undergoes electrophoresis, it yields a band pattern characteristic of the starting molecule and the restriction enzyme used. In fact, the relatively small DNA molecules of viruses and plasmids can be identified simply by their restriction fragment patterns. (Larger DNA molecules, such as those of eukaryotic chromosomes, yield so many fragments that they appear as a smear, rather than as distinct bands.) Because DNA can be recovered undamaged from gels, the procedure also provides a way to prepare pure samples of individual fragments.

Restriction fragment analysis is also useful for comparing two different DNA molecules—for example, two alleles of a gene. A restriction enzyme recognizes a specific sequence of nucleotides, and a change in even one base pair will prevent it from cutting at a particular site. Thus, if the nucleotide differences between the alleles occur within a restriction enzyme recognition sequence, digestion with that enzyme will produce a different mixture of fragments from each allele. And each mixture will give its own band pattern in gel electrophoresis. For example, sickle-cell disease is caused by a mutation in a

Figure 20.8

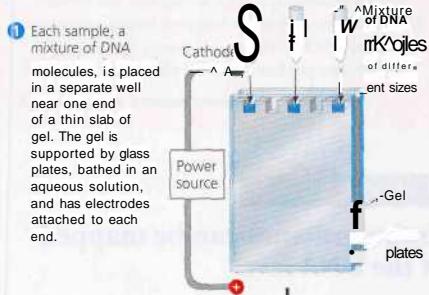

Research Method Gel Electrophoresis

APPLICATION

Gel electrophoresis is used for separating nucleic acids or proteins that differ in size, electrical charge, or other physical properties. DNA molecules are separated by gel electrophoresis in restriction fragment analysis of both cloned genes (see Figure 20.9) and genomic DNA (see Figure 20.10).

TECHNIQUE

Gel electrophoresis separates macromolecules on the basis of their rate of movement through a gel in an electric field. How far a DNA molecule travels while the current is on is inversely proportional to its length. A mixture of DNA molecules, usually fragments produced by restriction enzyme digestion, is separated into "bands"; each band contains thousands of molecules of the same length.

- 2 When the current is turned on, the negatively charged DNA molecules move toward the positive electrode, with shorter molecules moving faster than longer ones. Bands are shown here in blue, but on an actual gel, DNA bands are not visible until a DNA-binding dye is added. The shortest molecules, having traveled farthest, end up in bands at the bottom of the gel.

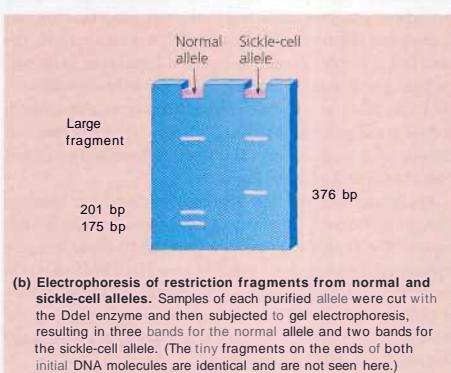

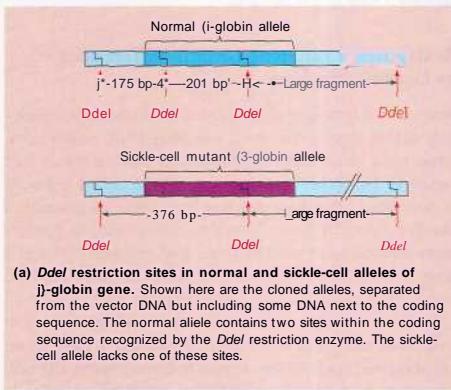

RESULTS

After the current is turned off, a DNA-binding dye is added. This dye fluoresces pink in ultraviolet light, revealing the separated bands to which it binds. In this actual gel, the pink bands correspond to DNA fragments of different lengths separated by electrophoresis. If all the samples were initially cut with the same restriction enzyme, then the different band patterns indicate that they came from different sources.

single nucleotide that is located within a restriction sequence in the β -globin gene (see Figure 17-23 and p. 267). As shown in Figure 20.9, restriction fragment analysis by electrophoresis can distinguish the normal and sickle-cell alleles of the β -globin gene.

The starting materials in Figure 20.9 are samples of the cloned and purified (β -globin alleles. Suppose, however, we wanted to compare genomic DNA samples from three individuals; a person homozygous for the normal (β -globin allele; a person with sickle-cell disease, homozygous for the mutant allele; and a heterozygous carrier. Electrophoresis of genomic DNA digested with a restriction enzyme yields too many bands to distinguish them

A Figure 20.9 Using restriction fragment analysis to distinguish the normal and sickle-cell alleles of the β -globin gene. (a) The sickle-cell mutation destroys one of the *Ddel* restriction sites within the β -globin gene. (b) As a result, digestion with the *Ddel* enzyme generates different fragments from the normal and sickle-cell alleles.

individually. But with a method called Southern blotting, which combines gel electrophoresis and nucleic acid hybridization, we can detect just those bands that include parts of the β -globin gene. The principle is the same as in nucleic acid hybridization for screening bacterial clones (see Figure 20.5). In this case, the probe is a radioactive single-stranded DNA molecule that is complementary to the β -globin gene. Figure 20.10 outlines the entire procedure and demonstrates how it can be used to compare DNA samples from the three individuals mentioned above. Southern blotting reveals not only whether a particular sequence is present in a sample of DNA but also the size of the restriction fragments that contain the sequence. One of its many applications, as in our (β -globin example), is to identify heterozygote carriers of mutant alleles associated with genetic diseases.

Restriction Fragment Length Differences as Genetic Markers

Restriction fragment analysis proved invaluable when biologists turned their attention to *noncoding* DNA, which comprises most of the DNA of animal and plant genomes (see Figure 19.14). When researchers subjected cloned segments of noncoding DNA from different individuals to procedures like that shown in Figure 20.8, they were excited to discover many differences in band patterns. Like different alleles of a gene, noncoding DNA sequences on homologous chromosomes may exhibit small nucleotide differences.

Differences in the restriction sites on homologous chromosomes that result in different restriction fragment patterns are called restriction fragment length polymorphisms (RFLPs, pronounced "Rif-lips"). RFLPs are scattered abundantly throughout genomes, including the human genome. This type of sequence difference in noncoding DNA is conceptually the same as a difference in coding sequence. Analogous to the single base-pair difference that identifies the sickle-cell allele, a RFLP can serve as a genetic marker for a particular location (locus) in the genome. A given RFLP may occur in numerous variants in a population. (The word *polymorphisms* comes from the Greek for "many forms")

RFLPs are detected and analyzed by Southern blotting, with the probe complementary to the sequence under consideration. The example shown in Figure 20.10 could as easily represent the detection of a RFLP in noncoding DNA as one in the coding sequences of two alleles. Because of the sensitivity of DNA hybridization, the entire genome can be used as the DNA starting material. (Samples of human DNA are typically obtained from white blood cells.)

Because RFLP markers are inherited in a Mendelian fashion, they can serve as genetic markers for making linkage maps. The geneticist uses the same reasoning illustrated in Figure 15.6: The frequency with which two RFLP markers—or a RFLP marker and a certain allele for a gene—are inherited

together is a measure of the closeness of the two loci on a chromosome. The discovery of RFLPs greatly increased the number of markers available for mapping the human genome. No longer were geneticists limited to genetic variations that lead to obvious phenotypic differences (such as genetic diseases) or even to differences in protein products.

Concept Check 20.2

- Suppose you carry out electrophoresis on a sample of genomic DNA isolated from an individual and treated with a restriction enzyme. After staining the gel with a DNA-binding dye, what would you see? Explain.
- Explain why restriction fragment length polymorphisms (RFLPs) can serve as genetic markers even though they produce no visible phenotypic differences.

For suggested answers, see Appendix A.

Concept 20.3

Entire genomes can be mapped at the DNA level

As early as 1980, molecular biologist David Botstein and colleagues proposed that the DNA variations reflected in RFLPs could serve as the basis for an extremely detailed map of the entire human genome. Since then, researchers have used such markers in conjunction with the tools and techniques of DNA technology to develop more and more detailed maps of the genomes of a number of species.

The most ambitious mapping project to date has been sequencing of the human genome, officially begun as the Human Genome Project in 1990. This effort was largely completed in 2003 when the nucleotide sequence of the vast majority of DNA in each human chromosome (the 22 autosomes and the pair of sex chromosomes) was obtained. Organized by an international, publicly funded consortium of researchers at universities and research institutes, the project proceeded through three stages that provided progressively more detailed views of the human genome: genetic (or linkage) mapping, physical mapping, and DNA sequencing. (The interview with Eric Lander on pp. 236–237 gives a personal view of the project.)

In addition to mapping human DNA, researchers with the Human Genome Project are also working on the genomes of other species important in biological research. They have completed sequences for *E. coli* and numerous other prokaryotes, *Saccharomyces cerevisiae* (yeast), *Cenorhabditis elegans* (nematode), *Drosophila melanogaster* (fruit fly), *Mus musculus* (mouse), and quite a few others. These genomes are of great

Figure 20.10

Research Method Southern Blotting of DNA Fragments

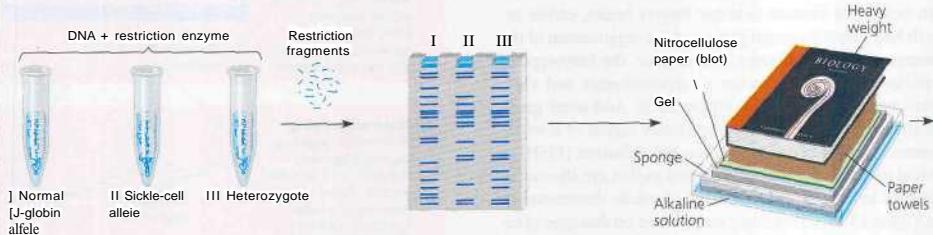

APPLICATION

ToscaniJUKI'S can detect specific nucleotide sequences within a DNA

restriction with this method. In particular, Southern blotting is useful for comparing the restriction fragments produced from different samples of genomic DNA.

TECHNIQUE

In this example, we compare genomic DNA samples from three individuals: a homozygote for the normal β -globin allele (I), a homozygote for the mutant sickle-cell allele (II), and a heterozygote (III).

① Preparation of restriction fragments.

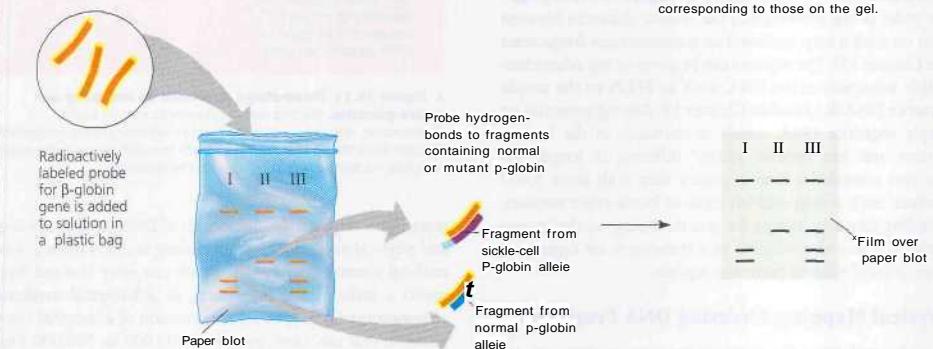

Each DNA sample is mixed with the same restriction enzyme, in this case *DdeI*. Digestion of each sample yields a mixture of thousands of restriction fragments.

② Gel electrophoresis.

The restriction fragments in each sample are separated by electrophoresis, forming a characteristic pattern of bands. (In reality, there would be many more bands than shown here, and they would be invisible unless stained.)

③ Blotting.

With the gel arranged as shown above, capillary action pulls the alkaline solution upward through the gel, transferring the DNA to a sheet of nitrocellulose paper (the blot) and denaturing it in the process. The single strands of DNA stuck to the paper blot are positioned in bands corresponding to those on the gel.

④ Hybridization with radioactive probe.

The paper blot is exposed to a solution containing a radioactively labeled probe. In this example, the probe is single-stranded DNA complementary to the β -globin gene. Probe molecules attach by base-pairing to any restriction fragments containing a part of the β -globin gene. (The bands would not be visible yet.)

⑤ Autoradiography.

A sheet of photographic film is laid over the paper blot. The radioactivity in the bound probe exposes the film to form an image corresponding to those bands containing DNA that base-pairs with the probe.

RESULTS

Because the band patterns for the three samples are clearly different, this method can be used to identify heterozygous carriers of the sickle-cell allele (III), as well as those with the disease, who have two mutant alleles (II), and unaffected individuals, who have two normal alleles (I). The band patterns for samples I and II resemble those observed for the purified normal and mutant alleles, respectively, seen in Figure 20.9b. The band pattern for the sample from the heterozygote (III) is a combination of the patterns for the two homozygotes (I and II).

interest in their own right and are also providing important insights of general biological significance, as we'll discuss later. In addition, the early mapping efforts on these genomes were useful for developing the strategies, methods, and new technologies necessary for deciphering the human genome, which is much larger.

Genetic (Linkage) Mapping: Relative Ordering of Markers

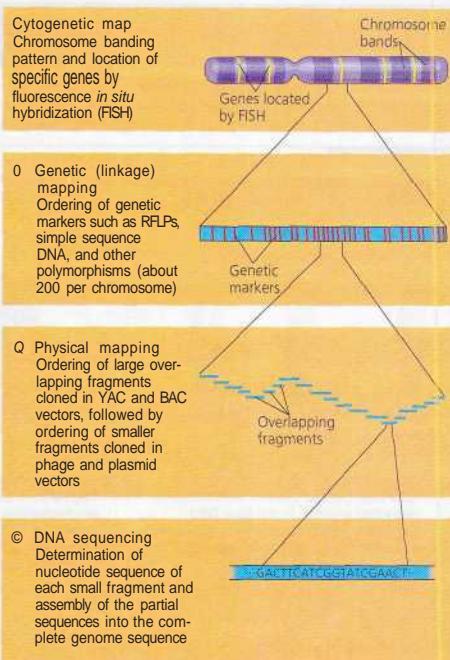

Even before the Human Genome Project began, earlier research had painted a rough picture of the organization of the genomes of many organisms. For instance, the karyotype of a species reveals the number of chromosomes and their overall banding pattern (see Figure 13.3). And some genes had already been located on a particular region of a whole chromosome by fluorescence *in situ* hybridization (FISH), a method in which fluorescently labeled probes are allowed to hybridize to an immobilized array of whole chromosomes (see Figure 15.1). Cytogenetic maps based on this type of information provided the starting point for more detailed mapping.

With cytogenetic maps of the chromosomes in hand, the initial stage in mapping a large genome is to construct a linkage map of several thousand genetic markers spaced throughout each of the chromosomes (**Figure 20.11**, stage Q). The order of the markers and the relative distances between them on such a map are based on recombination frequencies (see Chapter 15). The markers can be genes or any other identifiable sequences in the DNA, such as RFLPs or the simple sequence DNA discussed in Chapter 19. Relying primarily on simple sequence DNA, which is abundant in the human genome and has various “alleles” differing in length, researchers compiled a human genetic map with some 5,000 markers. Such a map enabled them to locate other markers, including genes, by testing for genetic linkage to the known markers. It was also valuable as a framework for organizing more detailed maps of particular regions.

Physical Mapping: Ordering DNA Fragments

In a physical map, the distances between markers are expressed in some physical measure, usually the number of base pairs along the DNA. For whole-genome mapping, a physical map is made by cutting the DNA of each chromosome into a number of restriction fragments and then determining the original order of the fragments in the chromosomal DNA. The key is to make fragments that overlap and then use probes or automated nucleotide sequencing of the ends to find the overlaps (Figure 20.11, stage ②). In this way, more and more fragments can be assigned to a sequential order that corresponds to their order in a chromosome.

Supplies of the DNA fragments used for physical mapping are prepared by cloning. In working with large genomes,

A Figure 20.11 Three-stage approach to mapping an entire genome. Starting with a cytogenetic map of each chromosome, researchers with the Human Genome Project proceeded through three stages of mapping to reach the ultimate goal, the nearly complete nucleotide sequence of every chromosome.

researchers carry out several rounds of DNA cutting, cloning, and physical mapping. The first cloning vector is often a yeast artificial chromosome (YAC), which can carry inserted fragments a million base pairs long, or a bacterial artificial chromosome (BAC), an artificial version of a bacterial chromosome that can carry inserts of 100,000 to 500,000 base pairs. After such long fragments are ordered, each fragment is cut into smaller pieces, which are cloned in plasmids or phages, ordered in turn, and finally sequenced.

DNA Sequencing

The ultimate goal in mapping a genome is to determine the complete nucleotide sequence of each chromosome (Figure 20.11, stage C). If a pure preparation of many copies of a DNA fragment up to about 800 base pairs in length is available, the sequence of the fragment can be determined by a sequencing machine. The usual sequencing technique, described in Figure 20.12, was developed by British scientist Frederick Sanger; it is

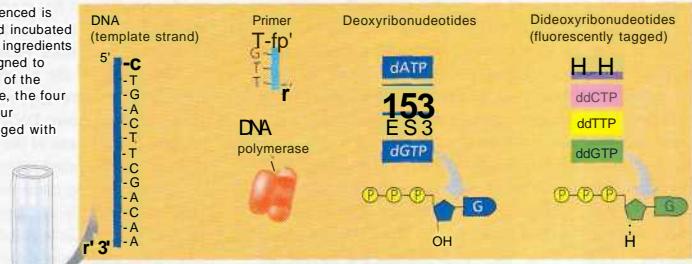

Figure 20.12**Research Method Dideoxy Chain-Termination Method for Sequencing DNA****APPLICATION**

The sequence of nucleotides in any cloned DNA fragment up to about 800 base pairs in length can be determined rapidly with specialized machines that carry out sequencing reactions and separate the labeled reaction products by length.

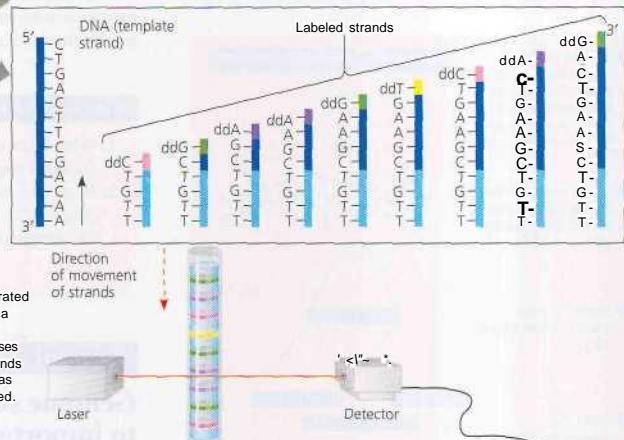

TECHNIQUE

This method synthesizes a nested set of DNA strands complementary to the original DNA fragment. Each strand starts with the same primer and ends with a dideoxynucleotide (ddNTP), a modified nucleotide. Incorporation of a ddNTP terminates a growing DNA strand because it lacks a 3'-OH group, the site for attachment of the next nucleotide (see Figure 16.13). In the set of strands synthesized, each nucleotide position along the original sequence is represented by strands ending at that point with the complementary ddNTP. Because each type of ddNTP is tagged with a distinct fluorescent label, the identity of the ending nucleotides of the new strands, and ultimately the entire original sequence, can be determined.

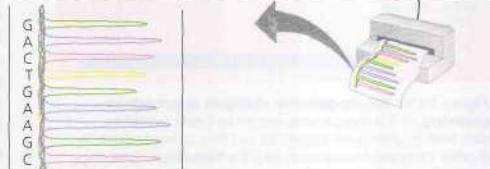

- (1) The fragment of DNA to be sequenced is denatured into single strands and incubated in a test tube with the necessary ingredients for DNA synthesis; a primer designed to base pair with the known 3' end of the template strand, DNA polymerase, the four deoxyribonucleotides, and the four dideoxyribonucleotides, each tagged with a specific fluorescent molecule.

- (2) Synthesis of each new strand starts at the 3' end of the primer and continues until a dideoxyribonucleotide is inserted, at random, instead of the normal equivalent deoxyribonucleotide. This prevents further elongation of the strand. Eventually, a set of labeled strands of various lengths is generated, with the color of the tag representing the last nucleotide in the sequence.

- (3) The labeled strands in the mixture are separated by passage through a polyacrylamide gel in a capillary tube, with shorter strands moving through faster. A fluorescence detector senses the color of each fluorescent tag as the strands come through. Strands differing by as little as one nucleotide in length can be distinguished.

**RESULTS**

The color of the fluorescent tag on each strand indicates the identity of the nucleotide at its end. The results can be printed out as a spectrogram, and the sequence, which is complementary to the template strand, can then be read from bottom to top. (Notice that the sequence here begins after the primer.)

often called the *dideoxyribonucleotide* (or *clidcoxv*, for short) *chain-termination method*. Even with automation, the sequencing of all 2.9 billion base pairs in a haploid set of human chromosomes presented a formidable challenge. In fact, as discussed in the interview on pp. 236–237, a major thrust of the Human Genome Project was the development of technology for faster sequencing, along with more sophisticated computer software for analyzing and assembling the partial sequences.

In practice, the three stages shown in Figure 20.11 overlap in a way that our simplified version does not portray, but they accurately represent the overarching strategy employed in the Human Genome Project. In 1992, emboldened by advances in sequencing and computer technology, molecular biologist J. Craig Venter devised an alternative approach to the sequencing of whole genomes. His idea was essentially to skip the genetic mapping and physical mapping stages and start directly with the sequencing of random DNA fragments. Powerful computer programs would then assemble the resulting very large number of overlapping short sequences into a single continuous sequence (**Figure 20.13**).

Despite the skepticism of many scientists, the value of Venter's approach became clear in 1995 when he and colleagues reported the first complete genome sequence of an organism, the bacterium *Hemophilus influenzae*. In May 1998, he set up a company, Celera Genomics, and promised a completed

human sequence in three years. His whole-genome shotgun approach was further validated in March 2000 with completion of the *Drosophila melanogaster* genome sequence. As promised, in February 2001, Celera announced the sequencing of over 90% of the human genome simultaneously with a similar announcement by the public Human Genome Project.

Representatives of the public consortium point out that Celera made much use of the consortium's maps and sequence data, which are immediately made freely available to all researchers, unlike Celera's data. They further assert that the infrastructure established by their approach greatly facilitated Celera's efforts. Venter, on the other hand, argues for the efficiency and economy of Celera's methods, and indeed, the public consortium has made some use of them. Clearly, both approaches are valuable and have contributed to the rapid completion of genome sequencing for quite a few species.

Sequencing of the human genome is now virtually complete, although some gaps remain to be mapped. Because of the presence of repetitive DNA and for other poorly understood reasons, certain parts of the chromosomes of multicellular organisms resist detailed mapping by the usual methods.

On one level, genome sequences of humans and other organisms are simply dry lists of nucleotide bases—millions of As, Ts, Cs, and Gs in mind-numbing succession. But on another level, analyses of these sequences for various species and comparisons between species are leading to exciting discoveries, which we discuss next.

Concept Check 20.3

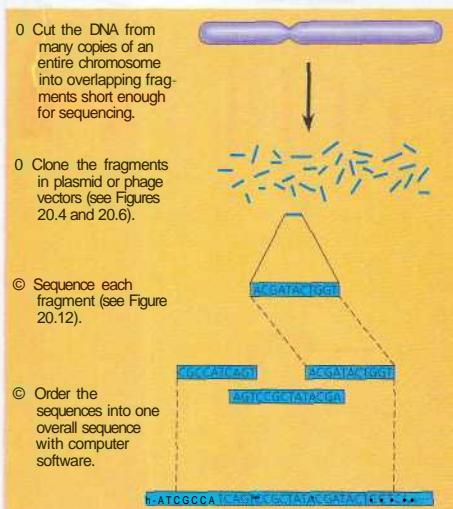

- What is the major difference between a genetic (linkage) map and a physical map of a chromosome?
- In general, how does the approach to genome mapping used in the Human Genome Project differ from the shotgun approach?

For suggested answers, see Appendix A.

Concept 20.4

Genome sequences provide clues to important biological questions

Now that the sequences of entire genomes are available, scientists can study whole sets of genes and their interactions, an approach called genomics. Genomics is yielding new insights into fundamental questions about genome organization, regulation of gene expression, growth and development, and evolution. Using the methods of DNA technology, geneticists can study genes directly, without having to infer genotype from phenotype, as in classical genetics. But the newer approach

A Figure 20.13 Whole-genome shotgun approach to sequencing. In this approach, developed by Celera Genomics, random DNA fragments are sequenced and then ordered relative to each other. Compare this approach with the hierarchical, three-stage approach shown in Figure 20.11.

poses the opposite problem, determining the phenotype from the genotype. Starting with a long DNA sequence, how does one recognize genes and determine their function?

Identifying Protein-Coding Genes in *lysA* Sequences

DNA sequences are collected in computer data banks available via the Internet to researchers all over the world. To identify as-yet unknown protein-coding genes, scientists use software to scan these stored sequences for transcriptional and translational start and stop signals, for RNA-splicing sites, and for other telltale signs of protein-coding genes. The software also looks for certain short coding sequences similar to those present in known genes. Thousands of such sequences, called *expressed sequence tags*, or ESTs, are cataloged in computer databases. This type of analysis identifies sequences that may be "new" protein-coding genes, so-called putative genes or gene candidates.

Although genome size generally increases from prokaryotes to eukaryotes, it does not always correlate with biological complexity among eukaryotes. For instance, the genome of *Fritillaria assyriaca*, a flowering plant, contains 120×10^9 base pairs, about 40 times the size of the human genome. Moreover, the number of genes an organism has is often lower than expected from the size of its genome. In particular, the current estimated number of human genes—about 25,000 or less—is much lower than the 50,000 to 100,000 expected an only about one and a half times the number found in the fruit fly and the nematode worm (Table 20.1). This initially seemed surprising, given the larger diversity of cell types in

humans and other vertebrates and their generally greater biological complexity. Relative to the other organisms studied so far, genes account for a much smaller fraction of the human genome. Much of the enormous amount of noncoding DNA in the human genome is repetitive DNA, but unusually long introns also contribute significantly.

So what makes humans and other vertebrates apparently more complex than flies or worms? For one thing, gene expression is regulated in more subtle and complicated ways in vertebrates than in other organisms. Some of the large amount of noncoding DNA in vertebrates may function in these regulatory mechanisms. Also, vertebrate genomes tend to "get more bang for the buck" from their coding sequences because of alternative splicing of RNA transcripts. Recall that this process generates more than one functional protein from a single gene (see Figure 19.8). For instance, nearly all human genes contain multiple exons, and an estimated 75% of these multi-exon genes are alternatively spliced. If we assume that each alternatively spliced human gene on average specifies three different polypeptides, then the total number of different human polypeptides would be about 75,000. Additional polypeptide diversity could result from variations in post-translational cleavage or addition of carbohydrate groups in different cell types or at different developmental stages. Another likely contribution to the biological complexity of vertebrates is the much larger number of possible interactions between gene products that result from greater polypeptide diversity. Later we will examine experimental methods for uncovering these interactions.

The identities of about half of the human genes were known before the Human Genome Project began. But what about the others, the new genes revealed by analysis of DNA sequences? Clues about their identities can come from comparing the sequences of new gene candidates with those of known genes from various organisms. In some cases, a newly identified gene sequence will match, at least partially, the sequence of a gene whose function is well known. For example, part of a new gene may match a known gene that encodes a protein kinase, suggesting that the new gene does, too. In other cases, however, the new gene sequence will be similar to a previously encountered sequence whose function is still unknown. In still other cases, the sequence may be entirely unlike anything ever seen before. In the organisms that have been sequenced so far, many of the gene candidate sequences are entirely new to science. For example, about a third of the genes of *E. coli*, the best studied of research organisms, are new to us.

Table 20.1 Genome Sizes and Estimated Numbers of Genes*

| Organism | Haploid Genome Size (Mb) | Number of Genes | Genes per Mb |
|--|--------------------------|-----------------|--------------|
| <i>Hemophilus influenzae</i> (bacterium) | 1.8 | 1,700 | 940 |
| <i>Escherichia coli</i> (bacterium) | 4.6 | 4,400 | 950 |
| <i>Saccharomyces cerevisiae</i> (yeast) | 12 | 5,800 | 480 |
| <i>Caenorhabditis elegans</i> (nematode) | 97 | 19,000 | 200 |
| <i>Arabidopsis thaliana</i> (plant) | 118 | 25,500 | 215 |
| <i>Drosophila melanogaster</i> (fruit fly) | 180 | 13,700 | 76 |
| <i>Oryza sativa</i> (rice) | 430 | 60,000 | 140 |
| <i>Danio rerio</i> (zebrafish) | 1,700 | 22,000 | 13 |
| <i>Mus musculus</i> (house mouse) | 2,600 | 25,000 | 11 |
| <i>Homo sapiens</i> (human) | 2,900 | 25,000 | 10 |
| <i>Fragaria ananassa</i> (plant) | 120,000 | ND | ND |

*Strictly defined, "genome" refers to the complete genome of an organism. Some values given here are likely to be revised as genome analysis continues. Mb = million base pairs. ND = not determined.

Determining Gene Function

So how do scientists determine the function of a new gene identified by genome sequencing and comparative analysis? Perhaps the most common approach is to disable the gene and then observe the consequences in the cell or organism. In one application of this approach, called *in vitro* mutagenesis, specific mutations are introduced into the sequence of a cloned gene, after which the mutated gene is returned to a cell. If the introduced mutations alter or destroy the function of the gene product, the phenotype of the mutant cell may help reveal the function of the missing normal protein. Researchers can even put such a mutated gene into cells from the early embryo of a multicellular organism (such as a mouse) to study the role of the gene in the development and functioning of the whole organism.

A simpler and faster method for silencing expression of selected genes exploits the phenomenon of **RNA interference (RNAi)**, described in Chapter 19. This experimental approach uses synthetic double-stranded RNA molecules matching the sequence of a particular gene to trigger breakdown or to block translation of the gene's messenger RNA. To date, the RNAi technique has had some limited success in mammalian cells, including human cells in culture. But in other organisms, such as the nematode and the fruit fly, RNAi is already proving valuable for analyzing the functions of genes on a large scale. In one study, RNAi was used to prevent expression of 86% of the genes in early nematode embryos, one gene at a time. Analysis of the phenotypes of the worms that developed from these embryos allowed the researchers to group most of the genes into a small number of functional groups. This type of genome-wide analysis of gene function is sure to become more common as research focuses on the importance of interactions between genes in the system as a whole—the basis of systems biology (see Chapter 1).

Studying Expression of Interacting Groups of Genes

A major goal of genomics is to learn how genes act together to produce and maintain a functioning organism. As mentioned earlier, part of the explanation for how humans get along with so few genes probably lies in the complexity of networks of interactions among genes and their products. Once the sequences of entire genomes of several organisms neared completion, some researchers began using these sequences to investigate which genes are transcribed in different situations, such as in different tissues or at different stages of development. They also consider whether groups of genes are expressed in a coordinated manner, with the aim of identifying global patterns or networks of expression. The results of such studies will begin to reveal how genes act together as a functional network in an organism.

The basic strategy in global expression studies is to isolate the mRNAs made in particular cells, use these molecules as templates for making the corresponding cDNAs by reverse transcription, and then compare this set of cDNAs with collections of genomic DNA fragments. DNA technology makes such studies possible; with automation, they are easily performed on a large scale. Scientists can now measure the expression of thousands of genes at one time.

Currently, the main approach for genome-wide expression studies uses DNA microarray assays. A DNA microarray consists of tiny amounts of a large number of single-stranded DNA fragments representing different genes fixed to a glass slide in a tightly spaced array (grid). (The array is also called a *DNA chip* by analogy.) Ideally, these fragments represent all the genes of an organism, as is already possible for organisms whose genomes have been completely sequenced. Figure 20.14 outlines how the DNA fragments on a microarray are tested for hybridization with samples of cDNA molecules prepared from the mRNAs in particular cells of interest and labeled with fluorescent dyes.

For example, in one study, researchers performed microarray assays of more than 90% of the genes of *C. elegans* during every stage of its life cycle. The results showed that expression of nearly 60% of the genes changed dramatically during development, and many were expressed in a sex-specific pattern. Such studies illustrate the value of DNA microarrays to reveal general profiles of gene expression over the lifetime of an organism.

In addition to uncovering gene interactions and providing clues to gene function, DNA microarray assays may contribute to a better understanding of certain diseases and suggest new diagnostic techniques or therapies. For example, comparing patterns of gene expression in breast cancer tumors and noncancerous breast tissue has already resulted in more informed and effective treatment protocols. Ultimately, information from DNA microarray assays should provide us a grander view—of how ensembles of genes interact to form a living organism.

Comparing Genomes of Different Species

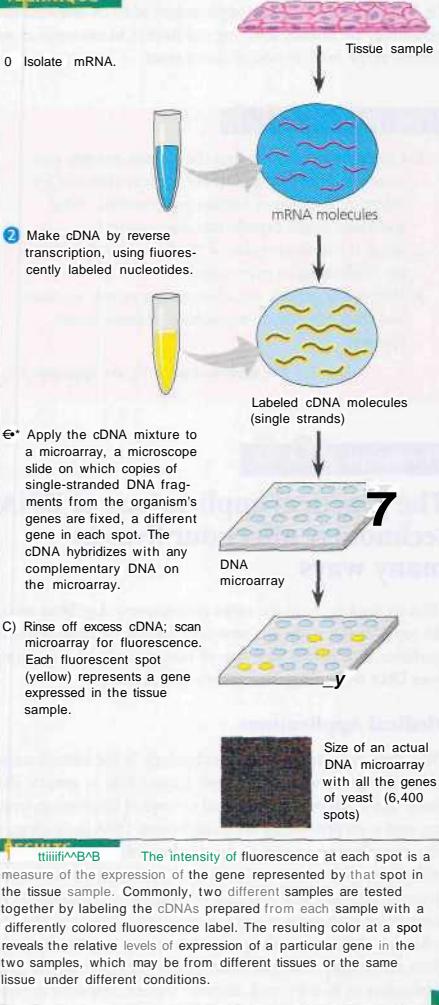

The genomes of about 150 species had been completely or almost completely sequenced by the spring of 2004, with many more in progress. Of these, the vast majority are genomes of prokaryotes, including about 20 archaean genomes. Among the 20 or so eukaryotic species in the group are vertebrates, invertebrates, and plants. The first eukaryotic genome to be completed was that of the yeast *Saccharomyces cerevisiae*, a single-celled organism; the nematode *Caenorhabditis elegans*, a simple worm, was the first multicellular organism whose genome was sequenced. The plant *Arabidopsis thaliana*, another important research organism, has also been completed. Other species whose genomes have been or are currently being sequenced include the honey bee, the dog, the rat, the chicken, and the frog.

Figure 20.14
Research Method DNA Microarray Assay of Gene Expression Levels

APPLICATION

With this method, researchers can test thousands of genes simultaneously to determine which ones are expressed in a particular tissue, under different environmental conditions in various disease states, or at different developmental stages. They can also look for coordinated gene expression.

TECHNIQUE

Comparisons of genome sequences from different species allow us to determine evolutionary relationships between those species. The more similar in sequence a gene is in two species, the more closely related those species are in their evolutionary history. Likewise, comparing multiple genes between species can shed light on higher groupings of species, which reflect their evolutionary history. Indeed, comparisons of the complete genome sequences of bacteria, archaea, and eukarya strongly support the theory that these are the three fundamental domains of life.

In addition to their value in evolutionary biology, comparative genome studies confirm the relevance of research on simpler organisms to our understanding of biology in general and human biology in particular. The similarities between genes of disparate organisms can be surprising, to the point that one researcher now views fruit flies as "little people with wings." The yeast genome also is proving quite useful in helping us to understand the human genome. For example, the large amount of noncoding DNA in the human genome initially hindered the search for regulatory control elements. But comparisons of non-coding sequences in the human genome with those in the much smaller yeast genome revealed regions with highly conserved sequences; these turned out to be important regulatory sequences in both organisms. In another example, several yeast protein-coding genes are so similar to certain human disease genes that researchers have figured out the functions of the disease genes by studying their normal yeast counterparts.

Comparing the genomes of two closely related species can also be quite useful, because their genomes are likely to be organized similarly. Once the sequence and organization of one genome is known, it can serve as a scaffold for organizing the DNA sequences from a closely related species as they are determined, greatly accelerating mapping of the second genome. For instance, the mouse genome, which is similar in size to the human genome, was mapped at a rapid pace, with the human genome sequence serving as a guide. This approach is particularly helpful when one of two related species has a much shorter genome than the other. An example is the tsetse fly, *Glossina palpalis*, which transmits the parasite causing African sleeping sickness. The tsetse fly genome contains 7×10^9 base pairs (more than twice the size of the human genome), but the genome of a closely related fly is only one-tenth as large. Researchers are sequencing the smaller genome first. Then they will set their sights on the much larger tsetse fly genome, focusing on the coding sequences the two species are expected to share.

The small number of gene differences between closely related species also makes it easier to correlate phenotypic differences between the species with particular genetic differences. For example, one gene that is clearly different in humans and chimpanzees appears to function in speech, a characteristic that obviously distinguishes the two species. And the genetic similarity between mice and humans, which share 80% of their genes, can

be exploited in studying certain human genetic diseases. If researchers know or can hypothesize the organ or tissue in which a defective gene causes a particular disease, they can look for genes that are expressed in these locations in experiments with mice. This approach has revealed several human genes of interest, including one that may be involved in Down syndrome.

Other research efforts are under way to extend genomic studies to many more microbial species and to neglected species from diverse branches of the tree of life. These studies will advance our understanding of all aspects of biology, including health, ecology, and evolution.

Future Directions in Genomics

The success in sequencing genomes and studying entire sets of genes is encouraging scientists to attempt similar systematic study of the full protein sets (*proteomes*) encoded by genomes, an approach called proteomics. For reasons already mentioned, the number of proteins in humans and our close relatives undoubtedly exceeds the number of genes. Because proteins, not genes, actually carry out the activities of the cell, we must study when and where they are produced in an organism, and also how they interact, if we are to understand the functioning of cells and organisms. Assembling and analyzing proteomes pose many experimental challenges, but ongoing technical advances are providing the necessary tools to meet those challenges.

Genomics and proteomics are enabling biologists to approach the study of life from an increasingly global perspective. Biologists are now in a position to compile catalogs of genes and proteins—a listing of all the “parts” that contribute to the operation of cells, tissues, and organisms. With such catalogs in hand, researchers are shifting their attention from the individual parts to their functional integration in biological systems. A first step in this systems biology approach is defining gene circuits and protein interaction networks (see Figure 1.10). With the use of computer science and mathematics to process and integrate vast amounts of biological data, researchers can detect and quantify the many combinations of interactions.

Another exciting prospect is our increasing understanding of the spectrum of genetic variation in humans. Because the history of the human species is so short, the amount of DNA variation among humans is small compared to that of many other species. Most of our diversity seems to be in the form of single nucleotide polymorphisms (SNPs, pronounced “snips”), which are single base-pair variations in the genome, usually detected by sequencing. In the human genome, SNPs occur on average about once in 1,000 base pairs. In other words, if you could compare your personal DNA sequence with that of a person of the same gender—either sitting next to you or on the other side of the world—you would find them to be 99.9% identical.

Scientists are already well on their way to identifying the locations of the several million SNP sites in the human genome. These will be useful genetic markers for studying human evolution, the differences between human populations, and the migratory routes of human populations throughout history. SNPs and other polymorphisms in noncoding (and coding) DNA will also be valuable markers for identifying disease genes and genes that affect our health in more subtle ways. This is likely to change the practice of medicine later in the 21st century. However, applications of DNA research and technology are already affecting our lives in many ways, as we discuss in the final section of the chapter.

Concept Check 20.4

1. Current estimates are that the human genome contains about 25,000 genes, but there is evidence for many more different human polypeptides. What processes might explain this discrepancy?
2. What is the major value of DNA microarray analysis for studying gene expression?
3. Why is the genetic variation among people so much less than it is among individuals of many other species?

For suggested answers, see Appendix A.

Concept 20.5

The practical applications of DNA technology affect our lives in many ways

DNA technology is in the news almost ever-day. Most often, the topic of the story is a new and promising application in medicine, but this is just one of numerous fields benefiting from DNA technology and genetic engineering.

Medical Applications

One obvious benefit of DNA technology is the identification of human genes whose mutation plays a role in genetic diseases. These discoveries may lead to ways of diagnosing, treating, and even preventing such conditions. DNA technology is also contributing to our understanding of “nongenetic” diseases, from arthritis to AIDS, since a person’s genes influence susceptibility to these diseases. Furthermore, diseases of all sorts involve changes in gene expression within the affected cells and often within the patient’s immune system. By using DNA microarray assays or other techniques to compare gene expression in healthy and diseased tissues, researchers hope

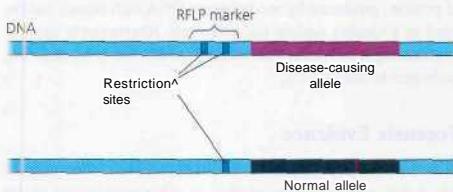

to find many of the genes that are turned on or off in particular diseases. These genes and their products are potential targets for prevention or therapy.

Diagnosis of Diseases

A new chapter in the diagnosis of infectious diseases has been opened by DNA technology, in particular the use of PCR and labeled nucleic acid probes to track down certain pathogens. For example, because the sequence of the HIV genetic material (RNA) is known, PCR can be used to amplify, and thus detect, HIV RNA in blood or tissue samples. RNA cannot be directly amplified by PCR, but the RNA genome is first converted to double-stranded cDNA with reverse transcriptase (RT). PCR is then performed on the cDNA, using a probe specific for one of the HIV genes. This technique, called *RT-PCR*, is often the best way to detect an otherwise elusive infection.

Medical scientists can now diagnose hundreds of human genetic disorders by using PCR and primers corresponding to cloned disease genes, then sequencing the amplified product to look for the disease-causing mutation. Among the genes for human diseases that have been cloned are those for sickle-cell disease, hemophilia, cystic fibrosis, Huntington's disease, and Duchenne muscular dystrophy. Affected individuals with such diseases often can be identified before the onset of symptoms, even before birth. It is also possible to identify symptomless carriers of potentially harmful recessive alleles (see Figure 20.10),

Even when a disease gene has not yet been cloned, the presence of an abnormal allele can be diagnosed with reasonable accuracy if a closely linked RFLP marker has been found (Figure 20.15). Alleles for Huntington's disease and a number of other genetic diseases were first detected in this indirect way. If the marker and the gene itself are close enough, crossing over between the marker and the gene is very unlikely to

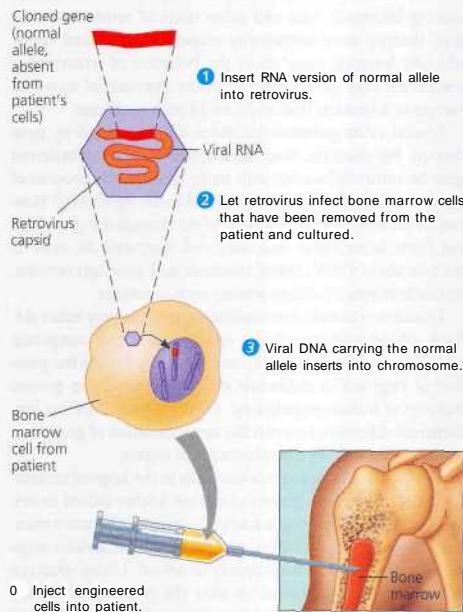

A Figure 20.15 RFLPs as markers for disease-causing alleles. This diagram depicts homologous segments of DNA from a family in which some members have a genetic disease. In this family, different versions of a RFLP marker are found in unaffected family members and in those who exhibit the disease. If a family member has inherited the version of the RFLP marker with two restriction sites near the gene (rather than one), there is a high probability that the individual has also inherited the disease-causing allele.

occur during gamete formation. Therefore, the marker and gene will almost always be inherited together, even though the RFLP marker is not part of the gene. The same principle applies to all kinds of markers, including SNPs.

Human Gene Therapy

Gene therapy—the alteration of an afflicted individual's genes—holds great potential for treating disorders traceable to a single defective gene. In theory, a normal allele of the defective gene could be inserted into the somatic cells of the tissue affected by the disorder.

For gene therapy of somatic cells to be permanent, the cells that receive the normal allele must be ones that multiply throughout the patient's life. Bone marrow cells, which include the stem cells that give rise to all the cells of the blood and immune system, are prime candidates. Figure 20.16 outlines one possible procedure for gene therapy of an individual

A Figure 20.16 Gene therapy using a retroviral vector. A retrovirus that has been rendered harmless is used as a vector in this procedure, which exploits the ability of a retrovirus to insert a DNA transcript of its RNA genome into the chromosomal DNA of its host cell (see Figure 18.10). If the foreign gene carried by the retroviral vector is expressed, the cell and its descendants will possess the gene product, and the patient may be cured. Cells that reproduce throughout life, such as bone marrow cells, are ideal candidates for gene therapy.

whose bone marrow cells do not produce a vital enzyme because of a single defective gene. One type of severe combined immunodeficiency (SCID) is caused by just this kind of defect. If the treatment is successful, the patients' bone marrow cells will begin producing the missing protein, and the patient will be cured.

The procedure shown in Figure 20.16 was used in the first gene therapy trial for SCID, which began in 1990. But the clinical results from this and succeeding studies during the 1990s did not convincingly demonstrate the effectiveness of the treatment. In another trial that started in 2000, ten young children with SCID were treated by the same procedure. Nine of these patients showed significant, definitive improvement after two years, the first indisputable success of gene therapy. However, two of the patients subsequently developed leukemia, a type of blood cell cancer. Researchers discovered that in both cases, the retroviral vector used to carry the normal allele into bone marrow cells had inserted near a gene involved in the proliferation and development of blood cells, causing leukemia. This and other trials of retrovirus-based gene therapy were temporarily suspended in several countries. By learning more about the behavior of retroviruses, researchers may be able to control the insertion of retroviral vectors to a location that might avoid such problems.

Several other technical questions are also posed by gene therapy. For example, how can the activity of the transferred gene be controlled so that cells make appropriate amounts of the gene product at the right time and in the right place? How can we be sure that the insertion of the therapeutic gene does not harm some other necessary cell function? As more is learned about DNA control elements and gene interactions, researchers may be able to answer such questions.

In addition to technical challenges, gene therapy raises difficult ethical questions. Some critics suggest that tampering with human genes in any way will inevitably lead to the practice of eugenics, a deliberate effort to control the genetic makeup of human populations. Other observers see no fundamental difference between the transplantation of genes into somatic cells and the transplantation of organs.

Treatment of human germ-line cells in the hope of correcting a defect in future generations raises further ethical issues. Such genetic engineering is routinely done in laboratory mice, and the technical problems relating to similar genetic engineering in humans will eventually be solved. Under what circumstances, if any, should we alter the genomes of human germ lines or embryos? In a way, this could be thought of as interfering with evolution. From a biological perspective, the elimination of unwanted alleles from the gene pool could backfire. Genetic variation is a necessary ingredient for the survival of a species as environmental conditions change with time. Genes that are damaging under some conditions may be advantageous under other conditions (one example is the sickle-cell allele, discussed in Chapter 14). Are we willing to

risk making genetic changes that could be detrimental to the survival of our species in the future? We may have to face this question soon.

Pharmaceutical Products

You learned earlier in the chapter about DNA cloning and expression systems for producing large quantities of proteins that are present naturally in only minute amounts. The host cells used in such expression systems can even be engineered to secrete a protein as it is made, thereby simplifying the task of purifying it by traditional biochemical methods.

Among the first pharmaceutical products "manufactured" in this way were human insulin and human growth hormone (HGH). Some 2 million people with diabetes in the United States depend on insulin treatment to control their disease. Human growth hormone has been a boon to children born with a form of dwarfism caused by inadequate amounts of HGH. Another important pharmaceutical product produced by genetic engineering is tissue plasminogen activator (TPA). If administered shortly after a heart attack, this protein helps dissolve blood clots and reduces the risk of subsequent heart attacks.

The most recent developments in pharmaceutical products involve truly novel ways to fight certain diseases that do not respond to traditional drug treatments. One approach is the use of genetically engineered proteins that either block or mimic surface receptors on cell membranes. One such experimental drug mimics a receptor protein that HIV binds to while entering white blood cells. The HIV binds to the drug molecules instead and fails to enter the blood cells.

DNA technology also can be used to produce vaccines, which stimulate the immune system to defend against specific pathogens (see Chapter 43). Traditional vaccines are of two types: inactivated (killed) microbes and viable but weakened (attenuated) microbes that generally do not cause illness. Most pathogens have one or more specific proteins on their surface that trigger an immune response against it. This type of protein, produced by recombinant DNA techniques, can be used as a vaccine against the pathogen. Alternatively, genetic engineering methods can be used to modify the genome of the pathogen to attenuate it.

Forensic Evidence

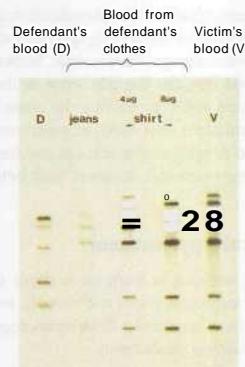

In violent crimes, body fluids or small pieces of tissue may be left at the scene or on the clothes or other possessions of the victim or assailant. If enough blood, semen, or tissue is available, forensic laboratories can determine the blood type or tissue type by using antibodies to detect specific cell-surface proteins. However, such tests require fairly fresh samples in relatively large amounts. Also, because many people have the same blood or tissue type, this approach can only exclude a suspect; it cannot provide strong evidence of guilt.

DNA testing, on the other hand, can identify the guilty individual with a high degree of certainty, because the DNA sequence of every person is unique (except for identical twins). RFLP analysis by Southern blotting is a powerful method for detecting similarities and differences in DNA samples and requires only tiny amounts of blood or other tissue (about 1,000 cells). In a murder case, for example, this method can be used to compare DNA samples from the suspect, the victim, and a small amount of blood found at the crime scene. The forensic scientist usually tests for about five RFLP markers; in other words, only a few selected portions of the DNA are tested. However, even such a small set of markers from an individual can provide a **DNA fingerprint**, or specific pattern of bands, that is of forensic use, because the probability that two people (who are not identical twins) would have the exact same set of RFLP markers is very small. The autoradiograph in **Figure 20.17** resembles the type of evidence presented to juries in murder trials.

DNA fingerprinting can also be used to establish paternity. A comparison of the DNA of a mother, her child, and the purported father can conclusively settle a question of paternity. Sometimes paternity is of historical interest: DNA fingerprinting has provided strong evidence that Thomas Jefferson or one of his close male relatives fathered at least one of the children of his slave Sally Flemings.

Today, instead of RFLPs, variations in the lengths of certain repeated base sequences in simple sequence DNA within the genome are increasingly used as markers for DNA fingerprinting. These repetitive DNA sequences are highly variable from person to person, providing even more markers than RFLPs. For example, one individual may have the repeat unit ACA repeated 65 times at one genome locus, 118 times at a second locus, and so on, whereas another individual is likely to have different numbers of repeats at these loci. Such polymorphic genetic loci are sometimes called **simple tandem repeats** (STRs). The greater the number of markers examined in a DNA sample, the more likely it is that the DNA fingerprint is unique to one individual. PCR is often used to amplify particular STRs or other markers before electrophoresis. PCR is especially valuable when the DNA is in poor condition or available only in minute quantities. A tissue sample as small as 20 cells can be sufficient for PCR amplification.

Just how reliable is DNA fingerprinting? In most forensic cases, the probability of two people having identical DNA fingerprints is between one chance in 100,000 and one in a billion. The exact figure depends on the number of markers compared and on the frequency of those markers in the general population. Information on how common various markers are in different ethnic groups is critical because these marker frequencies may vary considerably among ethnic groups and between a particular ethnic group and the population as a whole. With the increasing availability of frequency data, forensic scientists can make extremely accurate statistical

A Figure 20.17 DNA fingerprints from a murder case.

This autoradiograph shows that DNA in blood from the defendant's clothes matches the DNA fingerprint of the victim but differs from the DNA fingerprint of the defendant. This is evidence that the blood on the defendant's clothes came from the victim, not the defendant. The three DNA samples were subjected to Southern blotting using radioactive probes (see Figure 20.10). The DNA bands resulting from electrophoresis were exposed to probes for several different RFLP markers in succession, with the previous probe washed off before the next one was applied.

calculations. Thus, despite problems that can still arise from insufficient data, human error, or flawed evidence, DNA fingerprints are now accepted as compelling evidence by legal experts and scientists alike. In fact, DNA analysis on stored forensic samples has provided the evidence needed to solve many "cold cases" in recent years.

Environmental Cleanup

Increasingly, the remarkable ability of certain microorganisms to transform chemicals is being exploited for environmental cleanup. Scientists are now engineering these metabolic capabilities into other microorganisms, which are then used to help treat some environmental problems. For example, many bacteria can extract heavy metals, such as copper, lead, and nickel, from their environments and incorporate the metals into compounds such as copper sulfate or lead sulfate, which are readily recoverable. Genetically engineered microbes may become important in both mining minerals (especially as ore reserves are depleted) and cleaning up highly toxic mining wastes. Biotechnologists are also trying to engineer microbes that can degrade chlorinated hydrocarbons and other harmful compounds. These microbes could be used in wastewater treatment plants or by manufacturers before the compounds are ever released into the environment.

A related research area is the identification and engineering of microbes capable of detoxifying specific toxic wastes found in spills and waste dumps. For example, bacterial strains have been developed that can degrade some of the chemicals released during oil spills. By moving the genes responsible for these transformations into different organisms, bioengineers maybe able to develop strains that can survive the harsh conditions of environmental disasters and help detoxify the wastes.

Agricultural Applications

Scientists are working to learn more about the genomes of agriculturally important plants and animals, and for a number of years they have been using DNA technology in an effort to improve agricultural productivity:

Animal Husbandry and "Pharm" Animals

DNA technology is now routinely used to make vaccines and growth hormones for treating farm animals. On a still largely experimental basis, scientists can also introduce a gene from one animal into the genome of another animal, which is then called a transgenic animal. To do this, they first remove egg cells from a female and fertilize them *in vitro*. Meanwhile, they have cloned the desired gene from another organism. They then inject the cloned DNA directly into the nuclei of the fertilized eggs. Some of the cells integrate the foreign DNA, the *transgene*, into their genomes and are able to express the foreign gene. The engineered embryos are then surgically implanted in a surrogate mother. If an embryo develops successfully, the result is a transgenic animal, containing a gene from a third "parent" that may even be of another species.

The goals of creating a transgenic animal are often the same as the goals of traditional breeding—for instance, to make a sheep with better quality wool, a pig with leaner meat, or a cow that will mature in a shorter time. Scientists might, for example, identify and clone a gene that causes the development of larger muscles (muscles make up most of the meat we eat) in one variety of cattle and transfer it to other cattle or even to sheep.

Transgenic animals also have been engineered to be pharmaceutical "factories"—producers of a large amount of an otherwise rare biological substance for medical use. For example, a transgene for a desired human protein, such as a hormone or blood-clotting factor, can be inserted into the genome of a farm mammal in such a way that the transgene's product is secreted in the animal's milk (Figure 20.18). The protein can then be purified from the milk, usually more easily than from a cell culture. Recently, researchers have engineered transgenic chickens that express large amounts of the transgene's product in eggs. Their success suggests that transgenic chickens may emerge as relatively inexpensive pharmaceutical factories in the near future.

& Figure 20.18 "Pharm" animals. These transgenic sheep carry a gene for a human blood protein, which they secrete in their milk. This protein inhibits an enzyme that contributes to lung damage in patients with cystic fibrosis and some other chronic respiratory diseases. Easily purified from the sheep's milk, the protein is currently under evaluation as a treatment for cystic fibrosis.

Human proteins produced by farm animals may differ in some ways from the corresponding natural human proteins. Thus, these proteins must be tested very carefully to ensure that they will not cause allergic reactions or other adverse effects in patients receiving them. Also, the health and welfare of farm animals carrying genes from humans and other foreign species are important issues; problems such as low fertility or increased susceptibility to disease are not uncommon.

Genetic Engineering in Plants

Agricultural scientists have already endowed a number of crop plants with genes for desirable traits, such as delayed ripening and resistance to spoilage and disease. In one striking way, plants are easier to genetically engineer than most animals. For many plant species, a single tissue cell grown in culture can give rise to an adult plant (see Figure 21.5). Thus, genetic manipulations can be performed on a single cell and the cell then used to generate an organism with new traits.

The most commonly used vector for introducing new genes into plant cells is a plasmid, called the Ti plasmid, from the soil bacterium *Agrobacterium tumefaciens*. This plasmid integrates a segment of its DNA, known as T DNA, into the chromosomal DNA of its host plant cells. For vector purposes, researchers work with a version of the plasmid that does not cause disease, as the wild-type version does. Figure 20.19 outlines one method for using the Ti plasmid to produce transgenic plants. Scientists can introduce recombinant Ti plasmids into plant cells by electroporation. Alternatively, the recombinant plasmid can be put back into *Agrobacterium*; susceptible plants or plant cells growing in culture are then infected with bacteria that contain the recombinant plasmid.

Figure 20.19

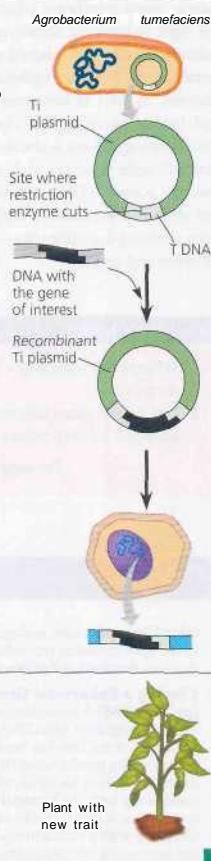

Research Method Using the Ti Plasmid to Produce Transgenic Plants

APPLICATION

Genes conferring useful traits, such as pest resistance, herbicide resistance, delayed ripening, and increased nutritional value, can be transferred from one plant variety or species to another using the Ti plasmid as a vector.

TECHNIQUE

- The Ti plasmid is isolated from the bacterium *Agrobacterium tumefaciens*. The segment of the plasmid that integrates into the genome of host cells is called T DNA.

- Isolated plasmids and foreign DNA containing a gene of interest are incubated with a restriction enzyme that cuts in the middle of T DNA. After base pairing occurs between the sticky ends of the plasmids and foreign DNA fragments, DNA ligase is added. Some of the resulting stable recombinant plasmids contain the gene of interest.

- Recombinant plasmids can be introduced into cultured plant cells by electroporation. Or plasmids can be returned to *Agrobacterium*, which is then applied as a liquid suspension to the leaves of susceptible plants, infecting them. Once a plasmid is taken into a plant cell, its T DNA integrates into the cell's chromosomal DNA.

RESULTS

Transformed cells carrying the transgene of interest can regenerate complete plants that exhibit the new trait conferred by the transgene.

Plant with new trait

Genetic engineering is rapidly replacing traditional plant-breeding programs, especially for useful traits, such as herbicide or pest resistance, determined by one or a few genes. For example, crops engineered with a bacterial gene making the plants resistant to herbicides can grow while weeds are destroyed. Similarly, genetically engineered crops that can resist

destructive microbes and insects have reduced the need for chemical insecticides.

Genetic engineering also has great potential for improving the nutritional value of crop plants. For instance, scientists have developed transgenic rice plants that produce yellow rice grains containing beta-carotene, which our body uses to make vitamin A (see Figure 38.16). This "golden" rice could help prevent vitamin A deficiency in the half of the world's population that depends on rice as a staple food. Currently, large numbers of young children in Southeast Asia suffer from vitamin A deficiency, which leads to vision impairment and increases susceptibility to disease.

In a novel twist, the pharmaceutical industry is beginning to develop "pharm" plants, analogous to "pharm" animals. Although natural plants have long been sources of drugs, researchers are now creating plants that make human proteins for medical use and viral proteins for use as vaccines. Several such products are being tested in clinical trials, including vaccines for hepatitis B and an antibody produced in transgenic tobacco plants that interferes with the bacteria that cause tooth decay. Large amounts of these proteins might be produced more economically by plants than by cultured cells.

Safety and Ethical Questions Raised by DNA Technology

Early concerns about potential dangers associated with recombinant DNA technology focused on the possibility that hazardous new pathogens might be created. What might happen, for instance, if cancer cell genes were transferred into bacteria or viruses? To guard against such rogue microbes, scientists developed a set of guidelines that were adopted as formal government regulations in the United States and some other countries. One safety measure is a set of strict laboratory procedures designed to protect researchers from infection by engineered microbes and to prevent the microbes from accidentally leaving the laboratory. In addition, strains of microorganisms to be used in recombinant DNA experiments are genetically crippled to ensure that they cannot survive outside the laboratory. Finally, certain obviously dangerous experiments have been banned.

Today, most public concern about possible hazards centers not on recombinant microbes but on genetically modified (GM) organisms used as food. In common language, a GM organism is one that has acquired by artificial means one or more genes from the same or another species. Salmon, for example, have been genetically modified by addition of a more active salmon growth hormone gene. However, the majority of the GM organisms that contribute to our food supply are not animals, but crop plants.

Some countries have been wary⁷ of the GM revolution, with the safety of GM foods and possible environmental consequences of growing GM plants being the major concerns. In

1999, for instance, the European Union suspended the introduction of new GM crops pending new legislation. Early in 2000, negotiators from 130 countries (including the United States) agreed on a Biosafety Protocol that requires exporters to identify GM organisms present in bulk food shipments and allows importing countries to decide whether the products pose environmental or health risks.

Advocates of a cautious approach toward GM crops fear that transgenic plants might pass their new genes to close relatives in nearby wild areas. We know that lawn and crop grasses, for example, commonly exchange genes with wild relatives via pollen transfer. If crop plants *carrying* genes for resistance to herbicides, diseases, or insect pests pollinated wild ones, the offspring might become "super weeds" that are very difficult to control. Another possible hazard, suggested by one laboratory-based study, is that a transgene encoding a pesticide-type protein might cause plants to produce pollen toxic to butterflies. However, scientists with the Agricultural Research Service concluded from a two-year study that butterflies were unlikely to be exposed to toxic levels of pollen.

As for the risks to human health from GM foods, some people fear that the protein products of transgenes might lead to allergic reactions. Although there is some evidence that this could happen, advocates claim that these proteins could be tested for their ability to cause allergic reactions.

Today, governments and regulatory agencies throughout the world are grappling with how to facilitate the use of biotechnology in agriculture, industry, and medicine while ensuring that new products and procedures are safe. In the United States, such applications of biotechnology are eval-

uated for potential risks by various regulatory agencies, including the Food and Drug Administration, Environmental Protection Agency, National Institutes of Health, and Department of Agriculture. These agencies are under increasing pressure from some consumer groups. Meanwhile, these same agencies and the public must consider the ethical implications of biotechnology.

Completion of the mapping of the human genome, for instance, raises significant ethical questions. Who should have the right to examine someone else's genes? How should that information be used? Should a person's genome be a factor in suitability for a job or eligibility for insurance? Ethical considerations, as well as concerns about potential environmental and health hazards, will likely slow some applications of biotechnology. There is always a danger that too much regulation will stifle basic research and its potential benefits. However, the power of DNA technology and genetic engineering—our ability to profoundly and rapidly alter species that have been evolving for millennia—demands that we proceed with humility and caution.

Concept Check 20.5

- What is the advantage of using stem cells for gene therapy?
- List at least three different properties that have been acquired by crop plants via genetic engineering.

Chapter 20 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 20.1

DNA cloning permits production of multiple copies of a specific gene or other DNA segment

• **DNA Cloning and Its Applications: A Preview**

(pp. 385–386) DNA cloning and other techniques, collectively termed DNA technology, can be used to manipulate and analyze DNA and to produce useful new products and organisms.

Activity Applications of DNA Technology

• **Using Restriction Enzymes to Make Recombinant DNA**

(p. 386) Bacterial restriction enzymes cut DNA molecules within short, specific nucleotide sequences to yield a set of double-stranded DNA fragments with single-stranded sticky ends. The sticky ends on fragments from one DNA source can base-pair with complementary sticky ends on fragments from

other DNA molecules; sealing of the base-paired fragments with DNA ligase produces recombinant DNA molecules.

Activity Restriction Enzymes

• **Cloning a Eukaryotic Gene in a Bacterial Plasmid**

(pp. 386–388) A recombinant plasmid is made by inserting restriction fragments from DNA containing a gene of interest into a plasmid vector that has been cut open by the same enzyme. Gene cloning results when the recombinant plasmid is introduced into a host bacterial cell and the foreign genes are replicated along with the bacterial chromosome as the host cell reproduces. A clone of cells carrying the gene of interest can be identified with a radioactively labeled nucleic acid probe that has a sequence complementary to the gene.

Activity Cloning a Gene in Bacteria

Investigation How Can Antibiotic-Resistant Plasmids Transform E. coli?

• **Storing Cloned Genes in DNA Libraries** (pp. 388–390)

A genomic library is the collection of recombinant vector clones produced by cloning DNA fragments derived from an entire genome. A cDNA (complementary DNA) library is made by cloning DNA made *in vitro* by reverse transcription of all the mRNA produced by a particular kind of cell.

- **Cloning and Expressing Eukaryotic Genes** (pp. 390–391) Several technical difficulties hinder the expression of cloned eukaryotic genes in bacterial host cells. The use of cultured eukaryotic cells as host cells and yeast artificial chromosomes (YACs) as vectors helps avoid these problems.
- **Amplifying DNA in Vitro: The Polymerase Chain Reaction (PCR)** (pp. 391–392) PCR can produce many copies of a specific target segment of DNA, using primers that bracket the desired sequence and a heat-resistant DNA polymerase.

Concept 20.2

Restriction fragment analysis detects DNA differences that affect restriction sites

- **Gel Electrophoresis and Southern Blotting**

(pp. 392–394) DNA restriction fragments of different lengths can be separated by gel electrophoresis. Specific fragments can be identified by Southern blotting, using labeled probes that hybridize to the DNA immobilized on a "blot" of the gel.

Activity Gel Electrophoresis of DNA

- **Restriction Fragment Length Differences as Genetic Markers** (p. 394) Restriction fragment length polymorphisms (RFLPs) are differences in DNA sequence on homologous chromosomes that result in restriction fragments of different lengths, which can be detected by Southern blotting. The thousands of RFLPs present throughout eukaryotic DNA can serve as genetic markers.

Activity Analyzing DNA Fragments Using Gel Electrophoresis: Investigation How Can Gel Electrophoresis Be Used to Analyze DNA?

Concept 20.3

Entire genomes can be mapped at the DNA level

- **Genetic (Linkage) Mapping: Relative Ordering of Markers** (p. 396) The order of genes and other inherited markers in the genome and the relative distances between them can be determined from recombination frequencies.

- **Physical Mapping: Ordering DNA Fragments** (p. 396) A physical map is constructed by cutting a DNA molecule into many short fragments and arranging them in order by identifying overlaps. A physical map gives the actual distance in base pairs between markers.

- **DNA Sequencing** (pp. 396–398) Relatively short DNA fragments can be sequenced by the dideoxy chain-termination method, which can be performed in automated sequencing machines.

Activity The Human Genome Project: Genes on Human Chromosome 17

Concept 20.4

Genome sequences provide clues to important biological questions

- **Identifying Protein-Coding Genes in DNA Sequences** (p. 399) Computer analysis of genome sequences helps researchers identify sequences that are likely to encode proteins. Current estimates are that, the human genome contains about 25,000 genes, but the number of human proteins is much larger. Comparison of the sequences of "new" genes with those of known genes in other species may help identify new genes.

- **Determining Gene Function** (p. 400) For a gene of unknown function, experimental inactivation of the gene and observation of the resulting phenotypic effects can provide clues to its function.

- **Studying Expression of Interacting Groups of Genes** (p. 400) DXA nucleic acid assays allow researchers to compare patterns of gene expression in different tissues, at different times, or under different conditions.
- **Comparing Genomes of Different Species** (pp. 400–402) Comparative studies of genomes from related and widely divergent species are providing valuable information in many fields of biology.
- **Future Directions in Genomics** (p. 402) Genomics is the systematic study of entire genomes; proteomics is the systematic study of all the proteins encoded by a genome. Single nucleotide polymorphisms (SNPs) provide useful markers for studying human genetic variation.

Concept 20.5

The practical applications of DNA technology affect our lives in many ways

- **Medical Applications** (pp. 402–404) DNA technology is increasingly being used in the diagnosis of genetic and other diseases and offers potential for better treatment of certain genetic disorders or even permanent cures.

- **Pharmaceutical Products** (p. 404) Large-scale production of human hormones and other proteins with therapeutic uses, including safer vaccines, are possible with DNA technology.

- **Forensic Evidence** (pp. 404–405) DNA "fingerprints" obtained by analysis of tissue or body fluids found at crime scenes can provide definitive evidence that a suspect is guilty or not. Such fingerprints are also useful in paternity disputes.

Activity DNA Fingerprinting

- **Environmental Cleanup** (pp. 405–406) Genetic engineering can be used to modify the metabolism of microorganisms so that they can be used to extract minerals from the environment or degrade various types of potentially toxic waste materials.

- **Agricultural Applications** (pp. 406–407) The aim of developing transgenic plants and animals is to improve agricultural productivity and food quality.

- **Safety and Ethical Questions Raised by DNA Technology** (pp. 407–408) The potential benefits of genetic engineering must be carefully weighed against the potential hazards of creating products or developing procedures that are harmful to humans or the environment.

Activity Making Decisions About DNA Technology: Golden Rice

TESTING YOUR KNOWLEDGE

Evolution Connection

If DNA-based technologies become widely used, how might they change the way evolution proceeds, as compared with the natural evolutionary mechanisms of the past 4 billion years?

Scientific Inquiry

You hope to study a gene that codes for a neurotransmitter protein in human brain cells. You know the amino acid sequence of the protein. Explain how you might (a) identify the genes expressed in

a specific type of brain cell, (b) identify the gene for the neurotransmitter, (c) produce multiple copies of the gene for study, and (d) produce a quantity of the neurotransmitter for evaluation as a potential medication.

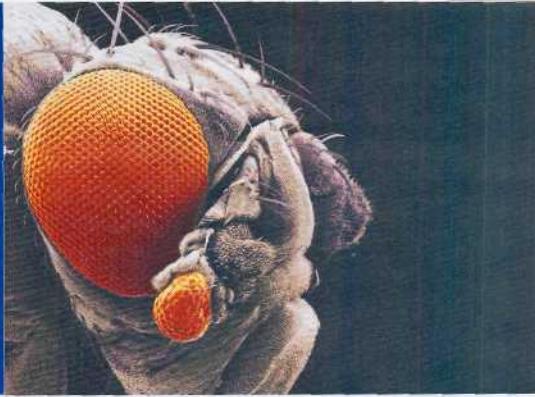

Investigation How Can Antibiotic-Resistant Plasmids Transform *E. coli*?

Investigation How Can Gel Electrophoresis Be Used to Analyze DNA?

Science, Technology, and Society

Is there danger of discrimination based on testing for "harmful" genes? What policies can you suggest that would prevent such abuses?

21 The Genetic Basis of Development

A Figure 21.1 Mutant *Drosophila* with an extra small eye on its antenna.

Key Concepts

- 21.1 Embryonic development involves cell division, cell differentiation, and morphogenesis
- 21*2 Different cell types result from differential gene expression in cells with the same DNA
- 21.3 Pattern formation in animals and plants results from similar genetic and cellular mechanisms
- 21.4 Comparative studies help explain how the evolution of development leads to morphological diversity

Overview

From Single Cell to Multicellular Organism

This chapter applies much of what you've learned about molecules, cells, and genes to one of biology's most important questions—how a complex multicellular organism develops from a single cell. The application of genetic analysis and DNA technology to the study of development has revolutionized the field. In much the same way that researchers have used mutations to deduce pathways of cellular metabolism, they now use mutations to dissect developmental pathways. In one striking example, Swiss researchers demonstrated in 1995 that a particular gene functions as a master switch that triggers development of the eye in *Drosophila*. The scanning electron micrograph in Figure 21.1 shows part of the head of an abnormal fly that has a small extra eye on each antenna. In this fly, the

master gene triggering eye development was expressed in an abnormal body location, causing extra eyes. A similar gene activates eye development in mice and other mammals. In fact, developmental biologists are discovering remarkable similarities in the mechanisms that form diverse organisms.

The scientific study of development got under way about 130 years ago, around the same time as genetics. But for decades, the two disciplines proceeded along mostly separate paths. Developmental biologists focused on embryology—the study of the stages of development leading from a fertilized egg to a fully formed organism. They studied animals that lay their eggs in water, including marine invertebrates and freshwater vertebrate amphibians, such as frogs. By studying these and other animals, as well as plants, biologists worked out a description of animal development (see Chapter 47) and plant development (see Chapter 35) at the macroscopic and microscopic levels.

In recent years, scientists have applied the concepts and tools of molecular genetics to the study of developmental biology with remarkably fruitful results. In this chapter, we introduce some of the basic mechanisms that control development in animals and plants, focusing on what has been learned from molecular and genetic studies. After introducing the basic cellular processes underlying development, we consider how cells become different from each other and the factors that establish the spatial pattern of these different types of cells in the embryo. Next, we examine in more detail the molecular basis of several specific developmental phenomena as examples of some general principles of development. Finally, we discuss what researchers can learn about evolution from comparing developmental processes in different species.

Figure 21.2

Exploring Model Organisms for Genetic Studies of Development

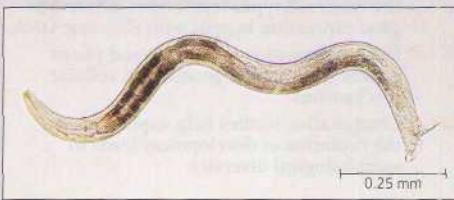

DROSOPHILA MELANOGASTER
(FRUIT FLY)

Researchers can draw on a wealth of information about the fruit fly *Drosophila melanogaster* (often referred to simply as *Drosophila*). One of the most important model organisms in developmental genetics, first chosen as a model organism by the pioneering geneticist T. H. Morgan in the early 20th century, *Drosophila* has been studied intensively by generations of geneticists since then. Small and easily grown in the laboratory, *Drosophila* has a generation time of only two weeks. It produces many offspring and the embryos develop outside the mother's body—both assets for developmental studies. Sequencing of the *Drosophila* genome was completed in 2000; it has 180×10^6 base pairs (180 million bases, Mb) and contains about 13,700 genes. Although early development of fruit flies is at least superficially quite different from that of many other animals, research on *Drosophila* development has yielded deep insights into basic principles of animal development.

CAENORHABDITIS ELEGANS
(NEMATODE)

The soil-dwelling nematode *Caenorhabditis elegans* (or *C. elegans*) is easily grown in the laboratory in petri dishes. It is about 1 mm long, has a simple, transparent body with only a few types of cells, and grows from zygote to mature adult in only three and a half days. The nematode genome is 97 Mb long and contains an estimated 19,300 genes. Most individuals are hermaphrodites, producing both eggs and sperm. Hermaphrodites are convenient for genetic studies because recessive mutations are easy to detect. If a worm with the wild-type phenotype self-fertilizes and one-fourth of its offspring have a mutant phenotype (homozygous for a recessive allele), then the parent must be heterozygous for the recessive mutant allele. Even if homozygotes with the recessive mutation do not reproduce, the mutation can be maintained in the heterozygotes. Another advantage of *C. elegans* is that every adult hermaphrodite has exactly 959 somatic cells, which arise from the zygote in virtually the same way for every individual. Using a microscope to follow all the cell divisions starting immediately after a zygote forms, biologists have been able to reconstruct the entire ancestry of every cell in the adult body.

When the primary research goal is to understand broad biological principles, the organism chosen for study is called a **model organism**. Researchers select model organisms that lend themselves to the study of a particular question, are representative of a larger group, and are easy to grow in the lab. For research aimed at uncovering the connections between genes and development, biologists have turned to organisms which have relatively short generation times and small genomes and about which much is already known. Organisms with these attributes are particularly convenient for genetic analysis. Among the favorite model organisms in developmental genetics are the fruit fly *Drosophila melanogaster*, the nematode *Caenorhabditis elegans*, the mouse *Mus musculus*, the zebrafish *Danio rerio*, and the plant *Arabidopsis thaliana*. Before proceeding, acquaint yourself with these model organisms in **Figure 21.2**. Developmental principles we have learned from studying these organisms will be presented throughout this chapter.

Concept 21.1

Embryonic development involves cell division, cell differentiation, and morphogenesis

In the embryonic development of most organisms, a single-celled zygote (fertilized egg) gives rise to cells of many different types, each type with a different structure and corresponding function. For example, an animal will have muscle cells that enable it to move and nerve cells that transmit signals to the muscle cells; a plant will have mesophyll cells that carry out photosynthesis and guard cells around stomata (pores) that regulate the passage of gases into and out of leaves. Within a multicellular organism, cells of different types are organized into tissues, tissues into organs, organs into organ systems, and

MUS MUSCULUS
(MOUSE)

DANIO RERIO
(ZEBRAFISH)

ARABIDOPSIS THALIANA
(COMMON WALL CRESS)

Among vertebrates, two in particular lend themselves to the genetic analysis of development, the mouse and the zebrafish. The mouse *Mus musculus* has a long history as a mammalian model, and much is known about its biology. The mouse genome is about 2,600 Mb long with about 25,000 genes, roughly the same as the human genome. Researchers are now adept at manipulating mouse genes to make transgenic mice and mice in which particular genes are "knocked out" by mutation. However, mice have a generation time of about nine weeks, and their embryos develop in the mother's uterus, hidden from view, both disadvantages for developmental studies.

Many of the disadvantages of the mouse as a vertebrate model are absent in the zebrafish *Danio rerio*. These small fish (2–4 cm long) are easy to breed in the laboratory, and the transparent embryos develop outside the mother's body. Although the generation time is relatively long (two to four months), early development proceeds quickly: By 24 hours after fertilization, most of the tissues and rudiments of the organs have formed, and by two days, a tiny fish hatches out of the egg case. The zebrafish genome (estimated to be 1,700 Mb long) is still being mapped and sequenced, but researchers have already identified many genes involved in this animal's development.

For studying the molecular genetics of plant development, researchers often use a small flowering plant in the mustard family called *Arabidopsis thaliana* (or simply *Arabidopsis*). One of these plants can grow in a test tube and produce thousands of progeny after eight to ten weeks; as in Mendel's pea plants, each flower makes both eggs and sperm. For research on gene function, scientists can make transgenic *Arabidopsis* plants (see Figure 20.19). Compared with some other plant species, *Arabidopsis* has a relatively small genome, about 118 Mb, which contains an estimated 25,500 genes.

organ systems into the whole organism. Thus, the process of embryonic development must give rise not only to cells of different types but to higher-level structures arranged in a particular way in three dimensions.

The photos in Figure 21.3 illustrate the dramatic transformation of a zygote into an organism. This transformation results from three interrelated processes: cell division, cell differentiation, and morphogenesis. Through a succession of mitotic cell divisions, the zygote gives rise to a large number of cells. Cell division alone, however, would produce only a great ball of identical cells, nothing like an animal or plant. During embryonic development, cells not only increase in number, but also undergo **cell differentiation**, the process by which cells become specialized in structure and function. Moreover, the different kinds of cells are not randomly distributed but are organized into tissues and organs. The physical processes that give an organism its shape constitute morphogenesis, meaning "creation of form."

(a) Fertilized eggs of a frog

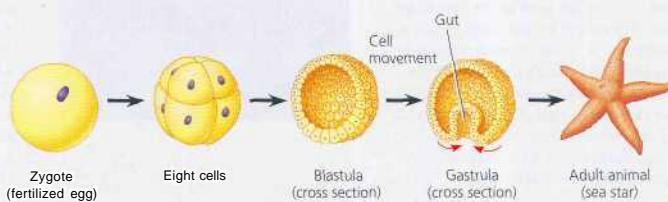

(b) Tadpole hatching from egg

A **Figure 21.3 From fertilized egg to animal: what a difference a week makes**, it takes just one week for cell division, differentiation, and morphogenesis to transform each of the fertilized frog eggs shown in (a) into a hatching tadpole like the one in (b). A protective jelly coat surrounds the eggs and tadpole.

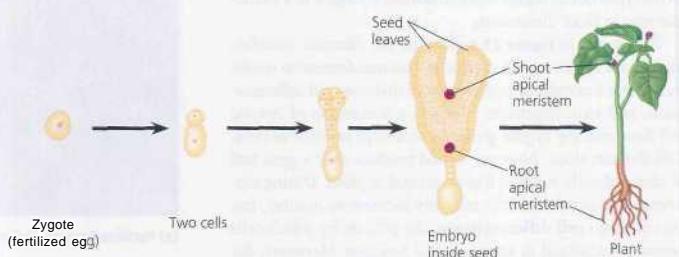

The processes of cell division, differentiation, and morphogenesis overlap in time (**Figure 21.4**). Morphogenetic events lay out the basic body plan very early in embryonic development, establishing, for example, which end of an animal embryo will be the head or which end of a plant embryo will become the roots. These early events determine the body axes of the organism, such as the anterior-posterior (head-to-tail) axis and the dorsal-ventral (back-to-belly) axis. Later morphogenetic events establish relative locations of structures within smaller regions of the embryo, such as the appendages on a fly's body, the fins on a fish, or the digits on a vertebrate limb—and then within regions still smaller.

Cell division and differentiation play important roles in morphogenesis in all organisms, as does the appropriately timed programmed death of certain cells. However, the overall schemes of morphogenesis in animals and plants exhibit significant differences. In addition to many shared developmental mechanisms, the development of animals and plants differs in two major ways:

- (a) **Animal development.** Most animals go through some variation of the blastula and gastrula stages. The blastula is a sphere of cells surrounding a fluid-filled cavity. The gastrula forms when a region of the blastula folds inward, creating a tube—a rudimentary gut. Once the animal is mature, differentiation occurs in only a limited way—for the replacement of damaged or lost cells.

- (b) **Plant development.** In plants with seeds, a complete embryo develops within the seed. Morphogenesis, which involves cell division and cell wall expansion rather than cell or tissue movement, occurs throughout the plant's lifetime. Apical meristems (purple) continuously arise and develop into the various plant organs as the plant grows to an indeterminate size.

A Figure 21.4 Some key stages of development in animals and plants. Cell division, morphogenesis, and cell differentiation occur in both animal development and plant development. Molecular events leading to cell differentiation begin as early as the two-cell stage, but observable differences among cells are not evident until much later.

- In animals, but not in plants, movements of cells and tissues are necessary to transform the early embryo into the characteristic three-dimensional form of the organism.
- In plants, but not in animals, morphogenesis and growth in overall size are not limited to embryonic and juvenile periods but occur throughout the life of the plant.

The structures responsible for a plant's continual growth and formation of new organs are **apical meristems**, perpetually embryonic regions in the tips of shoots and roots. In animals, ongoing development in adults is normally restricted to the generation of cells that must be continually replenished throughout the animal's lifetime. Examples are blood cells, skin cells, and the cells lining the intestines.

During differentiation and morphogenesis, embryonic cells behave and function in different ways from each other, even though all of them have arisen from the same cell—the zygote. In the next section, you will learn about the principal way in which this occurs.

Concept Check 21.1

- As you learned in Chapter 12, mitosis gives rise to two daughter cells that are genetically identical to the parent cell. Yet you, the product of many mitotic divisions, are not just a ball of identical cells. Why?
- What are the fundamental differences between plants and animals in their mechanisms of development?

For suggested answers, see Appendix A.

Concept 21.2

Different cell types result from differential gene expression in cells with the same DNA

In earlier chapters, we have stated that differences between cells in a multicellular organism come almost entirely from differences in gene expression, not from differences in the cells' genomes. (There are a few exceptions, such as antibody-producing cells; see Figure 43.11.) Furthermore, we have mentioned that these differences arise during development as regulatory mechanisms turn specific genes on and off. Let's now look at some of the evidence for this assertion.

Evidence for Genomic Equivalence

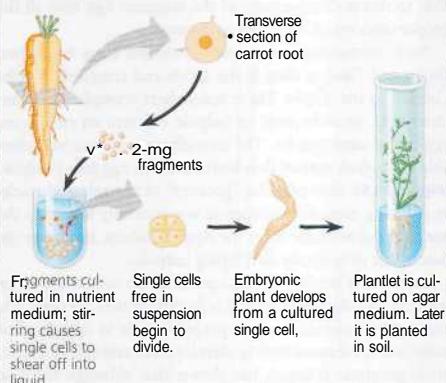

The results of many experiments support the conclusion that nearly all the cells of an organism have genomic "equivalence": that is, they all have the same genes. What happens to these genes as a cell begins to differentiate? We can shed some light on this question by asking whether genes are irreversibly inactivated during differentiation. For example, does an epidermal cell in your finger contain a functional gene specifying eye color, or has the eye-color gene been destroyed or permanently inactivated there?

Totipotency in Plants

One experimental approach for testing genomic equivalence is to see whether a differentiated cell can generate a whole organism. Such experiments were performed during the 1950s by Y.-C. Steward and his students at Cornell University, working with carrot plants (Figure 21.5). They found that differentiated cells taken from the root (the carrot) and placed in culture medium could grow into normal adult plants, each genetically identical to the "parent" plant. These results show that differentiation does not necessarily involve irreversible changes in the DNA. In plants, at least, mature cells can dedifferentiate and then give rise to all the specialized cell types of the mature organism. Any cell with this potential is said to be totipotent.

Figure 21.5
Inquiry Can a differentiated plant cell develop into a whole plant?

EXPERIMENT

RESULTS

A single somatic (nonproductive) carrot cell developed into a mature carrot plant. The new plant was a genetic duplicate (clone) of the parent plant.

Adult plant

CONCLUSION

At least some differentiated (somatic) cells in plants are totipotent, able to reverse their differentiation and then give rise to all the cell types in a mature plant.

Using one or more somatic cells from a multicellular organism to make another genetically identical individual is called **cloning**, and each new individual made in this way can be called a clone (from the Greek *klon*, twig). Plant cloning is now used extensively in agriculture. Indeed, if you have ever grown a new plant from a cutting, you have practiced cloning.

Nuclear Transplantation in Animals

Differentiated cells from animals generally do not divide in culture, much less develop into the multiple cell types of a new organism. Therefore, animal researchers had to use a different approach to the question of whether differentiated

animal cells can be totipotent. Their approach was to remove the nucleus of an unfertilized egg cell or zygote and replace it with the nucleus of a differentiated cell, a method called *nuclear transplantation*. If the nucleus from the differentiated donor cell retains its full genetic capability, then it should be able to direct development of the recipient egg into all the proper tissues and organs of an organism.

Such experiments were conducted on frogs by Robert Briggs and Thomas King in the 1950s and extended by John Gurdon in the 1980s. These researchers transplanted a nucleus from an embryonic or tadpole cell into an enucleated egg of the same species. The transplanted nucleus was often able to support normal development of the egg into a tadpole (**Figure 21.6**). However, the "potency" of transplanted nuclei in directing normal development was inversely related to the age of the donor: the older the donor nucleus, the lower the percentage of normally developing tadpoles.

From these results, we can conclude that something in the nucleus *does* change as animal cells differentiate. In frogs and most other animals, nuclear potency tends to be restricted more and more as embryonic development and cell differentiation progress. Research has shown that although the base sequence of the DNA usually does not change, the chromatin structure is altered in specific ways, usually involving chemical modifications of histones or DNA methylation (see Chapter 19). However, these chromatin changes are sometimes reversible, and biologists agree that the nuclei of most differentiated animal cells have all the genes required for making the entire organism. In other words, the various cell types in the body of an animal differ in structure and function not because they contain different genes, but because they express different sets of genes from a common genome.

Reproductive Cloning of Mammals. Evidence that all cells in an organism have the same DNA also comes from experiments with mammals. Researchers have long been able to clone mammals using nuclei or cells from a variety of early embryos. But it was not known whether a nucleus from a fully differentiated cell could be reprogrammed⁷ to be totipotent. However, in 1997, Scottish researchers captured newspaper headlines when they announced the birth of Dolly, a lamb cloned from an adult sheep by nuclear transplantation from a differentiated cell (**Figure 21.7**). These researchers achieved the necessary dedifferentiation of donor nuclei by culturing mammary cells in nutrient-poor medium. The researchers then fused these cells with sheep egg cells whose nuclei had been removed. The resulting diploid cells divided to form early embryos, which were implanted into surrogate mothers. One of several hundred implanted embryos successfully completed normal development, and Dolly was born.

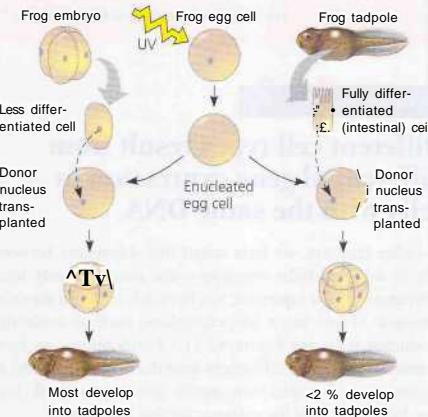

Later analyses showed that Dolly's chromosomal DNA was indeed identical to that of the nucleus donor. (Her mitochondrial DNA came from the egg cell donor, as expected.)

Figure 21.6

It's Not Just Eggs! Can the nucleus from a differentiated animal cell direct development of an organism?

EXPERIMENT

Researchers enucleated frog egg cells by exposing them to ultraviolet light, which destroyed the nucleus. Nuclei from cells of embryos up to the tadpole stage were transplanted into the enucleated egg cells.

RESULTS

Most of the recipient eggs developed into tadpoles when the transplanted nuclei came from cells of an early embryo, which are relatively undifferentiated cells. But with nuclei from the fully differentiated intestinal cells of a tadpole, fewer than 2% of the eggs developed into normal tadpoles, and most of the embryos died at a much earlier developmental stage.

CONCLUSION

The nucleus from a differentiated frog cell can direct development of a tadpole. However, its ability to do so decreases as the donor cell becomes more differentiated, presumably because of changes in the nucleus.

In 2003, at age 6, Dolly suffered complications from a lung disease usually seen in much older sheep and was euthanized. Dolly's premature death, as well as her arthritic condition, led to speculation that her cells were "older" than those of a normal sheep, possibly reflecting incomplete reprogramming of the original transplanted nucleus.

Since 1997, cloning has also been demonstrated in numerous other mammals, including mice, cats, cows, horses, and pigs. In most cases, the goal has been to produce new individuals; this is known as *reproductive cloning*. We have already learned much of interest from such experiments. For example, cloned animals of the same species do not always look or behave identically. In a herd of cows cloned from the same cell line, certain cows are dominant and others are more submissive. Another example is the first cloned

Figure 21.7

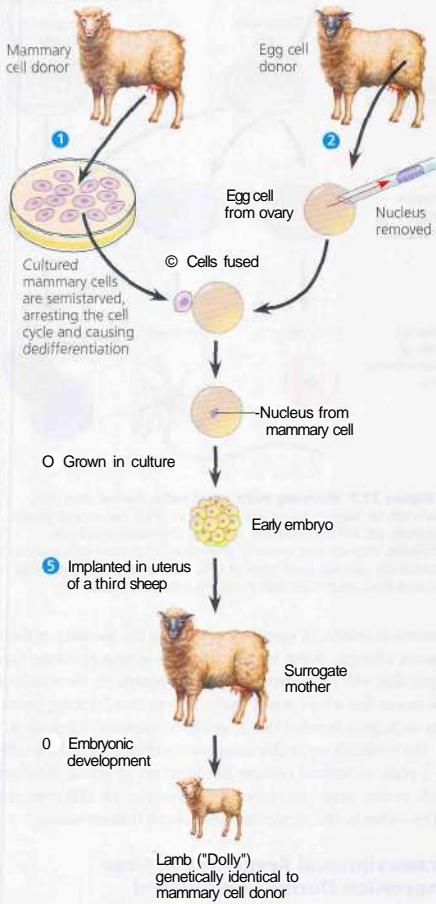

Research Method I Reproductive Cloning of a Mammal by Nuclear Transplantation

APPLICATION

This method is used to produce cloned animals whose nuclear genes are identical to the donor animal supplying the nucleus.

TECHNIQUE

Shown here is the procedure used to produce [Dolly, the first reported case of a mammal cloned using the nucleus of a differentiated cell.

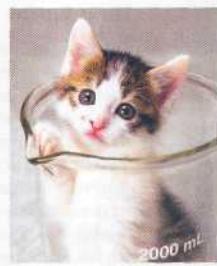

RESULTS

The cloned animal is identical in appearance and genetic makeup to the donor animal supplying the nucleus, but differs from the egg cell donor and surrogate mother.

cat, named Copy Cat (Figure 21.8). She has a calico coat, like her single female parent, but the color and pattern are different due to random X chromosome inactivation, which is a normal occurrence during embryonic development (see Figure 15.10). Clearly, environmental influences and random phenomena can play a significant role during development.

The successful cloning of various mammals has heightened speculation about the cloning of humans. In early 2004, South Korean researchers reported success in the first step of reproductive cloning of humans. In this work, nuclei from differentiated human cells were transplanted into unfertilized eggs from which the nuclei had been removed. These eggs were stimulated to divide, and some reached the blastocyst stage, an early embryonic stage similar to the blastula stage in Figure 21.4. Although the embryos were not allowed to develop beyond the blastocyst stage, the work of these researchers brings us one step closer to the possibility of human reproductive cloning, which raises unprecedented ethical issues. However, problems associated with the cloning process have bought us a little more time for thought.

A Figure 21.8 Copy Cat, the first cloned cat.

Problems Associated with Animal Cloning. In most nuclear transplantation studies thus far, only a small percentage of cloned embryos develop normally to birth. And like Dolly, many cloned animals exhibit various defects. Cloned mice, for instance, are prone to obesity, pneumonia, liver failure, and premature death. Scientists believe that even cloned animals that appear normal are likely to have subtle defects.

In recent years, we have begun to learn possible reasons underlying the low efficiency of cloning and the high incidence of abnormalities. In the nuclei of fully differentiated cells, a small subset of genes is turned on and expression of the rest is repressed. This regulation often is the result of epigenetic changes in chromatin, such as acetylation of histones or methylation of DNA (see Figure 19.4). Many of these changes must be reversed in the nucleus from a donor animal in order for genes to be expressed or repressed appropriately for early stages of development. Researchers have found that the DNA in embryonic cells from cloned embryos, like that of differentiated cells, often has more methyl groups than does the DNA in equivalent cells from uncloned embryos of the same species. This finding suggests that the reprogramming of donor nuclei is not always complete. Because DNA methylation helps regulate gene expression, misplaced methyl groups in the DNA of donor nuclei may interfere with the pattern of gene expression necessary for normal embryonic development.

The Stem Cells of Animals

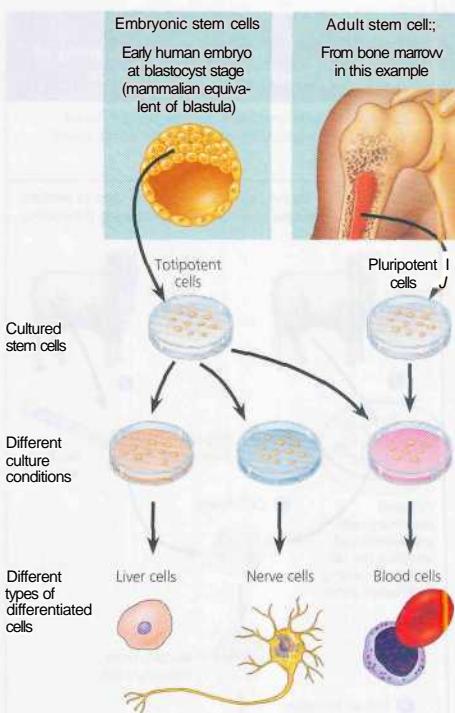

Further support for the idea that cells become different by expressing different sets of genes from the same genome comes from the study of a group of cells called stem cells. A stem cell is a relatively unspecialized cell that can both reproduce itself indefinitely and, under appropriate conditions, differentiate into specialized cells of one or more types. Thus, stem cells are able both to replenish their own population and to generate cells that travel down various differentiation pathways.

Many early animal embryos contain totipotent stem cells, which can give rise to differentiated cells of any type. Stem cells can be isolated from early embryos at the blastula stage or its human equivalent, the blastocyst stage (Figure 21.9). In culture, these *embryonic stem cells* reproduce indefinitely; and depending on culture conditions, they can differentiate into various specialized cells, including even eggs and sperm.

The adult body also has a variety of stem cells, which serve to replace nonreproducing specialized cells as needed. In contrast to totipotent embryonic stem cells, adult stem cells are said to be pluripotent, able to give rise to multiple but not all cell types. For example, stem cells in the bone marrow give rise to all the different kinds of blood cells (see Figure 21.9), and those in the intestinal wall regenerate the various cells forming the lining of the intestine. To the surprise of many, we have recently discovered that the adult brain contains stem cells that continue to produce certain kinds of nerve cells there. Although adult animals have only tiny numbers of stem cells, scientists are learning to identify and isolate these cells from various tissues and, in some cases, to grow them in culture. Taking this research further, scientists have found that with the right culture conditions (for instance, the addition of specific growth factors), cultured stem cells from adult animals can differentiate into multiple types of specialized cells.

Research with embryonic or adult stem cells is providing valuable information about differentiation and has enormous potential for medical applications. The ultimate aim is to supply cells for the repair of damaged or diseased organs; for example, insulin-producing pancreatic cells for people with diabetes or certain kinds of brain cells for people with Parkinson's disease or Huntington's disease. Currently, embryonic stem cells are more promising than adult stem cells for such applications, but because the cells are derived from human embryos, their use raises ethical and political issues.

Embryonic stem cells are currently obtained from embryos donated by patients undergoing infertility treatment or from long-term cell cultures originally established with cells isolated from donated embryos. With the recent cloning of human embryos to the blastocyst stage, scientists might be able to use such clones as the source of embryonic stem cells in the future. When the major aim of cloning is to produce embryonic stem cells to treat disease, the process is called *therapeutic cloning*. Although most people believe that reproductive cloning of

A Figure 21.9 Working with stem cells. Animal stem cells, which can be isolated from early embryos or adult tissues and grown in culture, are self-perpetuating, relatively undifferentiated cells. Embryonic stem cells are easier to grow than adult stem cells and can theoretically give rise to *all* types of cells. The range of cell types that can arise from adult stem cells is not yet fully understood.

humans is unethical, opinions vary about the morality of therapeutic cloning. Some believe that it is wrong to create embryos that will be destroyed, whereas others, in the words of the researcher who created Dolly, believe that "cloning promises such great benefits that it would be immoral not to do it."

The evidence we've discussed shows that nearly all the cells in a plant or animal contain the same set of genes. Next we look at the main processes that give rise to different cell types—that is, the molecular basis of cell differentiation.

Transcriptional Regulation of Gene Expression During Development

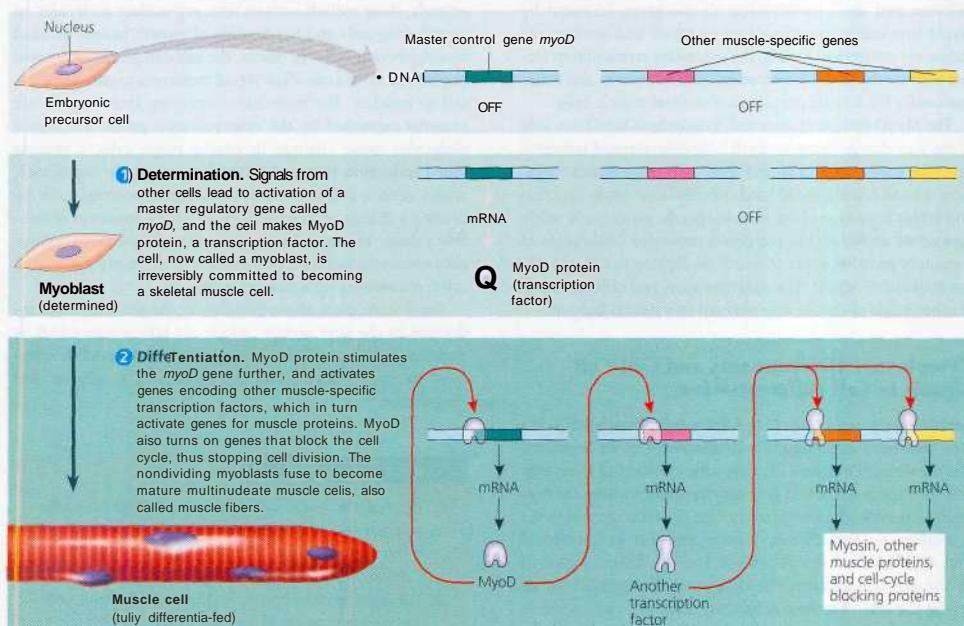

As the tissues and organs of an embryo take shape, the cells become visibly different in structure and function. These observable changes are actually the outcome of a cell's developmental

history extending back to the first mitotic divisions of the zygote. However, the earliest changes that set a cell on a path to specialization are subtle ones, showing up only at the molecular level. Before biologists knew much about the molecular changes occurring in embryos, they coined the term **determination** to refer to the events that lead to the observable differentiation of a cell. At the end of this process, an embryonic cell is irreversibly committed to its final fate, and it is said to be determined. If a committed cell is experimentally placed in another location in the embryo, it will still differentiate into the cell type that is its normal fate.

Today we understand determination in terms of molecular changes. The outcome of determination—observable cell differentiation—is marked by the expression of genes for **tissue-specific proteins**. These proteins are found only in a specific cell type and give the cell its characteristic structure and function. The first evidence of differentiation is the appearance of mRNAs for these proteins. Eventually, differentiation is observable with a microscope as changes in cellular structure. In most cases, the pattern of gene expression in a differentiated cell is controlled at the level of transcription.

Differentiated cells are specialists at making tissue-specific proteins. For example, as the result of transcriptional regulation, liver cells specialize in making albumin, and lens cells specialize in making crystallins (see Figure 19.7). Indeed, lens cells devote 80% of their capacity for protein synthesis to making crystallin proteins, which enable the lens to transmit and focus light. Skeletal muscle cells are another instructive example. The “cells” of skeletal muscle are long fibers containing many nuclei within a single plasma membrane. They contain high concentrations of muscle-specific versions of the contractile proteins myosin and actin, as well as membrane receptor proteins that detect signals from **nerve** cells.

Muscle cells develop from embryonic precursor cells that have the potential to develop into a number of alternative cell types, including cartilage cells or fat cells, but particular conditions commit them to becoming muscle cells. Although the committed cells appear unchanged under the microscope, determination has occurred, and they are now **myoblasts**. Eventually, myoblasts start to churn out large amounts of muscle-specific proteins and (use to form mature, elongated, multi-nucleate skeletal muscle cells (Figure 21.10, left).

A Figure 21.10 Determination and differentiation of muscle cells. This figure depicts a simplified version of how skeletal muscle cells arise from embryonic cells. These precursor cells resemble fibroblasts (see the photo in Figure 12.15).

Researchers have worked out what happens at the molecular level during muscle cell determination by growing myoblasts in culture and applying some of the techniques you learned about in Chapter 20. They first produced a cDNA library containing all the genes that are expressed in cultured myoblasts. The researchers then inserted each of the cloned genes into a separate embryonic precursor cell and looked for differentiation into myoblasts and muscle cells. In this way, they identified several so-called "master regulator" genes whose protein products commit the cells to becoming skeletal muscle. Thus, in the case of muscle cells, the molecular basis of determination is the expression of one or more of these master regulatory genes.

To understand more about how commitment occurs in muscle cell differentiation, let's focus on the master regulatory gene called *myoD* (see Figure 21.10, right). This gene encodes MyoD protein, a transcription factor that binds to specific control elements in the enhancers of various target genes and stimulates their expression (see Figure 19.6). Some target genes for MyoD encode still other muscle-specific transcription factors. MyoD also stimulates expression of the *myoD* gene itself, thus perpetuating its effect in maintaining the cell's differentiated state. Presumably all the genes activated by MyoD have enhancers recognized by MyoD and are thus coordinately controlled. Finally, the secondary transcription factors activate the genes for proteins, such as myosin and actin, that confer the unique properties of skeletal muscle cells.

The MyoD protein is powerful. Researchers have been able to use it to change some kinds of fully differentiated nonmuscle cells, such as fat cells and liver cells, into muscle cells. Why doesn't it work on *all* kinds of cells? One likely explanation is that activation of the muscle-specific genes is not solely dependent on MyoD but requires a particular combination of regulatory proteins, some of which are lacking in cells that do not respond to MyoD. The determination and differentiation of other kinds of tissues may play out in a similar fashion.

Cytoplasmic Determinants and Cell-Cell Signals in Cell Differentiation

Explaining the role of *myoD* in muscle cell differentiation is a long way from explaining the development of an organism. The *myoD* story immediately raises the question of what triggers the expression of *that* gene and then raises a series of similar questions leading back to the zygote. What generates the first differences that arise among the cells in an early embryo? And what controls morphogenesis and the differentiation of all the different cell types as development proceeds? As we saw in the case of muscle cells, this question comes down to which genes are transcribed in the cells of a developing organism. Two sources of information, used to varying extents in different species, "tell" a cell which genes to express at any given time during embryonic development.

One important source of information early in development is the egg cell's cytoplasm, which contains both RNA and protein molecules encoded by the mother's DNA. The cytoplasm of an unfertilized egg cell is not homogeneous. Messenger RNA, proteins, other substances, and organelles are distributed unevenly in the unfertilized egg; and this heterogeneity has a profound impact on the development of the future embryo in many species. Maternal substances in the egg that influence the course of early development are called cytoplasmic determinants. After fertilization, early mitotic divisions distribute the zygote's cytoplasm into separate cells. The nuclei of many of these cells are thus exposed to different cytoplasmic determinants, depending on which portions of the zygotic cytoplasm a cell received (Figure 21.11a). The set of cytoplasmic determinants a particular cell receives helps determine its developmental fate by regulating expression of the cell's genes during the course of cell differentiation.

The other important source of developmental information, which becomes increasingly important as the number of embryonic cells increases, is the environment around a particular cell. Most important are the signals impinging on an embryonic cell from other embryonic cells in the vicinity. In animals, these include contact with cell-surface molecules on neighboring cells and the binding of growth factors secreted by neighboring cells. In plants, the cell-cell junctions known as plasmodesmata can allow signal molecules to pass from one cell to another. The molecules conveying these signals are proteins expressed by the embryo's own genes. The signal molecules cause changes in nearby target cells, a process called induction (Figure 21.11b). In general, the signal molecules send a cell down a specific developmental path by causing a change in its gene expression that results in observable cellular changes. Thus, interactions between embryonic cells eventually induce differentiation of the many specialized cell types making up a new organism.

You'll learn more about cytoplasmic determinants and induction in the next section, where we take a closer look at some important genetic and cellular mechanisms of development in three model organisms: *Drosophila*, *C. elegans*, and *Arabidopsis*.

Concept Check 21.2

1. Why can't a single embryonic stem cell develop into an embryo?
2. If you clone a carrot, will all the progeny plants ("clones") look identical? Why or why not?
3. The signal molecules released by an embryonic cell can induce changes in a neighboring cell without entering the cell. How?

For suggested answers, see Appendix A.

Concept 21.3

Pattern formation in animals and plants results from similar genetic and cellular mechanisms

Before morphogenesis can shape an animal or plant, the organism's *body plan*—its overall three-dimensional arrangement—must be established. Cytoplasmic determinants and inductive signals contribute to this process, but what roles do they play? Well explore this question in the context of **pattern formation**, the development of a spatial organization in which the tissues and organs of an organism are all in their characteristic places. In the life of a plant, pattern formation occurs continually in the apical meristems (see Figure 21.4b). In animals, pattern formation is mostly limited to embryos and juveniles, except in those species where lost parts can be regenerated.

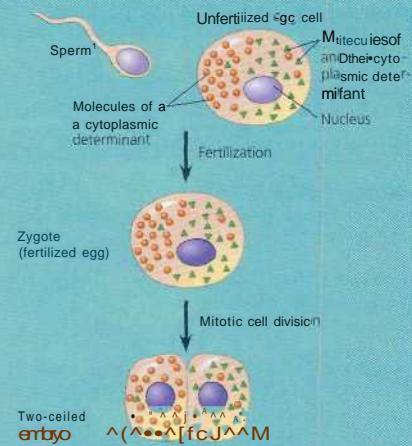

Pattern formation in animals begins in the early embryo, when the major axes of an animal are established. Before construction begins on a new building, the location of the front, back, and sides are determined. In the same way, before specialized tissues or organs of an animal appear, the relative positions of the animal's head and tail, right and left sides, and back and front are set up, thus establishing the three major body axes. In plants, the root-shoot axis is determined at a similarly early stage of development. The molecular cues that control pattern formation, collectively called **positional information**, are provided by cytoplasmic determinants and inductive signals (see Figure 21.11). These cues tell a cell its location relative to the body axes and to neighboring cells and determine how the cell and its progeny will respond to future molecular signals.

Drosophila Development: A Cascade of Gene Activations

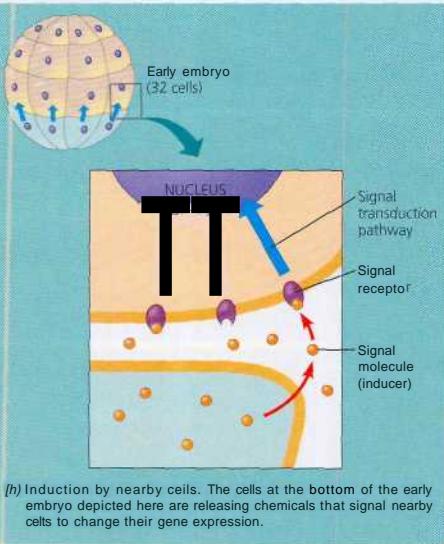

Pattern formation has been most extensively studied in *Drosophila melanogaster*, where genetic approaches have had spectacular success. These studies have established that genes control development and have led to an understanding of the key roles that specific molecules play in defining position and directing differentiation. Combining anatomical, genetic, and biochemical approaches to the study of *Drosophila* development, researchers have discovered developmental principles common to many other species, including humans.

The Life Cycle of *Drosophila*

Fruit flies and other arthropods have a modular construction, an ordered series of segments. These segments make up the body's three major parts: the head, the thorax (midbody from which the wings and legs extend), and the abdomen. Like other

(a) Cytoplasmic determinants in the egg. The unfertilized egg cell has molecules in its cytoplasm, encoded by the mother's genes, that influence development. Many of these cytoplasmic determinants, like the two shown here, are unevenly distributed in the egg. After fertilization and mitotic division, the cell nuclei of the embryo are exposed to different sets of cytoplasmic determinants and, as a result, express different genes.

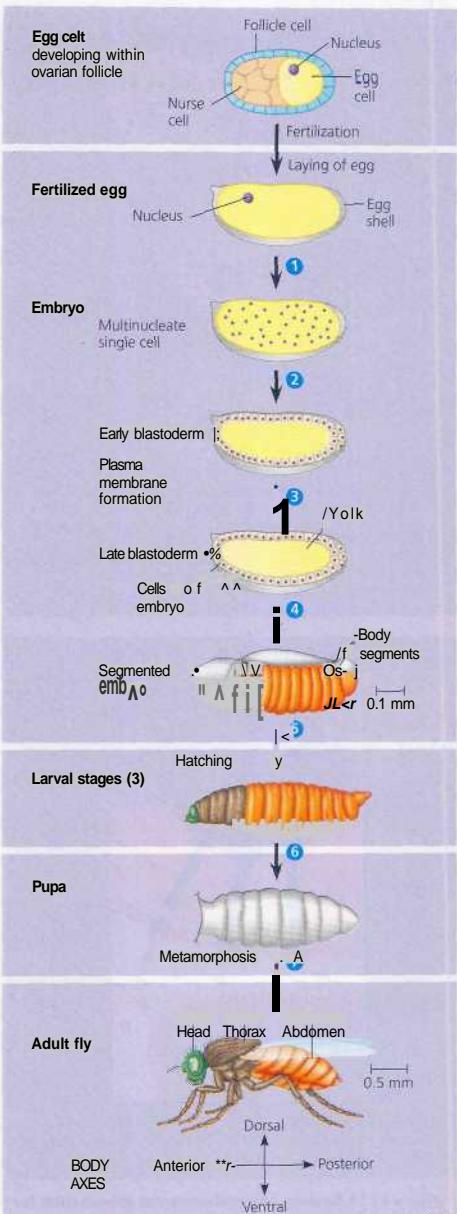

(b) Induction by nearby cells. The cells at the bottom of the early embryo depicted here are releasing chemicals that signal nearby cells to change their gene expression.

► Figure 21.11 Sources of developmental information for the early embryo.

bilaterally symmetrical animals, *Drosophila* has an anterior-posterior (head-to-tail) axis and a dorsal-ventral (back-to-belly) axis. In *Drosophila*, cytoplasmic determinants that are localized in the unfertilized egg provide positional information for the placement of these two axes even before fertilization. After fertilization, positional information operating on a finer and finer scale establishes a specific number of correctly oriented segments and finally triggers the formation of each segment's characteristic structures.

The *Drosophila* egg cell develops in the female's ovary, surrounded by ovarian cells called nurse cells and follicle cells (Figure 21.12, top). These supply the egg cell with nutrients, mRNAs, and other substances needed for development and make the egg shell. After fertilization and laying of the egg, the following events ensue (see key numbers in Figure 21.12):

- Q The first ten mitotic divisions have two notable features. First, these early divisions, which occur very quickly, consist of S and M phases only, with no growth, so the amount of cytoplasm does not change. Second, cytokinesis does not occur. As a result, the early *Drosophila* embryo is one big multinucleate cell (in contrast to vertebrate embryos; see Figure 21.4).
- ① At the tenth nuclear division, the nuclei begin to migrate to the periphery of the embryo, forming an early blastula-like stage called the blastoderm.
- ② At division 13, plasma membranes finally partition the 6,000 or so nuclei into separate cells of the late blastoderm. Although not yet apparent under the microscope, the basic body plan—including body axes and segment boundaries—has already been determined by this time. A centrally placed yolk nourishes the embryo, and the egg shell continues to protect it.
- Q Subsequent events in the embryo create clearly visible segments, which at first look very much alike.
- ③ Then, some cells move to new positions, organs form, and a wormlike larva (juvenile form) hatches out of the shell. *Drosophila* goes through three larval stages, during which the larva eats, grows, and molts (sheds its tough outer layer).
- ④ (D) The third larval stage becomes enclosed in a case, forming a pupa.
- Q Metamorphosis, the change from larva to adult fly, occurs inside the pupa, and the fly emerges.

▲ Figure 21.12 Key developmental events in the life cycle of *Drosophila*. The yellow egg cell (top) is surrounded by other cells, which form a structure called the follicle within one of the mother's ovaries. The nurse cells shrink and eventually disappear; the egg cell grows and matures, eventually filling the egg shell that is secreted by the follicle cells. The egg is fertilized within the mother and then laid. See text for description of steps 1–7, which generate the segmented adult fly, each segment bearing a characteristic appendage.

In the adult *Drosophila*, each segment is anatomically distinct, with characteristic appendages (see Figure 21.12, bottom). For example, the first thoracic segment bears a pair of legs; the second thoracic segment has a pair of legs plus a pair of wings; and the third thoracic segment bears a pair of legs plus a pair of balancing organs called halteres.

Genetic Analysis of Early Development: Scientific Inquiry

During the first half of the 20th century, classical embryologists made detailed anatomical observations of embryonic development in a number of species and performed experiments in which they manipulated embryonic tissues. Although this research laid the groundwork for understanding the mechanisms of development, it did not reveal the specific molecules that guide development or determine how patterns are established. Then, in the 1940s, a visionary American biologist, Edward B. Lewis, showed that a genetic approach—the study of mutants—could be used to investigate *Drosophila* development.

Lewis studied bizarre mutant flies with developmental defects that led to extra wings or legs in the wrong places (Figure 21.13). He located the mutations on the fly's genetic map, thus connecting the developmental abnormalities to specific genes. This research supplied the first concrete evidence that genes somehow direct the developmental processes studied by embryologists. The genes Lewis discovered control pattern formation in the late embryo; we'll return to them shortly.

Insight into pattern formation during early development did not come for another 30 years or so, when two researchers in Germany, Christiane Nüsslein-Volhard and Eric Wieschaus, set out to identify all the genes that affect segment formation in *Drosophila*. The project was daunting for three reasons. The first was the sheer number of *Drosophila* genes, now known to total about 13,700. The genes affecting segmentation might be just a few needles in a haystack or might be so numerous and varied that the scientists would be unable to make sense of them. Second, mutations affecting a process as fundamental as segmentation would surely be embryonic lethals, mutations with phenotypes causing death at the embryonic or larval stage. Because organisms with embryonic lethal mutations never reproduce, they cannot be bred for study. Third, cytoplasmic determinants in the

egg were known to play a role in axis formation, and thus the researchers knew

they would have to study the mothers' genes as well as those of the embryo.

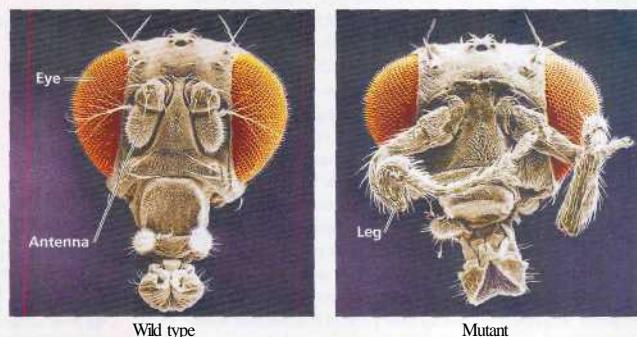

To get around the problem of embryonic lethality, Nüsslein-Volhard and Wieschaus looked for recessive mutations, which can be propagated in heterozygous flies. Their basic strategy was to expose flies to a mutagenic chemical to create mutations in the flies' gametes and then look among the flies' descendants for dead embryos (or larvae) with abnormal segmentation. By doing the appropriate crosses, they would be able to identify living heterozygotes carrying an embryonic lethal mutant allele and a normal allele of the same gene. The researchers hoped that the abnormalities visible in the dead homozygous embryos would suggest how the affected genes normally functioned.

Nüsslein-Volhard and Wieschaus eventually identified about 1,200 genes essential for embryonic development. Of these, about 120 were essential for pattern formation leading to normal segmentation. Over several years, the researchers were able to group these segmentation genes by general function, to map them, and to clone many of them. The result was a detailed molecular understanding of the early steps in pattern formation in *Drosophila*.

When the results of Nüsslein-Volhard and Wieschaus were combined with Lewis's earlier work, a coherent picture of *Drosophila* development emerged. In recognition of their discoveries, the three researchers were awarded a Nobel Prize in 1995. Before we discuss how the segmentation genes function, we need to back up and look at the cytoplasmic determinants deposited in the egg by the mother, for these control the expression of the segmentation genes.

Axis Establishment

As previously mentioned, cytoplasmic determinants in the egg are the substances that initially establish the axes of the *Drosophila* body. These substances are encoded by genes of the

* **Fig. 21.13 Abnormal pattern formation in *Drosophila*.** Mutations in certain genes, called homeotic mutations, cause a misplacement of structures in an animal. These micrographs contrast the head of a wild-type fly, bearing a pair of small antennae, with that of a homeotic mutant, bearing a pair of legs in place of antennae (SEMs).

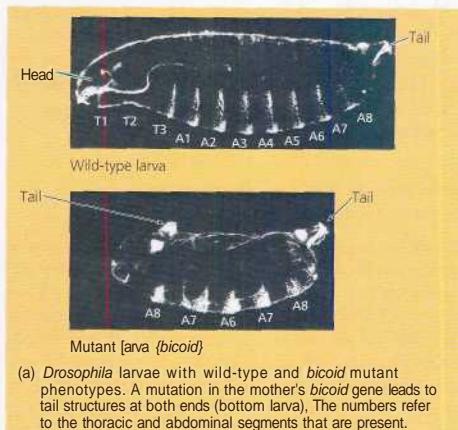

mother, fittingly called maternal effect genes. A maternal effect gene is a gene that, when mutant in the mother, results in a mutant phenotype in the offspring, regardless of their own genotype. In fruit fly development, the mRNA or protein products of maternal effect genes are placed in the egg while it is still in the mother's ovary. When the mother has a mutation in such a gene, she makes a defective gene product (or none at all), and her eggs are defective; when these eggs are fertilized, they fail to develop properly.

Because they control the orientation (polarity) of the egg and consequently of the fly, maternal effect genes are also called egg-polarity genes. One group of these genes sets up the anterior-posterior axis of the embryo, while a second group establishes the dorsal-ventral axis. Like mutations in segmentation genes, mutations in maternal effect genes are generally embryonic lethals.

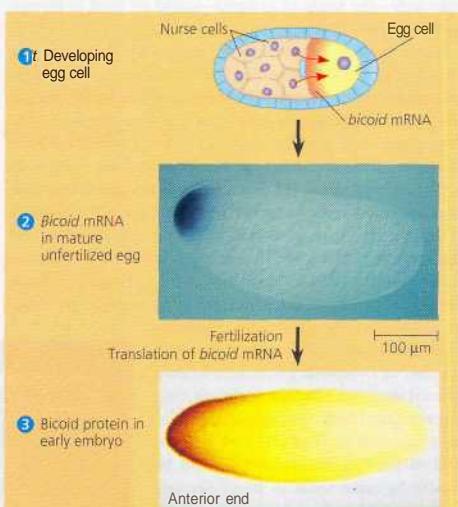

To see how maternal effect genes determine the body axes of the offspring, we focus on one such gene called *bicoid*, a term meaning "two-tailed."¹ An embryo whose mother has a mutant *bicoid* gene lacks the front half of its body and has posterior structures at both ends (**Figure 21.14a**). This phenotype suggested to researchers that the product of the mother's *bicoid* gene is essential for setting up the anterior end of the fly and might be concentrated at the future anterior end. This hypothesis is a specific example of the gradient hypothesis first proposed by embryologists a century ago. According to this idea, gradients of substances called morphogens establish an embryo's axes and other features of its form.

DNA technology and other modern biochemical methods enabled researchers to test whether the *bicoid* product is in fact a morphogen that determines the anterior end of the fly. The researchers cloned the *bicoid* gene and used a nucleic acid probe derived from the gene to reveal the location of *bicoid* mRNA in the eggs produced by wild-type female flies. As predicted by the hypothesis, the *bicoid* mRNA is highly concentrated at the extreme anterior end of the mature egg cell (**Figure 21.14b**). After the egg is fertilized, the mRNA is translated into protein. The Bicoid protein then diffuses from the anterior end toward the posterior, resulting in a gradient of protein within the early embryo, with the highest concentration at the anterior end. These results are consistent with the hypothesis that Bicoid protein is responsible for specifying the fly's anterior end. To test the hypothesis more specifically, scientists injected pure *bicoid* mRNA into various regions of early embryos. The protein that resulted from its translation caused anterior structures to form at the injection sites.

The *bicoid* research is important for several reasons. First, it led to the identification of a specific protein required for some of the earliest steps in pattern formation. Second, it increased our understanding of the mother's critical role in the initial phases of embryonic development. (As one developmental biologist has put it, "Mom tells Junior which way is up.") Finally, the principle that a gradient of molecules can determine

(a) *Drosophila* larvae with wild-type and *bicoid* mutant phenotypes. A mutation in the mother's *bicoid* gene leads to tail structures at both ends (bottom larva). The numbers refer to the thoracic and abdominal segments that are present.

(b) Gradients of *bicoid* mRNA and Bicoid protein in normal egg and early embryo. ① Transcribed from the maternal *bicoid* gene in nurse cells, *bicoid* mRNA reaches the egg cell via cytoplasmic bridges. It becomes anchored to the cytoskeleton at the anterior end of the egg as the egg grows and the nurse cells disappear. ② Labeled *bicoid* DNA (dark blue) was used as a probe to locate *bicoid* mRNA at the anterior end of the egg. ③ After fertilization, the mRNA is translated. In this early embryo, the gradient of color (brown) reveals a gradient of Bicoid protein. Bicoid protein is only one of several morphogens involved in axis specification.

A Figure 21.14 The effect of the *bicoid* gene, a maternal effect (egg-polarity) gene in *Drosophila*.

polarity and position has proved to be a key developmental concept for a number of species, just as early embryologists had thought. In *Drosophila*, gradients of specific proteins determine the posterior end as well as the anterior and also are responsible for establishing the dorsal-ventral axis.

Segmentation Pattern

The Bicoid protein and other proteins encoded by egg-polarity genes regulate the expression of some of the embryo's own genes. Gradients of these proteins bring about regional differences in the expression of segmentation genes, the genes of the embryo whose products direct formation of segments after the embryo's major body axes are defined.

In a cascade of gene activations, sequential activation of three sets of segmentation genes provides the positional information for increasingly fine details of the animal's modular body plan. The three sets are called the *gap genes*, the *pair-rule genes*, and the *segment polarity genes*.

The products of many segmentation genes, like those of egg-polarity genes, are transcription factors that directly activate the next set of genes in the hierarchical scheme of pattern formation. Other segmentation genes operate more indirectly, supporting the functioning of the transcription factors in various ways. For example, some are components of cell-signaling pathways, including signal molecules used in cell-cell communication and the membrane receptors that recognize them (see Chapter 11). Cell-signaling molecules are critically important once plasma membranes have divided the embryo into separate cellular compartments.

Working together, the products of egg-polarity genes like *bicoid* regulate the regional expression of gap genes, which control the localized expression of pair-rule genes, which in turn activate specific segment polarity genes in different parts of each segment. The boundaries and axes of the segments are now set. In the hierarchy of gene activations responsible for pattern formation, the next genes to be expressed determine the specific anatomy of each segment along the length of the embryo.

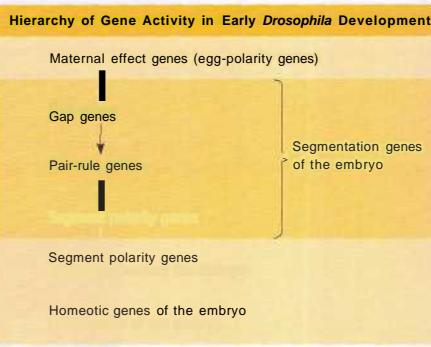

Identity of Body Parts

In a normal fly, structures such as antennae, legs, and wings develop on the appropriate segments. The anatomical identity of the segments is set by master regulatory genes called homeotic genes. These are the genes discovered by Edward Lewis. Once the segmentation genes have staked out the fly's segments, homeotic genes specify the types of appendages and other structures that each segment will form. Mutations in homeotic genes can cause an entire structure characteristic of a particular segment of the animal to arise in the wrong segment, as Lewis observed in flies (see Figure 21.13).

Like many of the egg-polarity and segmentation genes, the homeotic genes encode specific transcription factors. These regulatory proteins are gene activators or repressors, controlling

expression of genes responsible for particular anatomical structures. For example, a homeotic protein made in the cells of a particular head segment specifies antenna development. In contrast, a homeotic protein active in a certain thoracic segment selectively activates genes that bring about leg development. A mutant version of the gene encoding the thoracic homeotic protein causes the protein to be expressed also in the head segment. There it overrides the normal antennal gene-activating protein, labeling the segment as "thoracic" instead of "head" and causing legs to develop in place of antennae.

Scientists are now busy identifying the genes activated by the homeotic proteins—the genes specifying the proteins that actually build the fly structures. The following flowchart summarizes the cascade of gene activity in the *Drosophila* embryo:

Although this simplified summary suggests a strictly sequential series of gene actions, the reality is more complicated. For instance, the genes in each set not only activate the next set of genes but also maintain their own expression in most cases.

Amazingly, many of the molecules and mechanisms revealed by research on fly pattern formation have turned out to have close counterparts throughout the animal kingdom. The homeotic genes and their products exhibit these similarities in a most striking way. We will return to this point later in the chapter when we consider the evolution of development.

C. elegans: The Role of Cell Signaling

The development of a multicellular organism requires close communication between cells. Indeed, even before fertilization in *Drosophila*, molecules made in neighboring nurse cells cause localization of *bicoid* mRNA at one end of the egg, thus helping to establish the anterior end of the future embryo. Once the embryo is truly multicellular, with membranes enclosing each individual nucleus and accompanying cytoplasm, inductive

signaling among the embryo's own cells becomes increasingly important. As we've seen, the ultimate basis for the differences between cells is transcriptional regulation—the turning on and off of specific genes. It is induction, signaling from one group of cells to an adjacent group, that brings about differentiation. In some cases, cell signaling also leads to the programmed death of specific cells, a phenomenon that is also crucial to normal embryonic development.

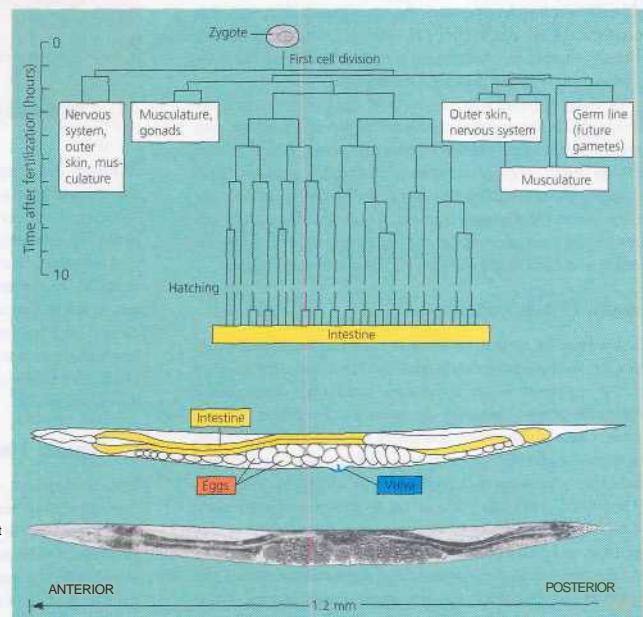

The nematode *C. elegans* has proved to be a very useful model organism for investigating the roles of cell signaling, induction, and programmed cell death in development (see Figure 21.2). Researchers know the entire ancestry of every cell in the body of an adult *C. elegans*, the organism's complete cell lineage. This information can be represented in a cell lineage diagram, somewhat like a pedigree, that shows the fates of all the cells in the developing embryo (Figure 21.15).

Because the lineage of each *C. elegans* cell is so reproducible, scientists at first thought that it must be determined from the start, suggesting that cytoplasmic determinants are the most important means of establishing cell fate in nematodes. However, although cytoplasmic determinants do play a key role very early in *C. elegans* development, a combination of genetic, biochemical, and embryological approaches have revealed important contributions of inductive events as well.

Induction

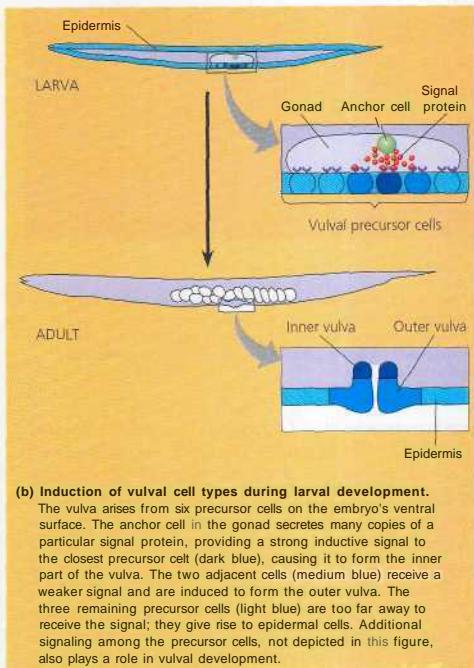

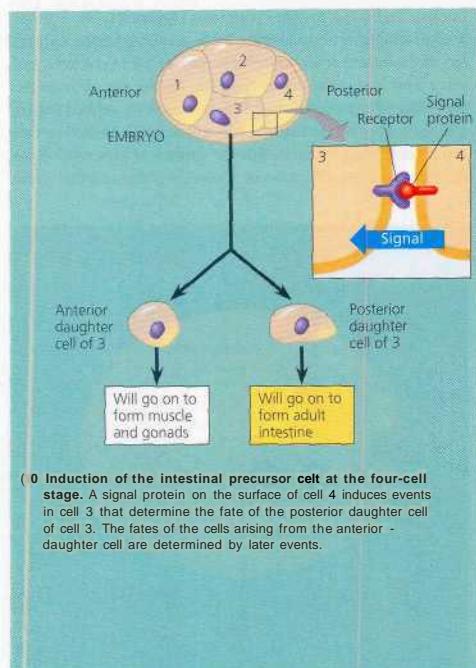

As early as the four-cell stage in *C. elegans*, cell signaling helps direct daughter cells down the appropriate pathways. For instance, as shown in Figure 21.16a, a signal from cell 4 acts on cell 3 so that one of the daughter cells of cell 3 eventually gives rise to the intestine. The signal is a cell-surface protein, made by cell 4, that can be recognized and bound by a cell-surface receptor protein on cell 3. This interaction triggers events inside cell 3 that result in one end of the cell (the posterior end) becoming different from the other. When cell 3 divides, the posterior daughter cell will go on to make the intestine, whereas the anterior daughter cell has a different fate. If cell 4 is experimentally removed early in the four-cell stage, no intestine forms, but if an isolated cell 3 and cell 4 are recombined, the intestine develops as normal. These results helped researchers recognize the role of induction in early nematode development.

Induction is also critical later in nematode development as the embryo passes through three larval stages prior to becoming an adult. The vulva, the tiny opening through which a worm lays its eggs, arises from six cells that are present on the ventral surface at the second larval stage (Figure 21.16b). A single cell of the embryonic gonad, the anchor cell, initiates a cascade of inductive signals that establishes the fates of the six

• Figure 21.15 Cell lineage in *C. elegans*.

The *Caenorhabditis elegans* embryo is transparent, making it possible for researchers to trace the lineage of every cell, from the zygote to the adult worm (LM). The diagram shows a detailed lineage only for the intestine (gold), which is derived exclusively from one of the first four cells formed from the zygote. The intestinal cell lineage does not happen to include any programmed cell death, an important aspect of the lineages for some other parts of the animal. The large white cells are eggs, which will be fertilized internally and released through the vulva.

A Figure 21.16 Cell signaling and induction during development of the rhabditid. In both examples, a protein on the surface of or secreted from one cell signals one or more nearby target cells, inducing differentiation of the target cells.

vulval precursor cells. If an experimenter destroys the anchor cell with a laser beam, the vulva fails to form, and the precursor cells simply become part of the worm's epidermis.

The signaling mechanisms in both of these examples are similar to those discussed in Chapter 11. Secreted growth factors or cell-surface proteins bind to a receptor on the recipient cell, initiating intracellular signal transduction pathways. Transcriptional regulation and differential gene expression in the induced cell are the usual results.

These two examples of induction during nematode development illustrate a number of important concepts that apply elsewhere in the development of *C. elegans* and many other animals:

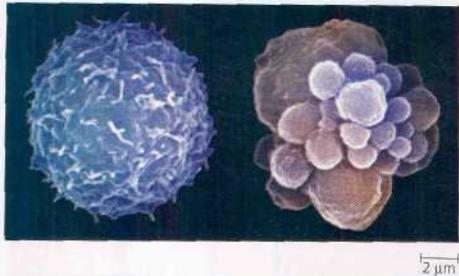

- I* In the developing embryo, sequential inductions drive the formation of organs.
- The effect of an inducer can depend on its concentration (just as we saw with cytoplasmic determinants in *Drosophila*).
- t* Inducers produce their effects via signal transduction pathways similar to those operating in adult cells.

- The induced cell's response is often the activation (or inactivation) of genes—transcriptional regulation—which in turn establishes the pattern of gene activity characteristic of a particular kind of differentiated cell.

Programmed Cell Death (*Apoptosis*)

Lineage analysis of *C. elegans* has underscored another outcome of cell signaling that is crucial in animal development: programmed cell death, or apoptosis. The timely suicide of cells occurs exactly 131 times in the course of normal development in *C. elegans*, at precisely the same points in the cell lineage of each worm. In worms and other species, apoptosis is triggered by signals that activate a cascade of "suicide" proteins in the cells destined to die. During apoptosis, a cell shrinks and becomes lobed (called "blebbing"), the nucleus condenses, and the DNA is fragmented (Figure 21.17, p. 428). Neighboring cells quickly engulf and digest the membrane-bound remains, leaving no trace.

Genetic screening of *C. elegans* has revealed two key apoptosis genes, *ced-3* and *ced-4* (*ced* stands for "cell death"), which

A Figure 21.17 Apoptosis of human white blood cells.

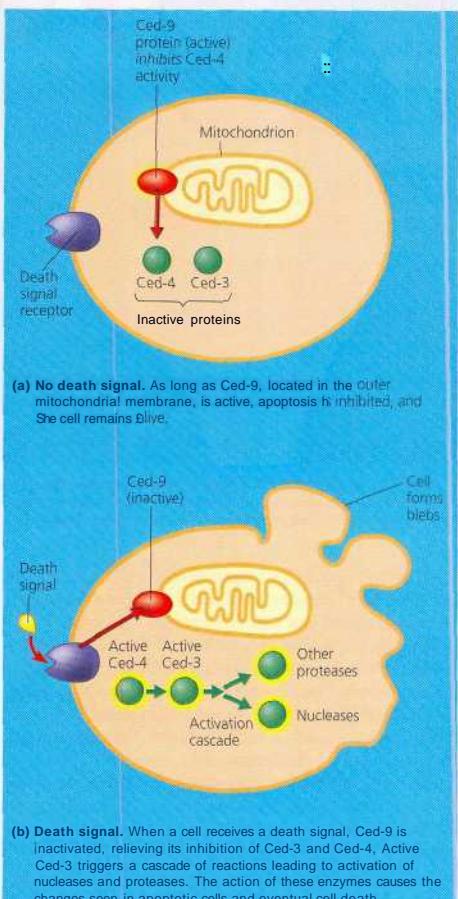

A normal white blood cell (left) is compared with a white blood cell undergoing apoptosis (right). The apoptotic cell is shrinking and forming lobes ("blebs"), which eventually are shed as membrane-bound cell fragments.

encode proteins essential for apoptosis. The proteins are called Ced-3 and Ced-4, respectively. These and most other proteins involved in apoptosis are continually present in cells, but in inactive form; thus, protein activity is regulated in this case, not transcription or translation. In *C. elegans*, a protein in the outer mitochondrial membrane, called Ced-9 (the product of gene *ced-9*), serves as a master regulator of apoptosis, acting as a brake in the absence of a signal promoting apoptosis (Figure 21.18). When a death signal is received by the cell, the apoptosis pathway activates proteases and nucleases, enzymes that cut up the proteins and DNA of the cell. The main proteases of apoptosis are called *caspases*; in the nematode, the chief caspase is Ced-3.

In humans and other mammals, several different pathways, involving about 15 different caspases, can lead to apoptosis. The pathway that is used depends on the type of cell and on the particular signal that triggers apoptosis. One important pathway involves mitochondrial proteins. Apoptosis pathway proteins or other signals somehow cause the mitochondrial outer membrane to leak, releasing proteins that promote apoptosis. Surprisingly, these include cytochrome *c*, which functions in mitochondrial electron transport in healthy cells (see Figure 9.15), but acts as a cell death factor when released from mitochondria. The mitochondrial apoptosis of mammals uses proteins homologous to the worm proteins Ced-3, Ced-4, and Ced-9. Mammalian cells make life-or-death "decisions"¹ by somehow integrating the signals they receive, both "death" signals and "life" signals such as growth factors.

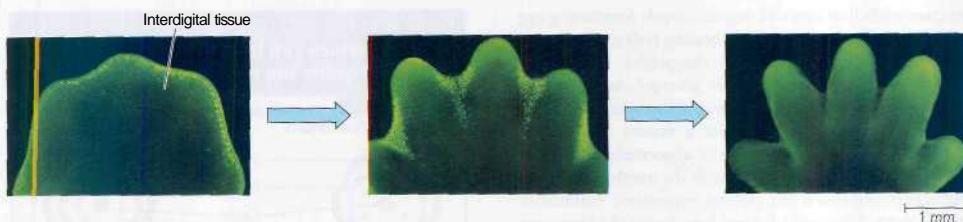

A built-in cell suicide mechanism is essential to development in all animals. The similarities between apoptosis genes in nematodes and mammals, as well as the observation that apoptosis occurs in multicellular fungi and single-cell yeasts, indicate that the basic mechanism evolved early in animal evolution. In vertebrates, apoptosis is essential for normal development of the nervous system, for normal operation of the immune system, and for nonnal morphogenesis of hands and feet in

humans and paws in other mammals (Figure 21.19). A lower level of apoptosis in developing limbs accounts for the webbed feet of ducks and other water birds, in contrast to chickens and other land birds with nonwebbed feet. In the case of humans, the failure of appropriate apoptosis can result in webbed fingers and toes. Also, researchers are investigating the possibility that certain degenerative diseases of the nervous system result from the inappropriate activation of apoptosis genes and that some

mm

HUB
> Figure 21.18 Molecular basis of apoptosis in *C. elegans*.
 Three proteins, Ced-3, Ced-4, and Ced-9, are critical to apoptosis and its regulation in the nematode. Apoptosis is more complicated in mammals but involves proteins similar to those in the nematode.

A Figure 21.19 Effect of apoptosis during paw development in the mouse. In mice, humans, and other mammals, as well as land birds, the embryonic region that develops into feet or hands initially has a solid,

platelike structure. Apoptosis eliminates the cells in the interdigital regions, thus forming the digits. The embryonic mouse paws shown here are stained so that cells undergoing apoptosis appear bright green. Apoptosis of cells begins

at the margin of each interdigital region (left), peaks as the tissue in these regions is reduced (middle), and is no longer visible when the interdigital tissue has been eliminated.

cancers result from a failure of cell suicide. Cells that have suffered irreparable damage, including DNA damage that could lead to cancer, normally generate *internal* signals that trigger apoptosis.

Studies on the roles of induction and apoptosis during development of *C. elegans* were begun less than 30 years ago by Sydney Brenner, John E. Sulston, and H. Robert Horvitz. The importance of their studies was highlighted in 2003, when the Nobel Prize for Medicine was awarded to these researchers for significantly advancing our understanding of how genes regulate organ growth (such as the nematode vulva) and the process of programmed cell death.

Plant Development: Cell Signaling and Transcriptional Regulation

The genetic analysis of plant development, using model organisms such as *Arabidopsis* (see Figure 21.2), has lagged behind that of animal models simply because there are fewer researchers working on plants. For example, in 2000, when the *Arabidopsis* DNA sequence was completed, fewer than 5% of its genes had been defined by mutational analysis, whereas over 25% of the genes in both *Drosophila* and *C. elegans* had been identified in that year. We are just beginning to understand the molecular basis of plant development in detail. Thanks to DNA technology and cues from animal research, plant research is now progressing rapidly.

Mechanisms of Plant Development

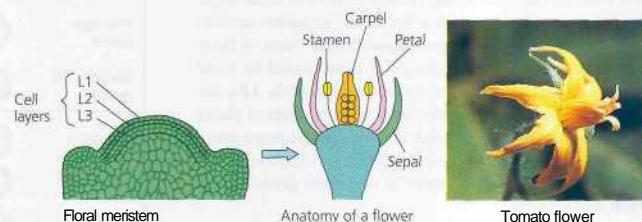

In general, cell lineage is much less important for pattern formation in plants than in animals. As mentioned previously, many plant cells are totipotent, and their fates depend more on positional information than on cell lineage. Therefore, the major

mechanisms regulating development are cell-signaling (induction) and transcriptional regulation.

The embryonic development of most plants occurs inside the seed and thus is relatively inaccessible to study (a mature seed already contains a fully formed embryo). However, other important aspects of plant development are observable throughout a plant's life in its meristems, particularly the apical meristems at the tips of shoots. It is there that cell division, morphogenesis, and differentiation give rise to new organs, such as leaves or the petals of flowers. We'll discuss two aspects of pattern formation in floral meristems, the apical meristems that produce flowers.

Pattern Formation in Flowers

Environmental signals, such as day length and temperature, trigger signal transduction pathways that convert ordinary shoot meristems to floral meristems, causing a plant to flower. Researchers have combined a genetic approach with tissue transplantation to study induction in the development of tomato flowers. As shown in Figure 21.20, a floral meristem is a bump consisting of three layers of cells (L1–L3). All three layers participate in the formation of a flower, a reproductive

• Figure 21.20 Flower development. A flower develops from three cell layers (L1–L3) in a floral meristem. A specific pattern of cell division, differentiation, and enlargement produces a flower. The four types of organs (carpels, stamens, petals, and sepals) that make up a flower are arranged in concentric circles (whorls). Each species has a characteristic number of organs in each whorl. The tomato has six sepals, six petals, six stamens, and four carpels.

structure with four types of organs: *carpels* (containing egg cells), stamens (containing sperm-bearing pollen), *petals*, and *sepals* (leaflike structures outside the petals). In a mature plant, the four types of organs are arranged radially, rather than linearly like the body structures in *Drosophila*.

Tomato plants homozygous for a mutant allele called *fasciated* (*ff*) produce flowers with an abnormally large number of organs. To study what controls the number of organs, researchers performed the grafting experiment outlined in **Figure 21.21**. They grafted stems from *fasciated* plants onto those of wild-type plants (*FF* homozygous for normal allele) and then grew new plants from the shoots that sprouted near the graft sites. Many of the new plants were chimeras, organisms with a mixture of genetically different cells. Some chimeras produced floral meristems in which the three cell layers did not all come from the same "parent." The researchers identified the parental sources of the meristem layers by monitoring other genetic markers, such as an unrelated mutation causing yellow leaves. The results showed that whether the number of floral organs was normal or abnormally high depended on whether the L3 layer arose from wild-type or mutant cells. Thus, the L3 cell layer induces the overlying L2 and L1 layers to form a particular number of organs. The mechanism of cell-cell signaling leading to this induction is not yet known, but is currently under study.

In contrast to genes controlling organ number in flowers are genes controlling organ identity. An organ identity gene determines the type of structure that will grow from a meristem—for instance, whether a particular outgrowth from a floral meristem becomes a petal or a stamen. Most of what we know about such organ identity genes comes from research on flower development in *Ambidopsis*.

Organ identity genes are analogous to homeotic genes in animals and are often referred to as plant homeotic genes. Just as a mutation in a fruit fly homeotic gene can cause legs to grow in place of antennae, a mutation in an organ identity gene can cause carpels to grow in place of sepals. By collecting and studying mutants with abnormal flowers, researchers have been able to identify and clone a number of floral organ identity genes. In plants with a "homeotic" mutation, specific organs are missing or repeated (Figure 21.22). Some of these mutant phenotypes are reminiscent of those caused by *hicoid* or other pattern formation mutations in *Drosophila*. Like the homeotic genes of animals, the organ identity genes of plants encode transcription factors that regulate specific target genes by binding to their enhancers in the DNA. In Chapter 35, you will learn about a current model of how these genes control organ development.

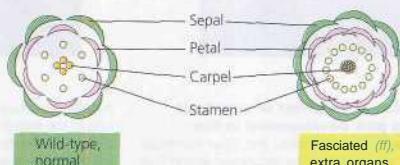

Clearly, the developmental mechanisms used by plants are similar to those used by the two animal species we discussed earlier. In the next section, we will see what can be learned from comparing developmental strategies and molecular mechanisms across all multicellular organisms.

Figure 21.21

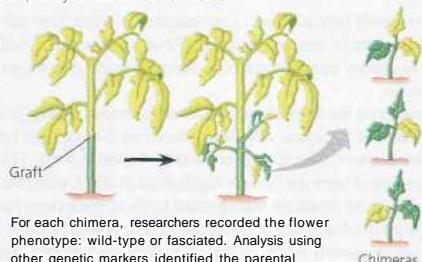

Inquiry Which cell layers in the floral meristem determine the number of floral organs?

EXPERIMENT

Tomato plants with the *fasciated* (*ff*) mutation develop extra floral organs.

Researchers grafted stems from mutant plants onto wild-type plants. They then planted the shoots that emerged near the graft site, many of which were chimeras.

For each chimera, researchers recorded the flower phenotype: wild-type or fasciated. Analysis using other genetic markers identified the parental source for each of the three cell layers of the floral meristem (L1-L3) in the chimeras.

RESULTS

The flowers of the chimeric plants had the fasciated phenotype only when the L3 layer came from the *fasciated* parent.

| Key | | Floral meristem | |
|-----------------------|----------------|-----------------|----------|
| HI Wild-type (FF) | Fasciated (ff) | L1 | L2 |
| Wild-type parent | | Wild-type | L1 L2 L3 |
| Fasciated (ff) parent | | Fasciated | L1 L2 L3 |
| Chimera 1 | | Fasciated | L1 L2 L3 |
| Chimera 2 | | Fasciated | L1 L2 L3 |
| Chimera 3 | | Wild-type | L1 L2 L3 |

» MHM1 h/w

Cells in the L3 layer induce the L1 and L2 layers to form flowers with a particular number of organs. (The nature of the inductive signal from L3 is not entirely understood.)

Wild type

Mutant

• Figure 21.22 Mutations in floral organ identity genes.

Wild-type *Arabidopsis* has four sepals, four petals, six stamens, and two carpels. If an organ identity gene called *apetala2* is mutated, the identities of the organs in the four whorls are carpels, stamens, stamens, and carpels (there are no petals or sepals).

Concept Check 21.3

1. Why are fruit fly maternal effect genes also called egg-polarity genes?
2. If a researcher removes the anchor cell from a *C. elegans* embryo, the vulva does not form, even though all the cells that would have made the vulva are present. Explain why.
3. Explain why cutting and rooting a shoot from a plant, then planting it successfully, provides evidence that plant cells are totipotent.

For suggested answers, see Appendix A.

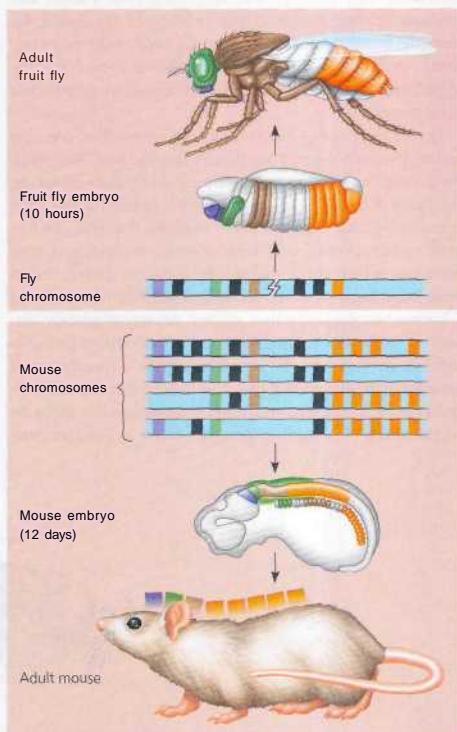

Concept 21.4

Comparative studies help explain how the evolution of development leads to morphological diversity

Biologists in the field of evolutionary developmental biology or "evo-devo" as it is often called, compare developmental processes of different multicellular organisms. Their aim is to understand how developmental processes have evolved and how changes in these processes can modify existing organismal features or lead to new ones. With the advent of molecular techniques and the recent flood of genomic information, we are beginning to realize that the genomes of related species with strikingly different forms may have only minor differences in gene sequence or regulation. Discovering the molecular basis underlying these differences, in turn, helps us understand how the myriad of diverse forms that cohabit this planet have arisen, thus informing the study of evolution.

Widespread Conservation of Developmental Genes Among Animals

Molecular analysis of the homeotic genes in *Drosophila* has shown that they all include a 180-nucleotide sequence called a homeobox, which specifies a 60-amino-acid *homeodomain* in the protein. An identical or very similar nucleotide sequence has been discovered in the homeotic genes of many invertebrates and vertebrates. In fact, the vertebrate genes homologous to the homeotic genes of fruit flies have even kept their chromosomal arrangement (Figure 21.23). (Homeotic genes in

A Figure 21.23 Conservation of homeotic genes in a fruit fly and a mouse. Homeotic genes that control the form of anterior and posterior structures of the body occur in the same linear sequence on chromosomes in *Drosophila* and mice. Each colored band on the chromosomes shown here represents a homeotic gene. In fruit flies, all homeotic genes are found on one chromosome. The mouse and other mammals have the same or similar sets of genes on four chromosomes. The color code indicates the parts of the embryos in which these genes are expressed and the adult body regions that result. All of these genes are essentially identical in flies and mice, except for those represented by blank bands, which are less similar in the two animals.

animals are often called *Hox* genes.) Furthermore, related sequences have been found in regulatory genes of much more distantly related eukaryotes, including plants and yeasts, and even in prokaryotes. From these similarities, we can deduce that the homeobox DNA sequence evolved very early in the history of life and was sufficiently valuable to organisms to have been conserved in animals and plants virtually unchanged for hundreds of millions of years.

Not all homeobox-containing genes are homeotic genes; that is, some do not directly control the identity of body parts. However, most of these genes, in animals at least, are associated with development, suggesting their ancient and fundamental importance in that process. In *Drosophila*, for example, homeoboxes are present not only in the homeotic genes but also in the egg-polarity gene *hicoid*, in several of the segmentation genes, and in the master regulatory gene for eye development.

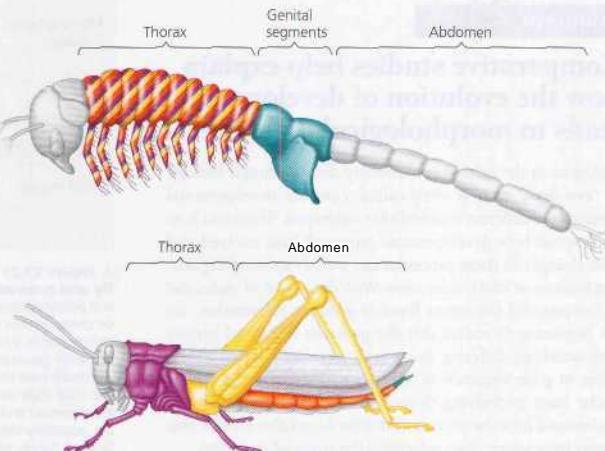

Researchers have found that the homeobox-encoded homeodomain is the part of a protein that binds to DNA when the protein functions as a transcriptional regulator. However, the shape of the homeodomain allows it to bind to any DNA segment; by itself it cannot select a specific sequence. Rather, more variable domains in a homeodomain-containing protein determine which genes the protein regulates. Interaction of these latter domains with still other transcription factors helps a homeodomain-containing protein recognize specific enhancers in the DNA. Proteins with homeodomains probably regulate development by coordinating the transcription of batteries of developmental genes, switching them on or off. In embryos of *Drosophila* and other animal species, different combinations of homeobox genes are active in different parts

of the embryo. This selective expression of regulatory genes, varying over time and space, is central to pattern formation.

Developmental biologists have found that in addition to homeotic genes, many other genes involved in development are highly conserved from species to species. These include numerous genes encoding components of signaling pathways. The extraordinary similarity among particular **developmental genes** in different animal species raises the question, How can the same genes be involved in the development of animals whose forms are so very different from each other?

Current studies are suggesting likely answers to this question. In some cases, small changes in regulatory sequences of particular genes can lead to major changes in body form. For example, the differing patterns of expression of the *Hox* genes along the body axis in insects and crustaceans can explain the different number of leg-bearing segments among these segmented animals (**Figure 21.24**). In other cases, similar genes direct different developmental processes in different organisms, resulting in different body shapes. Several *Hox* genes, for instance, are expressed in the embryonic and larval stages of the sea urchin, nonsegmented animals that have a body plan quite different from insects and mice. Sea urchin adults make the pincushion-shaped shells you may have seen on the beach. They are among the organisms long used in classical embryological studies (see Chapter 47).

Sequencing of the *Arabidopsis* genome has revealed that plants do have some homeobox-containing genes. However, these apparently do not function as master regulatory switches as do the homeobox-containing homeotic genes in animals. Other genes appear to carry out basic processes of pattern formation in plants.

* **Figure 21.24** Effect of differences in *Hox* gene expression during development in crustaceans and insects.

Changes in the expression patterns of four *Hox* genes have occurred over evolutionary time. These changes account in part for the different body plans of the brine shrimp *Artemia*, a crustacean (top), and the grasshopper, an insect. Shown here are regions of the adult body color-coded for expression of the *Hox* genes that determine formation of particular body parts during embryonic development.

Comparison of Animal and Plant Development

The last common ancestor of plants and animals was probably a single-celled microbe living hundreds of millions of years ago, so the processes of development must have evolved independently in the two lineages of organisms. Plants evolved with rigid cell walls that make the movement of cells and tissue layers virtually impossible, ruling out the morphogenetic movements of cells and tissues that are important in animals. Instead, morphogenesis in plants relies more heavily on differing planes of cell division and on selective cell enlargement. (You will learn about these processes in Chapter 35.) But despite the differences between plants and animals, there are some basic similarities in the actual mechanisms of development—legacies of their shared cellular origins.

In both plants and animals, development relies on a cascade of transcriptional regulators turning on or turning off genes in a finely tuned series—for example, setting up the head-to-tail axis in *Drosophila* and establishing the organ identity in a radial pattern in the *Arabidopsis* flower. But the genes that direct these processes differ considerably in plants and animals. While quite a few of the master regulatory switches in *Drosophila* are homeobox-containing *Hox* genes, those in *Arabidopsis* belong to a completely different family of genes, called the *Mads-box* genes. And although

homeobox-containing genes can be found in plants and *Mads-box* genes in animals, in neither case do they perform the same major roles in development that they do in the other group.

In this final chapter of the genetics unit, you have learned how genetic studies can reveal much about the molecular and cellular mechanisms underlying development. The unity of life is reflected in the similarity of biological mechanisms used to establish body pattern, although the genes directing development may differ among organisms. The similarities reflect the common ancestry of life on Earth. But the differences are also crucial, for they have created the huge diversity of organisms that have evolved. In the remainder of the book, we expand our perspective beyond the level of molecules, cells, and genes to explore this diversity on the organismal level.

Concept Check 21.4

1. The DNA sequences called homeoboxes, which help homeotic genes in animals direct development, are common to flies and mice. Given this similarity, explain why these animals are so different.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 21.1

Embryonic development involves cell division, cell differentiation, and morphogenesis

- In addition to mitosis, embryonic cells undergo differentiation, becoming specialized in structure and function. Morphogenesis encompasses the processes that give shape to the organism and its various parts. Several model organisms are commonly used to study different aspects of the genetic basis of development (pp. 412–415).

Concept 21.2

Different cell types result from differential gene expression in cells with the same DNA

- * **Evidence for Genomic Equivalence** (pp. 415–418) Cells differ in structure and function not because they contain different genes but because they express different portions of a common genome; they have genomic equivalence. Differentiated cells from mature plants are often totipotent, capable of generating a complete new plant. The nucleus from a differentiated animal cell can sometimes give rise to a new animal if transplanted

to an enucleated egg cell. Pluripotent stem cells from animal embryos or adult tissues can reproduce and differentiate in vitro as well as *in vivo*, offering the potential for medical use.

- **Transcriptional Regulation of Gene Expression During Development** (pp. 418–420) Differentiation is heralded by the appearance of tissue-specific proteins. These proteins enable differentiated cells to carry out their specialized roles.
- **Cyttoplasmic Determinants and Cell-Cell Signals in Cell Differentiation** (p. 420) Cyttoplasmic determinants in the cytoplasm of the unfertilized egg regulate the expression of genes in the zygote that affect the developmental fate of embryonic cells. In the process called induction, signal molecules from embryonic cells cause transcriptional changes in nearby target cells.
Activity Signal Transduction Pathways

Concept 21.3

Pattern formation in animals and plants results from similar genetic and cellular mechanisms

- Pattern formation, the development of a spatial organization of tissues and organs, occurs continually in plants, but is mostly limited to embryos and juveniles in animals. Positional information, the molecular cues that control pattern formation, tell a cell its location relative to the body's axes and to other cells (p. 42 L).
- **Drosophila Development: A Cascade of Gene Activations** (pp. 421–425) After fertilization, positional information on an increasingly fine scale specifies the segments in *Drosophila* and

finally triggers the formation of each segments characteristic structures. Gradients of morphogens encoded by maternal effect genes, such as *bicoid*, produce regional differences in the sequential expression of three sets of segmentation genes, the products of which direct the actual formation of segments. Finally, master regulator[®] genes, called homeotic genes, specify the type of appendages and other structures that form on each segment. Transcription factors encoded by the homeotic genes are regulatory proteins that control the expression of genes responsible for specific anatomical structures.

Activity Role of *bicoid* Gene in *Drosophila* Development
Investigation How Do *bicoid* Mutations Alter Development?

• ***C. elegans*: The Role of Cell Signaling** (pp. 425–429)

The complete lineage of each cell in *C. elegans* is known. Cell signaling and induction are critical in determining worm cell fates, including apoptosis (programmed cell death). An inducing signal produced by one cell in the embryo can initiate a chain of inductions that results in the formation of a particular organ, such as the intestine or vulva. In apoptosis, precisely timed signals trigger the activation of a cascade of “suicide” proteins in the cells destined to die.

• **Plant Development: Cell Signaling and Transcriptional Regulation** (pp. 429–431)

Induction by cell-cell signaling helps determine the numbers of floral organs that develop from a floral meristem. Organ identity genes determine the type of structure (stamen, carpel, sepal, or petal) that grows from each whorl of a floral meristem. The organ identity genes apparently act as master regulatory genes, each controlling the activity of other genes that more directly bring about an organ's structure and function.

Concept 21.4

Comparative studies help explain how the evolution of development leads to morphological diversity

• **Widespread Conservation of Developmental Genes**

Among Animals (pp. 431–432) Homeotic genes and some other genes associated with animal development contain a homeobox region, whose sequence is identical or similar in diverse species. Related sequences are present in the genes of yeasts, plants, and even prokaryotes. Other developmental genes also are highly conserved among animal species. In many cases, genes with conserved sequences play different roles in the development of different species. In plants, for instance, homeobox-containing genes do not function in pattern formation as they do in many animals.

• **Comparison of Animal and Plant Development** (p. 433)

During embryonic development in both plants and animals, a cascade of transcription regulators turns genes on or off in a carefully regulated sequence. But the genes that direct analogous developmental processes differ considerably in sequence in plants and animals, as a result of their remote ancestry.

Scientific Inquiry

Stem cells in an adult organism can divide to form two daughter stem cells, thus maintaining a population of relatively undifferentiated cells. Alternatively, a given mitotic division may yield one daughter cell that remains a stem cell and a second daughter cell that initiates a differentiation pathway. Propose one or more hypotheses to explain how this can happen. (Note: There is no easy answer to this question, but it is worth considering. For a hint, look at Figure 21.16a.)

Investigation How Do *bicoid* Mutations Alter Development?

Science, Technology, and Society

Government funding of embryonic stem cell research has been a contentious political issue. Why has this debate been so heated? Summarize the arguments for and against embryonic stem cell research, and explain your own position on the issue.

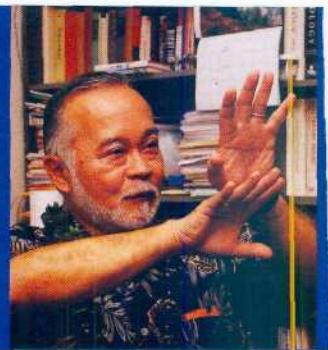

TESTING YOUR KNOWLEDGE

Evolution Connection

Genes important in the embryonic development of animals, such as homeobox-containing genes, have been relatively well conserved during evolution; that is, they are more similar among different species than are many other genes. Why is this?

4

Mechanisms of Evolution

AN INTERVIEW WITH **Kenneth Kaneshiro**

The Hawaiian Islands are one of Earth's greatest natural laboratories for understanding mechanisms of evolution. Dr. Kenneth Kaneshiro has contributed much to that understanding through his research on the diverse species of Hawaiian *Drosophila* flies. Professor Kaneshiro is the director of the Hawaiian Evolutionary Biology Program at the University of Hawaii, Manoa, where he is also the director of the Center for Conservation Research and Training. I first met Dr. Kaneshiro in 2003, when I was a visiting scholar at the University of Hawaii, Manoa, where he is also the director of the Center for Conservation Research and Training. It was a joy returning to Hawaii a year later to conduct this interview. I love this job!

How did the Hawaiian Islands form?

Geologically the islands are very young, with the oldest island, Kauai, being only about 5 to 6 million years old. The islands popped up in chronological fashion as the Pacific Plate moved northwest over a volcanic hotspot on the seafloor. The youngest island, the Big Island of Hawaii, is over the hotspot now, and there is a new island, Loihi, beginning to form as an undersea mountain to the southeast of the Big Island.

And what makes the Hawaiian Islands such a compelling place to study evolution?

First, they're the most isolated landmass in the world, sitting out in the middle of the Pacific nearly 2,000 miles away from continents in any direction. So for any species of organism that arrived here—by blowing across the ocean on the wind, for example—the founding population would have then been isolated from gene flow from other populations of that species.

And some of the organisms that made it here radiated profusely into new species by colonizing other islands. Since the islands formed in single file, from Kauai to the Big Island, you also have a chronological sequence in the origin of species as founders went from older islands to newer ones. In the case of *Drosophila*, the evidence points to a single founder (a fertilized female) that arrived several million years ago and whose progeny eventually radiated into the more than 500 described species of Hawaiian *Drosophila* flies. That's about a quarter of all known *Drosophila* species in the world.

Obviously, that's far more *Drosophila* species than there are islands. Did environmental variation on each island contribute to that radiation of species?

Yes, differences in elevation, rainfall, and other factors make each island very environmentally diverse. And each island also has what are called *kipukas*, "islands" o' vegetation surrounded by lava. So, there are islands within islands, with the lava forming barriers between the *kipukas*. For example, we have studied two *kipukas* on the Big Island that used to be connected before a lava flow separated them just 100 years ago. And we're already detecting significant genetic differences between *Drosophila* populations that live in these two *kipukas*. They're still the same species, but they've started to diverge. Speciation is still a very dynamic process on the Hawaiian Islands.

How did your interest in biology develop?

It probably started when I was a child growing up here in Hawaii. When my dad took us fishing around Oahu, it was very scientific, though it didn't seem that way to me at the time. My dad considered the tides and wind, and he matched the colors of his fishing lures to the kinds of baitfish that might be out there. When I fish today, I

still apply those lessons from my dad. I think it was that sort of scientific approach to fishing that first got me interested in biology.

When did that interest turn to evolutionary biology?

When I was a freshman here at the University of Hawaii, I wanted to go into marine biology. But because of family pressures, I enrolled in the pre-med program instead. To help pay my way, I took a job with The Hawaiian *Drosophila* Project, starting as a dishwasher in the lab and learning how to prepare the nutrient media for breeding the flies. Within a few months, I was involved in actual research, dissecting genitalia and looking at other morphological characters that give us clues about the evolutionary history of the Hawaiian *Drosophila* species. I also had the opportunity to go into the field. So ecology also became part of my undergraduate education, not so much from the classroom, but by being involved in the *Drosophila* research. Every summer, 10 or 12 top scientists with different research specialties would visit to work on various *Drosophila* projects. Looking over the shoulders of these eminent scientists when I was an undergraduate really got me hooked. After I graduated, I switched to entomology for my graduate work so I could continue studying the Hawaiian *Drosophila*.

And that work included your research on mating behavior in *Drosophila*. I think many students will be surprised to learn that these flies court their mates.

The courtship between males and females is very elaborate. And the mating behavior also includes competition between males. A male will defend a territory to which females are attracted for mating. In one *Drosophila* species, for example, the males have very wide heads, and two males will butt their heads together—like rains—and then push each other back and forth as they joust for territory. In another species, the

competition is more like sumo wrestling; the mates get up "tippy-toe" on their hind legs, grappling with their middle and forelegs, and lock heads. But being a good fighter doesn't mean that you're also a good lover. For a male fly, being able to fight off other males and defend a territory gives him the most opportunity to encounter females, but he still has to be able to perform the very complex behavior that satisfies the courtship requirements of a female.

Such as?

In one species, the male hoists his abdomen up and over his head, in a scorpion-like pose. This displays to the female a row of specialized bristles that are on the underside of the abdomen. Each bristle is flattened like a fan. Then the male vibrates his abdomen, and the bristles waft a sex-attractant vapor called a pheromone secreted from an abdominal gland. At the same time, the male spreads his wings and rocks back and forth, emitting a sound. While dancing and singing, the male extends his mouthparts from a velvety white lace. In response, the female actually kisses the male. Mating only occurs if the male can perform this elaborate display.

According to a model now known as the "Kaneshiro Hypothesis," changes in such mating behavior played a key role in the origin of Hawaiian *Drosophila* species, especially in the early stages of speciation. What's the basic idea? Shifts in mating behavior can occur in a small population after a founding event. Say we have

a population of flies on Kauai, the oldest island. Then Oahu pops up, and a fertilized female happens to make it there. She may found a new population on Oahu by producing a few hundred offspring. The males will vary in their ability to perform the species' original courtship rituals. But in such a small population, females who are very choosy will have less opportunity to reproduce than less choosy females, who will encounter more mates they are willing to accept. So selection favors fresh combinations of genes that combine adaptations to the new environment along with less rigid mating behavior than in the "parent" species back on Kauai. That would explain why mating behavior is typically the most complex in the oldest *Drosophila* species. I think such shifts in mating behavior have been very important in the evolution of the Hawaiian *Drosophila*, and probably in many other groups of organisms as well.

At the same time that biologists are studying the evolution of such a diversity of species on the Hawaiian islands, the islands have been designated a biodiversity hotspot, meaning that many species are endangered. What are the biggest threats to biodiversity in Hawaii? There is the destruction of habitat, but the impact of invasive species—non-native species that are accidentally or purposefully brought to the islands—is probably the biggest threat. And ants may be the number one problem. Hawaii doesn't have any native ants; they're all alien.

Their foraging in native forest ecosystems has severely impacted the native arthropod fauna. Invasive rats threaten the native birds by getting into nests and eating the eggs and young. Wild pigs are also a serious problem. They descended from hybridization between pigs the native Hawaiians brought to the islands and the pigs brought by Europeans. The wild pigs root in the forests, which creates puddles in which mosquitoes breed. The mosquitoes carry pathogens that cause malaria in birds. Also, invasive plants are crowding out many of the native plant species. Unfortunately, in spite of its small size, Hawaii is the extinction capital of the United States, if not the world.

One of your many hats is your role as director of the Center for Conservation Research and Training here at the University of Hawaii. What kind of work does the Center conduct?

Our research interest in conservation biology mainly takes an ecosystem and ecological approach: What happens on the mountaintops affects ecosystems all the way down to the coral reefs and beyond. I think we have to understand such relationships between ecosystems in order to protect the islands' biodiversity. The Center also has a major commitment to education. We have a National Science Foundation grant that supports outreach programs where our graduate students work with schoolchildren and mentor their teachers. We get these K-12 students out into the field participating in research. They are collecting valid scientific data, discovering new species, and helping us understand how to eradicate some of the alien species. The sheer numbers of these young scientists enable us to make certain kinds of measurements that would be impossible otherwise. For example, researchers would usually monitor contaminants in a stream by collecting water samples at a few points along the stream. But our graduate students worked with 320 seventh graders to sample the water all the way from a mountain waterfall to where the stream drains into the ocean. To me, this kind of environmental education, beginning at a young age, will eventually increase public awareness and make us all more effective in protecting our water sources and our native ecosystems.

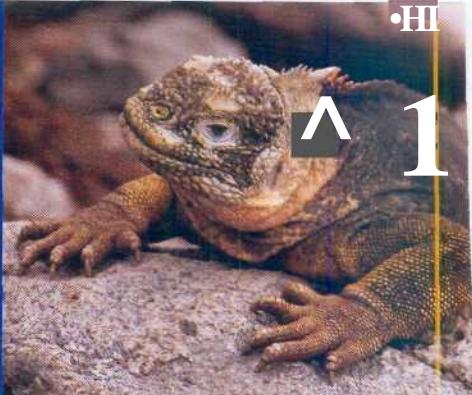

*In the case of *Drosophila*, the evidence points to a single founder (a fertilized female) that arrived several million years ago and whose progeny eventually radiated into the more than 300 described species of Hawaiian *Drosophila* flies.*

Aloha and mahalo, Dr. Kaneshiro!

22 Descent with Modification

A Darwinian View of Life

A Figure 22.1 A marine iguana, well-suited to its rocky habitat in the Galapagos Islands.

Key Concepts

- 22.1** The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species
- 22.2** In *The Origin of Species*, Darwin proposed that species change through natural selection
- 22.3** Darwin's theory explains a wide range of observations

Overview

Darwin Introduces a Revolutionary Theory

A new era of biology began on November 24, 1859, the day Charles Darwin published *On the Origin of Species by Means of Natural Selection*. Darwin's book drew a cohesive picture of life by connecting the dots among what had once seemed a bewildering array of unrelated observations. *The Origin of Species* focused biologists' attention on the great diversity of organisms—their origins and relationships, their similarities and differences, their geographic distribution, and their adaptations to surrounding environments (Figure 22.1).

Darwin made two major points in *The Origin of Species*. First, he presented evidence that the many species of organisms presently inhabiting Earth are descendants of ancestral species that were different from the modern species. Second, he proposed a mechanism for this evolutionary process, which he termed natural selection. The basic idea of natural selection is that a population can change over generations if individuals that possess certain heritable traits leave more offspring than other individuals. The result of natural selection is

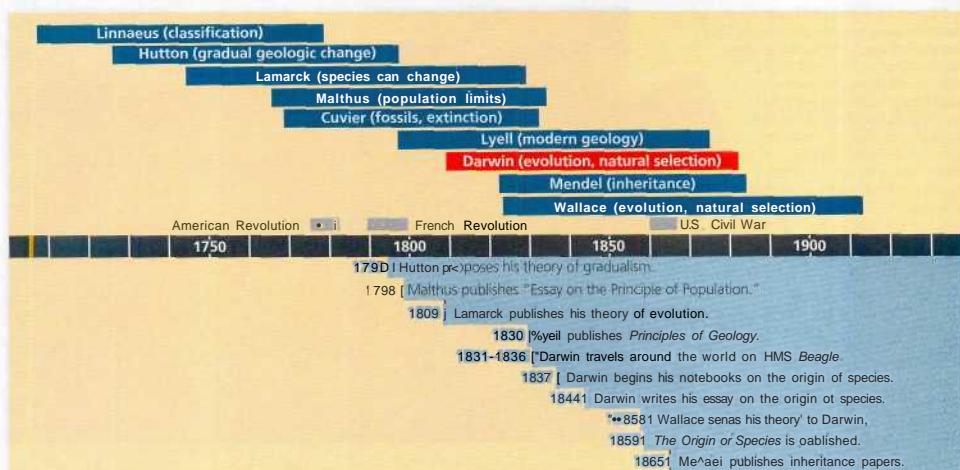

evolutionary adaptation, an accumulation of inherited characteristics that enhance organisms' ability to survive and reproduce in specific environments. In modern terms, we can define evolution as a change over time in the genetic composition of a population. Eventually, a population may accumulate enough change that it constitutes a new species—a new life-form. Thus we can also use the term *evolution* on a grand scale to mean the gradual appearance of all of biological diversity, from the earliest microbes to the enormous variety of organisms alive today.

Evolution is such a fundamental concept that, its study illuminates biology at every level from molecules to ecosystems, and it continues to transform medicine, agriculture, biotechnology and conservation biology. You have already encountered evolution as the main thematic thread woven throughout this book. In this chapter, you will learn about the historical development of the Darwinian view of life.

Concept 22.1

The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species

The impact of an intellectual revolution such as Darwinism depends on timing as well as logic. To understand why Darwin's ideas were revolutionary, we need to examine his views in the context of other Western ideas about Earth and its life (Figure 22.2).

A Figure 22.2 The historical context of Darwin's life and ideas. The dark blue bars above the timeline represent the lives of some individuals whose ideas have contributed to our modern understanding of evolution.

Resistance to the Idea of Evolution

The Origin of Species not only challenged prevailing scientific views but also shook the deepest roots of Western culture. Darwin's view of life contrasted sharply with traditional beliefs of an Earth only a few thousand years old, populated by forms of life that had been created at the beginning and remained unchanged ever since. Darwin's book challenged a worldview that had been prevalent for centuries.

The Scale of Nature and Classification

a) Species

Although several Greek philosophers suggested that life might have evolved gradually, one philosopher who greatly influenced early Western science, Aristotle (384-322 B.C.), viewed species as fixed (unchanging). Through his observations of nature, Aristotle recognized certain "affinities" among living things, leading him to conclude that life-forms could be arranged on a ladder, or scale, of increasing complexity later called the *scala naturae* ("scale of nature"). Each form of life, perfect and permanent, had its allotted rung on this ladder.

These ideas coincided with the Old Testament account of creation, which holds that species were individually designed by God and therefore perfect. In the 1700s, many scientists interpreted the superb adaptations of organisms to their environments as evidence that the Creator had designed each species for a particular purpose.

One such scientist was Carolus Linnaeus (1707-1778), a Swedish physician and botanist who sought to classify life's diversity "for the greater glory of God." Linnaeus was a founder of taxonomy, the branch of biology concerned with naming and classifying organisms. He developed the two-part, or binomial, system of naming organisms according to genus and species that is still used today. In contrast to the linear hierarchy of the *scala naturae*, Linnaeus adopted a nested classification system, grouping similar species into increasingly general categories. For example, similar species are grouped in the same genus, similar genera (plural of genus) are grouped in the same family, and so on (see Figure 1.14).

To Linnaeus, the observation that some species resemble each other did not imply evolutionary kinship, but rather the pattern of their creation. However, a century later his taxonomic system would play a role in Darwin's arguments for evolution.

Fossils, Cuxier, and Catastrophism

The study of fossils also helped to lay the groundwork for Darwin's ideas. Fossils are remains or traces of organisms from the past. Most fossils are found in sedimentary rocks formed from the sand and mud that settle to the bottom of seas, lakes, and marshes. New layers of sediment cover older ones and compress them into superimposed layers of rock called strata (singular, stratum). Later, erosion may carve

• **Figure 22.3 Fossils from strata of sedimentary rock.** The Colorado River carved the Grand Canyon through more than 2,000 m of rock, exposing sedimentary layers that are like huge pages from the book of life. Each stratum entombs fossils that represent some of the organisms from that period of Earth's history. The seed fern leaf fossil (top) is from the shallower Hermit Shale layer (265 million years old), and the trilobite fossil (bottom) is from the deeper Bright Angel Shale layer (530 million years old).

through upper (younger) strata and reveal older strata that had been buried. Fossils in each layer provide a glimpse of some of the organisms that populated Earth at the time that layer formed (**Figure 22.3**).

Paleontology, the study of fossils, was largely developed by French scientist Georges Cuvier (1769–1832). In examining rock layers in the region around Paris, Cuvier noted that the deeper (older) the strata, the more dissimilar the fossils are from current life. He also observed that from one stratum to the next, some new species appear while others disappear. He inferred that extinctions must have been a common occurrence in the history of life. Yet Cuvier staunchly opposed the idea of gradual evolutionary change. Instead, he advocated catastrophism, speculating that each boundary between strata represent a catastrophe, such as a flood or drought, that destroyed many of the species living at that time. He proposed that these periodic catastrophes were usually confined to local geographic regions, which were repopulated by species immigrating from other areas.

Theories of Gradualism

In contrast to catastrophism, the work of other scientists promoted the concept of **gradualism**—the idea that profound change can take place through the cumulative effect of slow but continuous processes. In 1795, Scottish geologist James Hutton (1726–1797) proposed that Earth's geologic features could be explained by gradual mechanisms *currently* operating in the world. He suggested that valleys were formed by rivers wearing through rocks and that sedimentary rocks containing marine fossils were formed from particles that had eroded from the land and been carried by rivers to the sea.

The leading geologist of Darwin's time, Charles Lyell (1797–1875), incorporated Hutton's thinking into a more comprehensive theory known as **uniformitarianism**. Lyell proposed that the same geologic processes are operating today as in the past, and at the same rate.

Hutton and Lyells ideas exerted a strong influence on Darwin's thinking. Darwin agreed that if geologic change results from slow, continuous actions rather than sudden events, then Earth must be much older than the 6,000 years that theologians estimated. He later reasoned that perhaps similarly slow and subtle processes could act on living organisms over a long period of time, producing substantial change. Darwin was not the first to apply the principle of gradualism to biological evolution, however.

Lamarck's Theory of Evolution

During the 18th century, several naturalists (including Darwin's grandfather, Erasmus Darwin) suggested that life evolves as environments change. But only one of Charles Darwin's predecessors developed a comprehensive model for how life evolves: French biologist Jean-Baptiste de Lamarck (1744–1829). Alas, Lamarck is primarily remembered today not for his visionary recognition that evolutionary change explains the fossil record and organisms' adaptations to their environments, but for the incorrect mechanism he proposed to explain how evolution occurs.

Lamarck published his theory in 1809, the year Darwin was born. By comparing current species with fossil forms, Lamarck had found what appeared to be several lines of descent, each a chronological series of older to younger fossils leading to a living species. He explained this with two principles that

Jk **Figure 22.4** Acquired traits cannot be inherited. This bonsai tree was "trained" to grow as a dwarf by pruning and shaping. However, seeds from this tree would produce offspring of normal size.

were commonly accepted at that time. The first was *use and disuse*, the idea that parts of the body that are used extensively become larger and stronger, while those that are not used deteriorate. As an example, he cited a giraffe stretching its neck to reach leaves on high branches. The second principle, *inheritance of acquired characteristics*, stated that an organism could pass these modifications to its offspring. Lamarck reasoned that the long, muscular neck of the living giraffe had evolved over many generations as giraffes stretched their necks ever higher. Lamarck also thought that evolution happens because organisms have an innate drive to become more complex. Darwin rejected this idea in favor of natural selection, but he too thought that variation was introduced into the evolutionary process through inheritance of acquired characteristics. However, our modern understanding of genetics refutes this principle; there is no evidence that acquired characteristics can be inherited (**Figure 22.4**).

Lamarck was vilified in his own time, especially by Cuvier, who denied that species ever evolve. In retrospect, however, Lamarck deserves credit for his insightful observations of nature and recognition of gradual evolutionary change as the best explanation for those observations.

Concept 22.2

In *The Origin of Species*, Darwin proposed that species change through natural selection

As the 19th century dawned, it was generally believed that species had remained unchanged since their creation. A few clouds of doubt about the permanence of species were beginning to gather, but no one could have forecast the thundering storm just over the horizon.

Darwin's Research

Charles Darwin (1809–1882) was born in Shrewsbury in western England. Even as a boy, he had a consuming interest in nature. When he was not reading nature books, he was fishing, hunting, and collecting insects. Darwin's father, an eminent physician, could see no future for his 16-year-old son as a naturalist and sent him to the University of Edinburgh to study medicine. But Charles found medical school boring and surgery before the days of anesthesia horrifying. He left Edinburgh without a degree and enrolled at Cambridge University with the intention of becoming a clergyman. At that time in England, many scholars of science belonged to the clergy.

At Cambridge, Darwin became the protege of the Reverend John Henslow, a professor of botany. Soon after Darwin received his B.A. degree, Henslow recommended the young graduate to Captain Robert FitzRoy, who was preparing the survey ship HMS *Beagle* for a voyage around the world. FitzRoy accepted Darwin on board because of his education and because of his age and social class, which were similar to FitzRoy's.

The Voyage of the Beagle

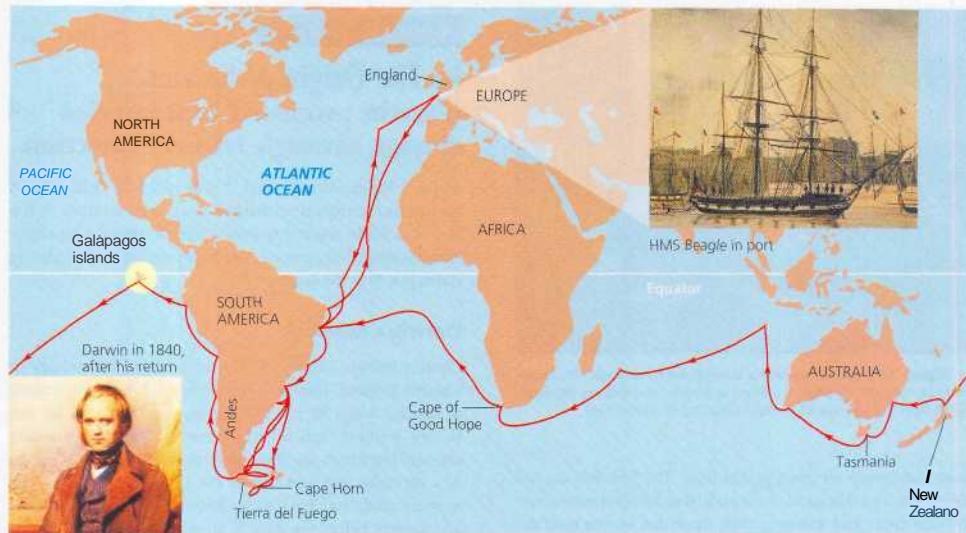

In 1831, the 22-year-old Darwin left England aboard the *Beagle*. The primary mission of the voyage was to chart poorly known stretches of the South American coastline. While the ship's crew surveyed the coast, Darwin spent most of his time on shore, observing and collecting thousands of South American plants and animals. He observed the various adaptations of plants and animals that inhabited such diverse environments as the Brazilian jungles, the expansive grasslands of the Argentine pampas, the desolate lands of Tierra del Fuego near Antarctica, and the towering heights of the Andes Mountains.

Darwin noted that the plants and animals in temperate regions of South America more closely resembled species living in the South American tropics than species in temperate regions of Europe. Furthermore, the fossils he found, though clearly different from living species, were distinctly South American in their resemblance to the living organisms of that continent.

Concept Check 22.1

- Which of the individuals discussed in this section viewed species as fixed, and which viewed species as being able to change over time?
- What was Lamarck's theory of evolution? Explain its significance.

For suggested answers, see Appendix A.

A Figure 22.5 The voyage of HMS Beagle.

Geologic observations also impressed Darwin during the voyage. Despite bouts of seasickness, he read Lyell's *Principles of Geology* while aboard the *Beagle*. He experienced geologic change firsthand when a violent earthquake rocked the coast of Chile, and he observed afterward that the coastline had risen by several feet. Finding fossils of ocean organisms high in the Andes Mountains, he inferred that the rocks containing the fossils must have been raised there by a long series of similar earthquakes. These observations reinforced what he had learned from Lyell—the physical evidence did not support the traditional view of a static Earth only a few thousand years old.

Darwin's interest in the geographic distribution of species was further kindled by the *Beagle's* stop at the Galapagos, a group of geologically young volcanic islands located near the equator about 900 km (540 miles) west of South America (Figure 22.5). Darwin was fascinated by the unusual organisms he found there. Among the birds he collected on the Galapagos were several kinds of finches that, although quite similar, seemed to be different species. Some were unique to individual islands, while others were distributed on two or more adjacent islands. But Darwin did not fully grasp the significance of these observations until after his return to England in 1836. He and others found that although the animals on the Galapagos resemble species living on the South American mainland, most of the Galapagos animals live nowhere else in the world. He hypothesized that the Galapagos had been colonized by organ-

isms that had strayed from South America and had then diversified on the various islands.

Darwin's Focus on Adaptation

As Darwin reassessed all that he had observed during the voyage, he began to perceive adaptation to the environment and the origin of new species as closely related processes. Could a new species arise from an ancestral form by the gradual accumulation of adaptations to a different environment? From studies made years after Darwin's voyage, biologists have concluded that this is indeed what happened to the Galapagos finches. Their beaks and behaviors are adapted to the specific foods available on their home islands (Figure 22.6). Darwin realized that an explanation for such adaptations was essential to understanding evolution.

By the early 1840s, Darwin had worked out the major features of his theory of natural selection as the mechanism of evolution. However, he had not yet published his ideas. He was in poor health, and he rarely left his home near London. Despite his reclusiveness, Darwin was not isolated. Already famous as a naturalist because of the letters and specimens he had sent to England during the voyage of the *Beagle*, Darwin corresponded extensively with scientists around the world and was often visited by Lyell, Henslow, and others.

In 1844, Darwin wrote a long essay on the origin of species; and natural selection. However, he was reluctant to introduce

> **Figure 22.6 Beak variation in Galápagos finches.** The Galápagos Islands are home to more than a dozen species of closely related finches, some found only on a single island. The most striking differences among them are their beaks, which are adapted for specific diets.

him, theory publicly, apparently because he anticipated the uproar it would cause. Darwin asked his wife to publish his essay if he were to die before finishing a more thorough dissertation. Even as he procrastinated, he continued to compile evidence in support of his theory. Lyell, not yet himself convinced of evolution, nevertheless urged Darwin to publish on the subject before someone else came to the same conclusions and published first.

In June 1858, Lyell's prediction came true. Darwin received a manuscript from Alfred Russel Wallace (1823–1913), a young British naturalist working in the East Indies who had developed a theory of natural selection similar to Darwin's. Wallace asked Darwin to evaluate his paper and forward it to be edited if it merited publication. Darwin complied, writing to Wallace: "Your words have come true with a vengeance. ... I never saw a more striking coincidence ... so all my originality; whatever it may amount to, will be smashed." Lyell and a colleague then presented Wallace's paper, along with extracts from Darwin's unpublished 1844 essay, to the Linnean Society of London on July 1, 1858. Darwin quickly finished *The Origin of Species* and published it the next year. Although Wallace had written up his ideas for publication first, he was a great admirer of Darwin and agreed that Darwin had developed the theory of natural selection so extensively that he should be known as its main architect.

Within a decade, Darwin's book and its proponents had convinced most biologists that biological diversity was the product of evolution. Darwin succeeded where previous evolutionists had failed, mainly because he presented his reasoning with immaculate logic and an avalanche of sup-

porting evidence. He soon followed up his first book with other pioneering work, in particular an exploration of the type of natural selection known as sexual selection (see Chapter 23).

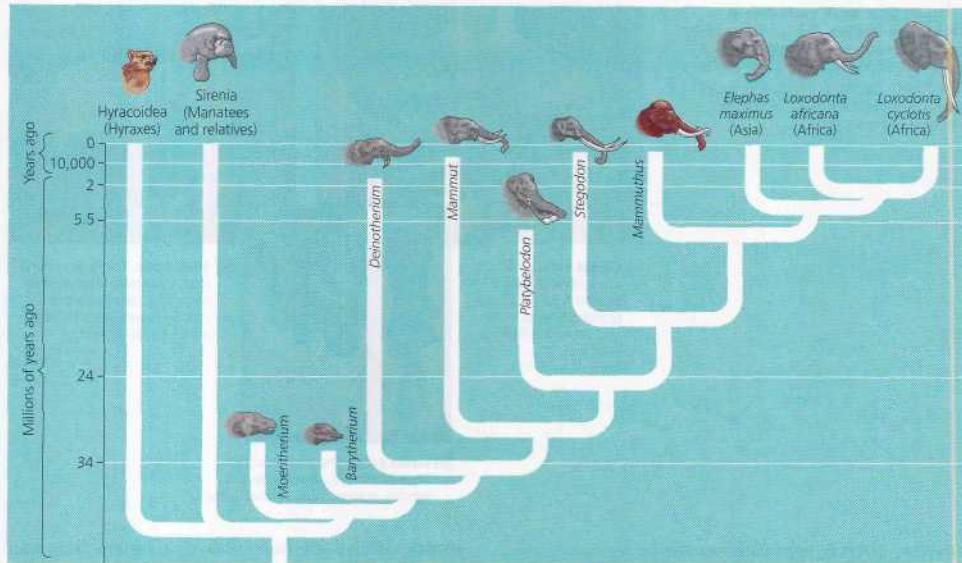

The Origin of Species

In publishing his theory, Darwin developed two main ideas: that evolution explains life's unity and diversity and that natural selection is a cause of adaptive evolution.

Descent with Modification

In the first edition of *The Origin of Species*, Darwin did not use the word evolution until the very end. Instead, he referred to descent with modification, a phrase that summarized his view of life. Darwin perceived unity in life, with all organisms related through descent from an ancestor that lived in the remote past. As the descendants of that ancestral organism spilled into various habitats over millions of years, they accumulated diverse modifications, or adaptations, that fit them to specific ways of life.

In the Darwinian view, the history of life is like a tree, with multiple branchings from a common trunk to the tips of the youngest twigs that represent the diversity of living organisms. Each fork of the tree represents an ancestor of all the lines of evolution that subsequently branched from that point. Closely related species, such as the Asian elephant and African elephants, are very similar because they shared the same line of descent until a relatively recent divergence

A Figure 22.7 Descent with modification. This evolutionary tree of the elephants is based mainly on fossils—their anatomy, order of appearance in strata, and geographic distribution. Note that most branches of descent ended in extinction. Despite their very different appearances, the manatees and hyraxes are the elephants' closest living relatives. (Timeline not to scale.)

from their common ancestor (Figure 22.7). Most branches of evolution, even some major ones, are dead ends; about 99% of all species that have ever lived are now extinct. Thus, there are no living animals that fill the gap between the elephants and their nearest relatives today, the manatees and hyraxes, though some fossils have been found.

Linnaeus had realized that some organisms resemble each other more closely than others, but he had not linked these resemblances to evolution. Nonetheless, because he had recognized that the great diversity of organisms could be organized into "groups subordinate to groups" (Darwin's phrase), his taxonomic scheme largely fit with Darwin's theory. To Darwin, the Linnaean hierarchy reflected the branching history of the tree of life, with organisms at the various taxonomic levels related through descent from common ancestors.

Natural Selection and Adaptation

How does natural selection work, and how does it explain adaptation? Evolutionary biologist Ernst Mayr has dissected the logic of Darwin's theory of natural selection into three inferences based on five observations:^{*}

* Adapted from E. Mayr, *The Growth of Biological Theory: Evolutionary Thought Since Darwin* (Old Cambridge, MA: Harvard University Press, 1982).

OBSERVATION #1: For any species, population sizes would increase exponentially if all individuals that are born reproduced successfully (Figure 22.8).

OBSERVATION #2: Nonetheless, populations tend to remain stable in size, except for seasonal fluctuations.

OBSERVATION #3: Resources are limited.

INFERENCE #1: Production of more individuals than the environment can support leads to a struggle for existence among individuals of a population, with only a fraction of their offspring surviving each generation.

OBSERVATION #4: Members of a population vary extensively in their characteristics; no two individuals are exactly alike (Figure 22.9).

OBSERVATION #5: Much of this variation is heritable.

INFERENCE #2: Survival depends in part on inherited traits. Individuals whose inherited traits give them a high probability of surviving and reproducing in a given environment have higher fitness and are likely to leave more offspring than less fit individuals.

INFERENCE #3: This unequal ability of individuals to survive and reproduce will lead to a gradual change in a population, with favorable characteristics accumulating over generations.

c **Figure 22.8**
Oviposition of offspring.

Just one branch of a maple tree bears dozens of winged seeds. If all the tree's offspring survived, we would quickly be overwhelmed by maple forests.

A Figure 22.9 Variation in a population. To the extent that the variation in color and dot patterns among the members of this population of ladybird beetles is heritable, it can be acted on by natural selection.

Darwin perceived an important connection between natural selection, which results from what he called the struggle for existence, and the capacity of organisms to "overreproduce." Apparently, this insight came after he read a 1798 essay on population growth by Thomas Malthus. Malthus contended that much of human suffering—disease, famine, homelessness, and war—was the inescapable consequence of the human populations potential to increase faster than food and other resources. The capacity to overreproduce seems to be characteristic of all species (see Figure 22.8). Of the many eggs laid, young born, and seeds spread, only a tiny fraction complete their development and leave offspring of their own. The rest are eaten, starved, diseased, unmated, or unable to reproduce for some other reason.

In each generation, environmental factors filter heritable variations, favoring some over others. Organisms with traits favored by the environment tend to produce more offspring than do organisms without those traits. This differential re-

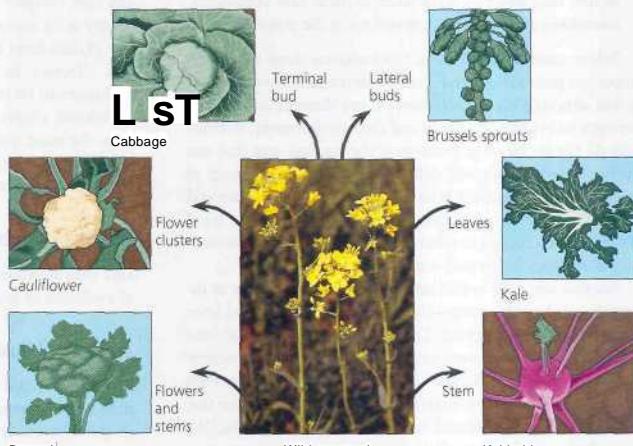

productive success results in favored traits being disproportionately represented in the next generation. Increases in the frequencies of favored traits in a population, which are always taking place regardless of whether the environment is changing, are an important source of evolutionary modification.

Artificial Selection. Darwin derived another piece of his theory from the many familiar examples of selective breeding of domesticated plants and animals. Humans have modified other species over many generations by selecting and breeding individuals that possess desired traits—a process called **artificial selection**. As a result of artificial selection, crop plants and animals bred as livestock or pets often bear little resemblance to their wild ancestors (Figure 22.10).

If artificial selection can achieve so much change in a relatively short period of time, Darwin reasoned, then what he termed "natural selection" should be capable of considerable modification of species over hundreds or thousands of generations. Even if the advantages of some heritable traits over others are slight, the advantageous variations will gradually accumulate in the population, and less favorable variations will diminish.

Summary of Natural Selection. Let's once more state the main ideas of natural selection:

- Natural selection is the differential success in reproduction (the unequal ability of individuals to survive and reproduce) that results from the interaction between individuals that vary in heritable traits and their environment.

A. Figure 22.10 Artificial selection. These vegetables have all been selected from one species of wild mustard. By selecting variations in different parts of the plant, breeders have obtained these divergent results.

(a) A flower mantid in Malaysia

(b) A stick mantid in Africa

A Figure 22.11 Camouflage as an example of evolutionary adaptation. Related species of the insects called mantids have diverse shapes and colors that evolved in different environments.

- Over time, natural selection can increase the adaptation of organisms to their environment (**Figure 22.11**).
- If an environment changes over time, or if individuals of a particular species move to a new environment, natural selection may result in adaptation to these new conditions, sometimes giving rise to new species in the process.

Before continuing, we need to emphasize three subtle but important points about evolution by natural selection. The first is that although natural selection occurs through interactions between individual organisms and their environment, individuals do not evolve. A population is the smallest unit that can evolve. (For now, we will define a population as a group of interbreeding individuals belonging to a particular species and sharing a common geographic area.) Evolution can be measured only as changes in relative proportions of heritable variations in a population over a succession of generations.

Another key point is that natural selection can amplify or diminish *only* heritable traits—that is, traits that are passed from organisms to their offspring. Though an organism may become modified through its own interactions with the environment during its lifetime, and these acquired characteristics may even adapt the organism to its environment, there is no evidence that such acquired characteristics can be inherited by offspring. We must distinguish between adaptations that an organism acquires during its lifetime and inherited adaptations that accumulate in a population over many generations as a result of natural selection.

Also, remember that environmental factors vary from place to place and from time to time. A trait that is favorable in one situation may be useless—or even detrimental—in different circumstances. Natural selection is always operating, but which traits are favored depends on the environment.

Thus, Darwin envisioned life as evolving through this gradual accumulation of small changes. He postulated that natural selection, operating in varying contexts over vast spans of time as revealed by the emerging science of geology, could account for the entire diversity of life.

Concept Check 22.2

1. Describe how the following concepts relate to Darwin's theory of evolution by natural selection: overreproduction of populations, limited resources, and heritable variation.
2. Explain why an individual organism cannot be said to evolve.

For suggested answers, see Appendix A.

Concept 22.3

Darwin's theory explains a wide range of observations

Scientific inquiry seeks *natural* causes for natural phenomena (see Chapter 1). The power of evolution, as a unifying theory is its versatility as a natural explanation for a diversity of data from biology's many subfields. And like all general theories in science, Darwin's theory of evolution continues to be tested by how effectively it can account for additional observations and experimental outcomes. Perhaps the most direct validations of Darwin's theory are provided by the many cases where scientists can actually observe natural selection at work.

Natural Selection in Action

Let's look at two examples of natural selection as a mechanism of evolution in populations.

Differential Predation and Guppy Populations

Guppies (*Poecilia reticulata*) are small freshwater fish that you may know as aquarium pets. For many years, John Endler, of the University of California, Santa Barbara, and David Reznick, of the University of California, Riverside, have studied wild guppy populations living in pools in the Aripo River system on the Caribbean island Trinidad.

The researchers observed significant differences between populations in the average age and size at which the guppies reached sexual maturity. These variations were correlated to the type of predator most active on that population. In some pots, the main predator is the small killifish, which preys predominantly on juvenile guppies. In other pools, the major predator is the pike-cichlid, a larger fish that primarily eats sexually mature individuals. Guppies in populations preyed on by pike-cichlids begin reproducing at a younger age and are smaller at maturity, on average, than guppies that are preyed on by killifish.

But although correlation with type of predator was suggestive, it does not necessarily indicate cause and effect. To test whether these differences are due to natural selection, Reznick and Endler introduced guppies from "pike-cichlid pools" to new pools that contained killifish but no guppies (Figure 22.12). Over the next 11 years, the researchers compared the age and size at maturity of the transplanted guppies with the original population. After periods of 30 to 60 generations, the transplanted guppies were an average of 14% heavier at maturity than the nontransplanted individuals. Their average age at maturity had also risen. This result supports the hypothesis that natural selection caused the difference in the populations. The conclusion is that because pike-cichlids prey mainly on reproductively mature adults, the chance that a guppy will survive to reproduce several times is relatively low. The guppies with greatest reproductive success in these ponds are those that mature at a young age and small size, enabling them to produce

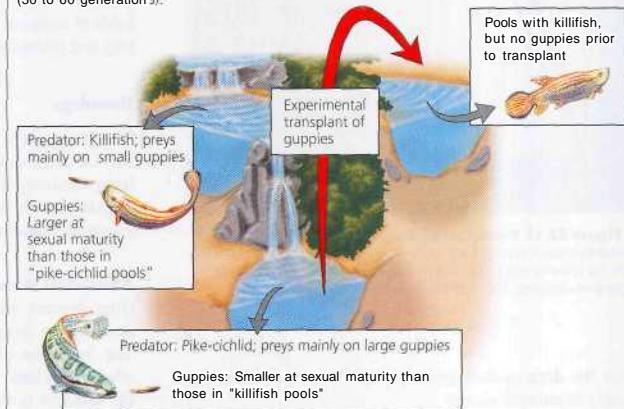

at least one brood before growing to a size preferred by the pike-cichlids. But in ponds with killifish the guppies that survive early predation can grow slowly and still produce many broods of young. This research by Reznick and Endler is one of many documented examples of evolution in natural settings over relatively short time periods.

!The Evolution of Drug-Resistant HIV

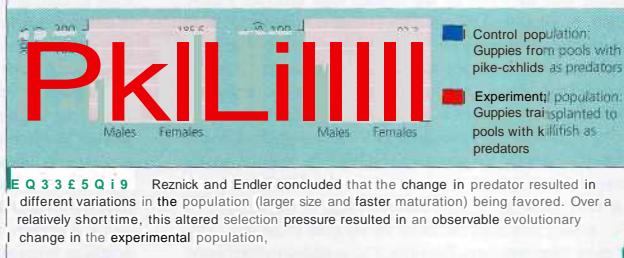

An unsettling example of ongoing natural selection that directly affects our own lives is the evolution of drug-resistant

Figure 22.12
Inquiry Can predation pressure select for size and age at maturity in guppies?

EXPERIMENT Reznick and Endler transplanted guppies from pike-cichlid pools to killifish pools and measured the average age and size of guppies at maturity over an 11-year period (30 to 60 generations).

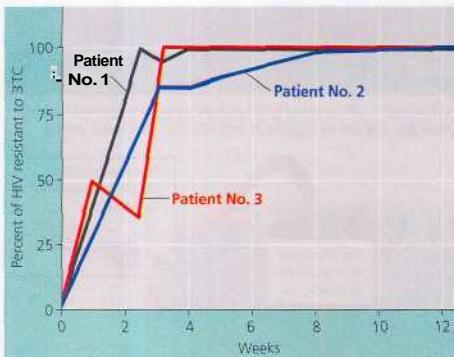

RESULTS After 11 years, the average size and age at maturity of guppies in the transplanted populations increased compared to those of guppies in control populations.

pathogens. This is a particular problem in bacteria and viruses with rapid rates of reproduction, because a variation that makes individuals resistant to a particular drug can increase in frequency very quickly in the population.

Consider the example of HIV (human immunodeficiency virus), which causes AIDS (see Chapter 18 and Chapter 43). Researchers have developed numerous drugs to combat this pathogen, but using these medications selects for viruses resistant to the drugs. A few drug-resistant viruses may be present by chance at the beginning of treatment. Those that survive the early doses pass on the genes that enable them to

A Figure 22.13 Evolution of drug resistance in HIV. Rare resistant viruses multiply quickly when each of these patients is treated with the anti-HIV drug 3TC. Within just a few weeks, 3TC-resistant organisms comprise 100% of the virus population in each case.

resist the drug to their progeny, rapidly increasing the frequency of resistant viruses.

Figure 22.13 illustrates the evolution of HIV resistance to the drug 3TC. Scientists designed 3TC to interfere with reverse transcriptase, the enzyme HIV uses to copy its RNA genome into the DNA of the human host cell (see Figure 18.10). Because the 3TC molecule is similar in shape to the C (cytosine) nucleotide of DNA, the HIV's reverse transcriptase picks up a 3TC molecule instead of C and inserts it into a growing DNA chain. This error terminates further elongation of the DNA and thus blocks reproduction of the HIV.

The 3TC-resistant varieties of HIV carry slightly different versions of reverse transcriptase that are able to discriminate between the drug and the normal C nucleotide. The viruses that carry these genes have no advantage in the absence of 3TC; in fact, they replicate more slowly than those that carry the more common form. But once 3TC is added to their environment it becomes a powerful selecting force, favoring reproduction of resistant individuals.

These examples highlight two key points about natural selection. First, natural selection is more a process of editing than a creative mechanism. A drug does not *create* resistant pathogens; it *selects for* resistant individuals that were already present in the population. Second, natural selection depends on time and place. It favors those characteristics in a genetically variable population that increase fitness in the current, local environment. What is adaptive in one situation may be useless or even harmful in another. In the guppy example, individuals that mature at an early age and small size are at an advantage in a pool with pike-cichlids, but at a disadvantage in a pool with killifish.

Homology, Biogeography, and the Fossil Record

The two examples you just read about show that natural selection can bring about change rapidly enough to be observed directly. In addition, Darwin's theory provides a cohesive explanation for observations made by researchers in the fields of anatomy, embryology, molecular biology, biogeography, and paleontology.

Homology

Darwin's concept of descent with modification can explain why certain characteristics in related species have an underlying similarity even though they may have very different functions. Such similarity resulting from common ancestry is known as homology.

Anatomical Homologies. The view of evolution as a remodeling process accounts for the findings of comparative anatomy, the comparison of body structures between species. The forelimbs of all mammals, including humans, cats, whales, and bats, show the same arrangement of bones from the shoulder to the tips of the digits, even though these appendages can have very different functions—lifting, walking, swimming, and flying (**Figure 22.14**). Such striking anatomical resemblances would not exist if these structures had arisen anew in each species. The arms, forelegs, flippers, and wings of different mammals are homologous structures that represent variations on a structural theme that was present in their common ancestor.

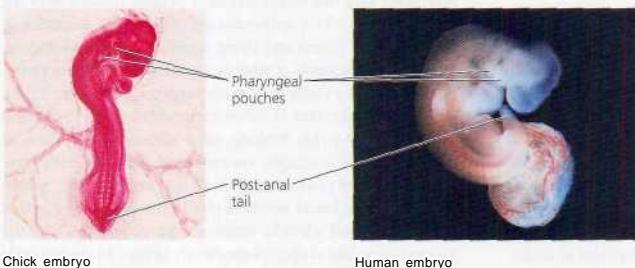

Comparative embryology, the comparison of early stages of animal development, reveals additional anatomical homologies not visible in adult organisms. For example, at some point in their development, all vertebrate embryos have tails posterior to the anus, as well as structures called pharyngeal (throat) pouches (**Figure 22.15**). These embryonic structures develop into homologous structures with very different functions, such as gills in fishes and parts of the ears and throat in humans.

Some of the most intriguing homologous structures are vestigial organs, structures of marginal, if any, importance to the organism. Vestigial organs are remnants of structures that served important functions in the organism's ancestors. For instance, the skeletons of some snakes retain vestiges of the pelvis and leg bones of walking ancestors. Because limbs are a hindrance to a snake's way of life, natural selection has favored snake ancestors with successively smaller limbs. We would not expect to see these vestigial structures if snakes had an origin separate from other vertebrate animals.

Because evolution can only modify existing structures and functions, it often produces less than perfect results. For example, the human knee joint and spine derive from ancestral structures that supported four-legged mammals. Few people

A Figure 22.14 Mammalian forelimbs: homologous structures. Even though they have become adapted for different functions, the forelimbs of all mammals are constructed from the same basic skeletal elements: one large bone (gray), attached to two smaller bones (dark and light orange), attached to several small bones (yellow), attached to approximately five digits, or phalanges (brown).

B Figure 22.15 Anatomical similarities in vertebrate embryos. At some stage in their embryonic development, all vertebrates have a tail located posterior to the anus, as well as pharyngeal (throat) pouches. Descent from a common ancestor can explain such similarities.

reach old age without experiencing knee or back problems. If these structures had originally evolved to support our bipedal posture, we would expect them to be less subject to injury. The anatomical remodeling that enabled our ancestors to stand upright was apparently constrained by our evolutionary history.

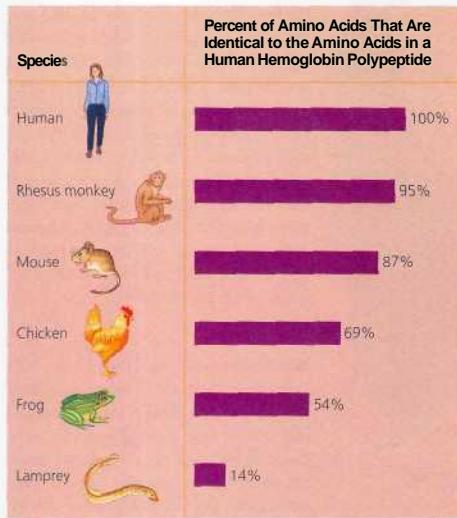

Molecular Homologies. Biologists also observe similarities among organisms at the molecular level. All forms of life use

the same genetic machinery of DNA and RNA, and the genetic code is essentially universal (see Chapter 17). Because the genetic code is shared by all organisms, it is likely that all species descended from a common ancestor. Molecular homologies also go beyond a shared code. Organisms as dissimilar as humans and bacteria share many genes that have been inherited from a distant common ancestor. Like the forelimbs of humans and whales, these genes have often acquired different functions.

Homologies and the Tree of Life. The Darwinian concept of an evolutionary tree of life can explain the homologies that researchers have observed. Some homologies, such as the genetic code, are shared by all species because they date to the deep ancestral past. Homologies that evolved more recently are shared only within smaller branches of the tree. For example, all tetrapods (from the Greek *tetra*, four, and *pod*, foot), the vertebrate branch consisting of amphibians, reptiles (including birds), and mammals, possess the same basic five-digit limb structure illustrated in Figure 22.14. Thus, homologies result in a nested pattern, with all life sharing the deepest layer and each smaller group adding homologies to those they share with larger groups. This nested pattern is exactly what we would expect if life evolved and diversified **from** a common ancestor.

Anatomical resemblances among species are generally reflected in their molecules—in their genes (DNA) and gene products (proteins). **Figure 22.16**, on the next page, compares the amino acid sequence of human hemoglobin,

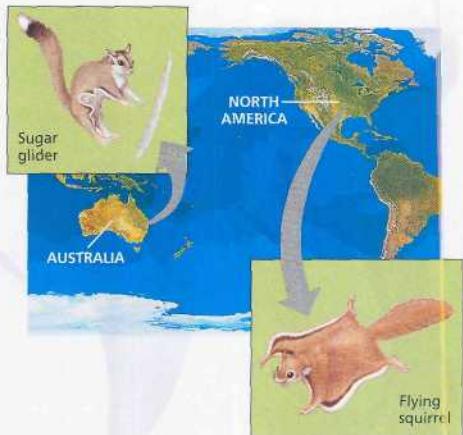

the protein that transports oxygen in blood, with the hemoglobin of other vertebrates. The data show the same pattern of evolutionary relationships that researchers find when they compare other proteins or assess relationships based on nonmolecular methods such as comparative anatomy. The Darwinian view of life predicts that different kinds of homologies in a group of organisms will all tend to show the same branching pattern through evolutionary history.

A Figure 22.16 Comparison of a protein found in diverse vertebrates.

Biogeography

Darwin's observations of the geographic distribution of species—or biogeography—formed an important part of his theory of evolution. Closely related species tend to be found in the same geographic region, whereas the same ecological niches in distant regions are occupied by very different (though sometimes similar-looking) species. Consider Australia, which is home to a group of mammals—the marsupials—that are distinct from another group of mammals—the eutherians—that live elsewhere on Earth. (Eutherians are mammals that complete their embryonic development in the uterus, whereas marsupials are born as embryos and complete their development in an external pouch.) Some Australian marsupials have eutherian look-alikes with similar adaptations living on other continents. For instance, a forest-dwelling Australian marsupial called the sugar glider is superficially very similar to "flying" squirrels, gliding eutherians that live in North American forests (Figure 22.17). But the sugar glider has many other characteristics that define it as distinctly marsupial, much more closely related to kangaroos and other Australian marsupials than to flying squirrels or other eutherians. Once again Darwin's theory can explain these observations. Although these two mammals have adapted to similar environments in similar ways, they evolved independently from different ancestors. The sugar glider is a marsupial not because that is a requirement for its gliding lifestyle, but simply because

A Figure 22.17 Different geographic regions, different mammalian "brands." The sugar glider is an example of the diverse marsupial life that evolved in isolation on the island continent of Australia. While sugar gliders superficially resemble the eutherian flying squirrels of North America, the ability to glide through the air evolved independently in these two distantly related groups of mammals,

its ancestors were marsupials. The unique fauna of Australia diversified after that island continent became isolated from the landmasses on which eutherians diversified. The resemblance between sugar gliders and flying squirrels is not homologous; rather, it is an example of what biologists call convergent evolution (we'll take a closer look at convergence in Chapter 25).

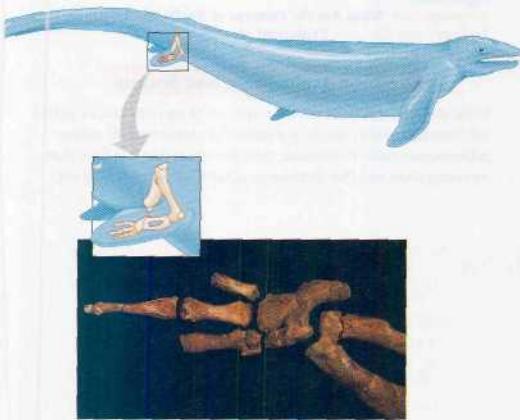

It's no wonder that Darwin's experiences in the Galapagos were so pivotal to his thinking, since islands are showcases of the influence of geography on evolution. They generally have many species of plants and animals that are endemic, which means they are found nowhere else in the world. And yet, as Darwin observed when he reassessed his collections from the voyage, most island species are closely related to species from the nearest mainland or neighboring island. This explains why two islands with similar environments in different parts of the world are populated not by closely related species but rather by species close to those of the nearest mainland, where the environment is often quite different. Island chains like the Galapagos, or archipelagos, are especially interesting in their biogeography. If a species that disperses from a mainland to an island succeeds in its new environment, it may give rise to several new species as populations spread to other islands in the archipelago. The finches of the Galapagos archipelago are an example of this process (see Figure 1.23), as are the hundreds of Hawaiian *Drosophila* species studied by Kenneth Kaneshiro (see interview on pages 436–437).

The Fossil Record

Th: succession of forms observed in the fossil record is consistent with other inferences about the major branches of descent in the tree of life. For instance, comparative data from biochemistry, molecular biology, and cell biology suggest that prokaryotes are the ancestors of all life and predict that prokaryotes should precede all eukaryotic life in the fossil record. Indeed, the oldest known fossils are prokaryotes (see Chapter 26).

The Darwinian view of life predicts that evolutionary transitions should leave signs in the fossil record. Paleontologists have discovered fossils of many such transitional forms that link ancient organisms to modern species. For example, researchers have found fossil evidence that birds descended from one branch of dinosaurs, and they have also found fossilized whales linking these aquatic mammals to their terrestrial ancestors (**Figure 22.18**).

•Darwin's theory endures in biology because it explains so many different kinds of observations: anatomical and molecular homologies that match patterns in space (biogeography) and time (the fossil record). Natural selection can also explain how similar adaptations can evolve independently among distantly related species, such as sugar gliders and flying squirrels.

k Figure 22.18 A transitional fossil linking past and present. The hypothesis that whales evolved from terrestrial (land-dwelling) ancestors predicts a four-limbed beginning for whales. Paleontologists digging in Egypt and Pakistan have identified extinct whales that had hind limbs. Shown here are the fossilized leg bones of *Basilosaurus*, one of those ancient whales. Other fossil whales have been found with larger or smaller limbs, and all are related to still older animals that spent only part of their time in the water.

What Is Theoretical about the Darwinian View of Life?

Some people dismiss the Darwinian view of life as "just a theory." However, as we have seen, Darwin's explanation makes sense of massive amounts of data, and the effects of natural selection can be observed in nature.

What, then, is theoretical about evolution? The term *theory* has a very different meaning in science than in everyday use. The colloquial use of the word *theory* comes close to what scientists mean by a hypothesis. In science, a theory is more comprehensive than a hypothesis. A theory, such as Newton's theory of gravitation or Darwin's theory of evolution by natural selection, accounts for many observations and data and attempts to explain and integrate a great variety of phenomena. Such a unifying theory does not become widely accepted unless its predictions stand up to thorough and continual testing by experiment and additional observation (see Chapter 1). As the next three chapters demonstrate, this has certainly been the case with the theory of evolution by natural selection.

The skepticism of scientists as they continue to test theories prevents these ideas from becoming dogma. For example, many evolutionary biologists now question whether natural selection is the only evolutionary mechanism responsible for the evolutionary history inferred from the fossil and molecular data. As we'll explore further in this unit, other factors have also played an important role, particularly in the evolution of genes and proteins. The study of evolution is livelier than ever as scientists find more ways to test the predictions of Darwin's theory.

By attributing the diversity of life to natural processes, Darwin gave biology a sound, scientific basis. Nevertheless, the diverse products of evolution remain elegant and inspiring. As Darwin said in the closing paragraph of *The Origin of Species*, "There is grandeur in this view of life. . . ."

Concept Check 22.3

1. Explain why the following statement is inaccurate: "Anti-HIV drugs have created drug resistance in the virus."
2. How does Darwin's theory account for both the similar mammalian forelimbs with different functions shown in Figure 22.14 and the similar lifestyle of the two distantly related mammals shown in Figure 22.17?
3. Explain how the fossil record can be used to test predictions of evolutionary theory.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 22.1

The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species

- **Resistance to the Idea of Evolution** (pp. 439–440) Darwin's theory that life's diversity has arisen from fewer ancestral species through natural selection was a radical departure from the prevailing views of Western culture,
- **Theories of Gradualism** (p. 440) Geologists Hutton and Lyell perceived that changes in Earth's surface can result from slow, continuous actions still operating at the present time.
- **Lamarck's Theory of Evolution** (pp. 440–441) Lamarck hypothesized that species evolve, but the mechanisms he proposed are unsupported by evidence.

Concept 22.2

In *The Origin of Species*, Darwin proposed that species change through natural selection

- **Darwin's Research** (pp. 441–443) Darwin's experiences during the voyage of HMS *Beagle* provided much of the background for his idea that new species originate from ancestral forms through the gradual accumulation of adaptations. After returning to England, he refined his theory and finally published it in 1859 after learning that Wallace had the same idea.
Activity Darwin and the Galapagos Islands
Activity The Voyage of the Beagle: Darwin's Trip Around the World
Biology Labs On-Line EvolutionLab
- **The Origin of Species** (pp. 443–446) In his book describing his theory of descent with modification, Darwin recognized that there are heritable variations in populations and that some of those variations are better suited than others to a particular environment. Because organisms tend to produce many more offspring than the environment can support, there is a struggle for existence, and those that are better suited to the environment tend to have greater success in surviving and reproducing. Thus, these better-suited individuals leave more offspring than other individuals. Over time, this process of natural selection can result in adaptation of organisms to their environment.

Concept 22.3

Darwin's theory explains a wide range of observations

- **Natural Selection in Action** (pp. 446–448) Researchers have observed natural selection leading to adaptive evolution in wild guppy populations. In humans, the use of drugs selects for pathogens that through chance mutations are resistant to the drugs' effects. The ability of bacteria and viruses to evolve rapidly poses a challenge to our society.
Investigation How Do Environmental Changes Affect a Population?
Investigation What Are the Patterns of Antibiotic Resistance?

- **Homology, Biogeography, and the Fossil Record** (pp. 448–451) Evolutionary theory explains many kinds of observations, including structural and molecular similarities, geographic distribution of organisms, and the fossil record.
Activity Reconstructing Forelimbs

- **What Is Theoretical about the Darwinian View of Life?** (p. 451) Darwin's theory of evolution by natural selection integrates diverse areas of biological study and stimulates many new research questions.

TESTING YOUR KNOWLEDGE

Evolution Connection

Explain why anatomical and molecular homologies generally fit 2 similar nested pattern.

Scientific Inquiry

Darwin's argument for the idea that evolution has occurred is largely inductive, while his argument for the mechanism of natural selection is essentially deductive. Summarize in your own words the inductive and deductive components of Darwin's theory. (You can review induction and deduction in Chapter 1.)

Biology Labs On-Line EvolutionLab

Science, Technology, and Society

Is the concept of natural selection relevant in an economic or political context? In other words, if a particular corporation or nation achieves success or dominance, does this mean that it is fitter than its competitors and that dominance is justified? Why or why not?

23

The Evolution of Populations

▲ Figure 23.1 Variation in a natural population.

Key Concepts

- 23.1 Population genetics provides a foundation for studying evolution
- 23.2 Mutation and sexual recombination produce the variation that makes evolution possible
- 23.3 Natural selection, genetic drift, and gene flow can alter a population's genetic composition
- 23.4 Natural selection is the primary mechanism of adaptive evolution

Overview

The Smallest Unit of Evolution

One common misconception about evolution is that individual organisms evolve, in the Darwinian sense, during their lifetimes; it is true that natural selection acts on individuals; each organism's combination of traits affects its survival and reproductive success compared to other individuals. But the evolutionary impact of natural selection is only apparent in the changes in a population of organisms over time. Consider, for example, the collection of shells from a population of Cuban tree snails (*Polymita pista*) shown in **Figure 23.1**. Their different patterns and colors are largely the result of genetic differences among the individuals. Suppose that predators are less likely to feed on snails with a particular coloration, perhaps because these snails are better camouflaged against their surroundings. The proportion of snails of that color will tend to increase from one generation to the next. Thus, the population, not its individual members, evolves; some traits become more common within the population, while other traits become less common.

Concept 23.1

Population genetics provides a foundation for studying evolution

Today we can define evolutionary change on its smallest scale, or **microevolution**, as change in the genetic makeup of a population from generation to generation (**Figure 23.2**). But Darwin did not define evolution in this way. In natural selection, Darwin had found a mechanism for change in species

A **Figure 23.2** Individuals are selected; populations evolve. The bent grass (*Agrostis tenuis*) in the foreground is growing on the tailings of an abandoned mine. These plants tolerate concentrations of heavy metals that are toxic to other plants of the same species in the pasture beyond the fence. Many seeds from the pasture drift onto the tailings, but only those with genes that enable them to tolerate metallic soil survive and reproduce.

over time. However, he did not have a satisfactory explanation for how the heritable variations required for natural selection appear in populations or how organisms transmit these variations to their offspring. Ideas about inheritance from Darwin's time could not explain how inherited variations are maintained in populations. For instance, the widely accepted blending hypothesis proposed that the traits of parents are blended in the offspring. But Darwin and others realized that over time, blending would eliminate the differences between individuals. Although breeding experiments and observations of nature refuted this prediction, Darwin lacked an alternate model of inheritance that could support his hypothesis.

just a few years after Darwin published *On the Origin of Species*, Gregor Mendel proposed just such a model: the particulate hypothesis of inheritance, which stated that parents pass on discrete heritable units (genes) that retain their identities in offspring. But Darwin never saw Mendel's paper, and its implications were not understood by the few scientists who read it at the time. Mendel's contribution to evolutionary theory was not appreciated until half a century later.

The Modern Synthesis

Ironically, when Mendel's work was reconsidered in the early 20th century, many geneticists thought that his laws of inheritance were at odds with Darwin's theory. Darwin considered the raw material for natural selection to be "quantitative" characters—those characteristics in a population that vary along a continuum, such as fur length in mammals or the running speed of animals fleeing from predators. But Mendel and other early geneticists worked only with discrete "either-or" traits, such as purple or white flowers in pea plants. It was therefore not obvious that there was a genetic basis to the more subtle variations that were central to Darwin's theory. Within a few decades, however, geneticists determined that quantitative characters are influenced by multiple genetic loci and that the alleles at each of these loci follow Mendelian patterns of inheritance (see Chapter 14). These discoveries helped reconcile Darwin's and Mendel's ideas and led to the formal founding of population genetics, the study of how populations change genetically over time.

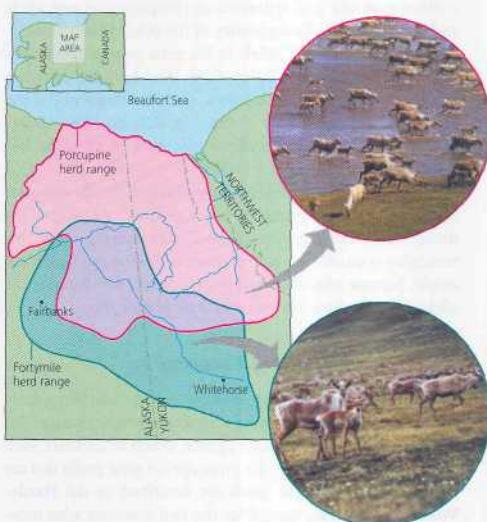

By the mid-20th century, population genetics also gave rise to what is called the modern synthesis, a comprehensive theory of evolution that integrated ideas from many other fields. The first architects of the modern synthesis included statistician R. A. Fisher (1890–1962), who demonstrated the rules by which Mendelian characters are inherited, and biologist J. B. S. Haldane (1892–1964), who studied the rules of natural selection. Later contributors included geneticists Theodosius Dobzhansky (1900–1975) and Sewall Wright (1889–1988), biogeographer Ernst Mayr (1904–), paleontologist George Gaylord Simpson (1902–1984), and botanist G. Ledyard Stebbins (1906–2000).

Of course, scientific paradigms rarely endure without modification. The modern synthesis is still expanding to integrate, for example, the discovery of genetic changes in populations caused by mechanisms other than natural selection. Although the modern synthesis itself continues to evolve, its focus on populations has shaped much of our current thinking about evolutionary processes.

Gene Pools and Allele Frequencies

Before continuing our discussion of population genetics, we need to define what we mean by a population. A **population** is a localized group of individuals that are capable of interbreeding and producing fertile offspring. Populations of the same species may be isolated from one another, thus exchanging genetic material only rarely. Such isolation is common for populations confined to different, widely separated islands or lakes. But not all populations are isolated, nor must they have sharp boundaries (Figure 23.3). Still, individuals near the population center are more likely to breed with members of their own population than with members of other populations and thus on average are more closely related to one another than to members of other populations.

The total aggregate of genes in a population at any one time is called the population's **gene pool**. It consists of all

A Figure 23.3 One species, two populations. These two caribou populations in the Yukon are not totally isolated—they sometimes share the same area. Nonetheless, members of either population are more likely to breed with members of their own population than with members of the other population.

alleles at all gene loci in all individuals of the population. If only one allele exists at a particular locus in a population, that allele is said to be *fixed* in the gene pool, and all individuals are homozygous for that allele. (Recall that homozygous individuals have two identical alleles for a given locus, while heterozygous individuals have two different alleles at that locus.) But if there are two or more alleles for a particular locus in a population, individuals may be either homozygous or heterozygous.

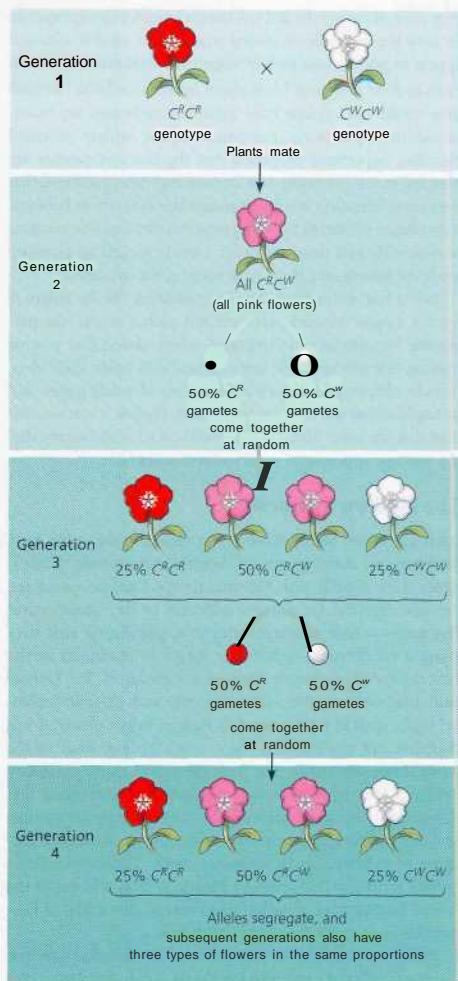

Each allele has a frequency (proportion) in the population. For example, imagine a population of 500 wildflower plants with two alleles, C^R and C^W , at a locus that codes for flower pigment. Plants homozygous for the C^R allele ($C^R C^R$) produce red pigment and have red flowers; plants homozygous for the C^W allele ($C^W C^W$) produce no red pigment and have white flowers; and heterozygotes ($C^R C^W$) produce some red pigment and have pink flowers. In our population there are 320 plants with red flowers, 160 with pink flowers, and 20 with white flowers. These alleles show incomplete dominance (see Chapter 14). Because these are diploid organisms, there are a total of 1,000 copies of genes for flower color in the population of 500 individuals. The C^R allele accounts for 800 of these genes ($320 \times 2 = 640$ for $C^R C^R$ plants, plus $160 \times 1 = 160$ for $C^R C^W$ plants).

When there are two alleles at a particular locus, the convention is to use p to represent the frequency of one allele and q to represent the frequency of the other allele. Thus, p , the frequency of the C^R allele in the gene pool of this population, is $800/1,000 = 0.8 = 80\%$. And because there are only two allelic forms of this gene, then the frequency of the C^W allele, represented by q , must be 0.2, or 20%. At loci that have more than two alleles, the sum of all allele frequencies must still equal 1 (100%).

We can easily measure genetic variability at this flower-color locus because each genotype has a distinct phenotype. Although many loci in gene pools have more than one allele, this variability is usually less easy to quantify than in our flower example, because one allele may be completely dominant or the alleles may not have obvious effects on phenotypes.

The Hardy-Weinberg Theorem

In a moment we will explore how genes and allele frequencies can change over time, representing evolutionary change. But first, to provide a benchmark against which to measure such changes, we'll investigate the properties of gene pools that are *not* evolving. Such gene pools are described by the Hardy-Weinberg theorem, named for the two scientists who independently derived the principle in 1908. The theorem states that the frequencies of alleles and genotypes in a populations gene pool remain constant from generation to generation, provided that only Mendelian segregation and recombination of alleles are at work (Figure 23.4).

A **Figure 23.4** Mendelian inheritance preserves genetic variation from one generation to the next.

Preservation of Allele Frequencies

The Hardy-Weinberg theorem describes how Mendelian inheritance preserves genetic variation from one generation to the next in populations that are not evolving. But it does more than this. We will see that the theorem lays the groundwork for understanding long-term evolutionary changes that Darwin, lacking knowledge of genetics, could not have envisioned. The

preservation of genetic variation provides the opportunity for natural selection to act over many generations.

Let's apply the Hardy-Weinberg theorem to our hypothetical wildflower population. Recall that 80% (0.8) of the flower color alleles in the gene pool are C^R and 20% (0.2) are C^W . Because each gamete produced by the flowers is haploid, it carries only one allele for flower color. The chance that a gamete will carry a C^R allele is 0.8, and the chance that it will carry a C^W allele is 0.2. The allele frequencies in all the gametes produced by the population will be the same as in the original population. Provided that gametes are contributed to the next generation at random, allele frequencies will be unchanged.

Hardy-Weinberg Equilibrium

Suppose that the individuals in a population not only donate gametes to the next generation at random but also mate at random—that is, all male-female matings are equally likely. Not only will this population have the same allele frequencies from one generation to the next, but its genotype frequencies can be predicted from the allele frequencies. Such populations are in a state of Hardy-Weinberg **equilibrium**.

It turns out that our wildflower population is in Hardy-Weinberg equilibrium (Figure 23.5). Using the rule of multiplication (see Chapter 14), we can calculate the frequencies of the three possible genotypes assuming random unions of sperm and ova. The probability that two C^R alleles will come together is $0.8 \times 0.8 = p \times p = p^2 = 0.64$. Thus, about 64% of the plants in the next generation will have the genotype $C^R C^R$. The frequency of $C^W C^W$ individuals will be about $0.2 \times 0.2 = q^2 = 0.04$, or 4%. $C^R C^W$ heterozygotes can arise in two different ways. If the sperm provides the C^R allele and the ovum provides the C^W allele, the resulting heterozygotes will be $0.8 \times 0.2 = 16\%$ of the total. If the ovum provides the C^R allele and the sperm the C^W allele, the heterozygous offspring will make up another $0.8 \times 0.2 = 16\%$. We can summarize these unions of gametes in an algebraic equation:

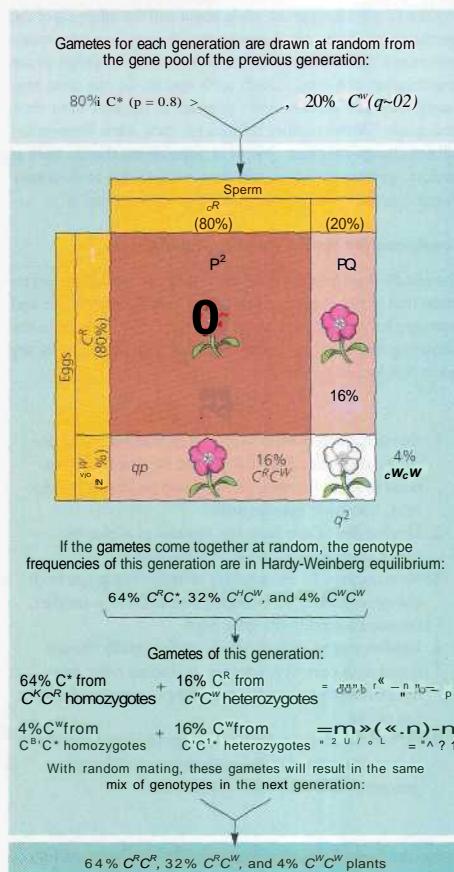

$$(p + q) \times (p + q) = p^2 + 2pq + q^2$$

| | | |
|------------------------------------|--------------------------------------|---|
| Allele frequencies of male gametes | Allele frequencies of female gametes | Genotype frequencies in the next generation |
|------------------------------------|--------------------------------------|---|

As with allele frequencies, all of these genotype frequencies sum to 1. Thus, the equation for Hardy-Weinberg equilibrium states that at a locus with two alleles, the three genotypes will appear in the following proportions:

$$p^2 + 2pq + q^2 = 1$$

If a population were in Hardy-Weinberg equilibrium and its members continued to mate randomly generation after generation, allele and genotype frequencies would remain constant. The system operates somewhat like a deck of cards: No matter how many times the deck is reshuffled to deal out new hands, the deck itself remains the same. Aces do not grow more numerous than jacks. And the repeated shuffling of a population's

A. Figure 23.5 The Hardy-Weinberg theorem. In our wildflower population, the gene pool remains constant from one generation to the next. Mendelian processes alone do not alter frequencies of alleles or genotypes.

gene pool over the generations cannot, in itself, change the frequency of one allele relative to another.

Note that a population does not need to be in Hardy-Weinberg equilibrium for its allele frequencies to remain constant. Many species, such as the peas that Mendel used in his experiments, do not mate randomly. Since pea pollen normally matures before the flower opens, it fertilizes the same flower that contains it. (In fact, Mendel could cross plants only by artificial fertilization.) Because of self-fertilization, pea populations are far from Hardy-Weinberg equilibrium. All the homozygous plants

produce only homozygotes, while about half the offspring of the heterozygous plants are homozygous. It does not take many generations before almost all the plants in the population are homozygous. But even though such species do not mate randomly, they still produce their gametes at random from their gene pools. Without other influences, their allele frequencies will not change over time. Just as in populations that do mate at random, genetic variation—the raw material for evolutionary change—is preserved even in the self-fertilizing peas.

Conditions for Hardy-Weinberg Equilibrium

The Hardy-Weinberg theorem describes a hypothetical population that is not evolving. But in real populations, allele and genotype frequencies *do* change over time. This is because the following five conditions for non-evolving populations are rarely met for long in nature:

1. *Extremely large population size.* The smaller the population, the greater the role played by chance fluctuations in allele frequencies from one generation to the next, known as genetic drift.
2. *No gene flow.* Gene flow, the transfer of alleles between populations, can alter allele frequencies.
3. *No mutations.* By introducing or removing genes from chromosomes or by changing one allele into another, mutations modify the gene pool.
4. *Random mating.* If individuals preferentially choose mates with certain genotypes, including close relatives (inbreeding), random mixing of gametes does not occur.
5. *No natural selection.* Differential survival and reproductive success of individuals carrying different genotypes will alter allele frequencies.

Departure from these conditions usually results in evolution. While natural populations rarely if ever are in true Hardy-Weinberg equilibrium, in many populations the rate of evolutionary change is so slow that these populations *appear* to be close to equilibrium. This enables us to obtain approximate estimates of allele and genotype frequencies, as the following example shows.

Population Genetics and Human Health

The Hardy-Weinberg equation can be used to estimate the percentage of the population carrying the allele for an inherited disease. For example, about one out of every 10,000 babies in the United States is born with phenylketonuria (PKU), a metabolic disorder that results from homozygosity for a recessive allele. Left untreated, PKU results in mental retardation and other problems. (Newborns are now tested for PKU,

and their symptoms can be lessened with a phenylalanine-free diet.)

To use the Hardy-Weinberg equation, we must assume that people do not choose their mates because of whether or not they carry this gene and do not generally mate with close relatives (inbreeding). We must also neglect any effects of gene flow from other populations into the United States, introduction of new PKU mutations, and differential survival and reproductive success among PKU genotypes. These assumptions are reasonable, since inbreeding in the United States is not common, populations outside the United States have PKU allele frequencies similar to those seen in the United States, the mutation rate for the PKU gene is low, and selection occurs only against the rare homozygotes.

If all these assumptions hold, then the frequency of individuals in the population born with PKU will correspond to q^2 in the Hardy-Weinberg equation (q^2 = frequency of the homozygotes for this allele). Because the allele is recessive, we must estimate the number of heterozygotes rather than counting them directly as we did with the pink flowers. Since we know there is one PKU occurrence per 10,000 births ($f_f = 0.0001$), the frequency of the recessive allele for PKU is

$$q = \sqrt{0.0001} = 0.01$$

and the frequency of the dominant allele is

$$p = 1 - q = 1 - 0.01 = 0.99$$

The frequency of carriers, heterozygous people who do not have PKU but may pass the PKU allele to offspring, is

$$2pq = 2 \times 0.99 \times 0.01 = 0.0198 \text{ (approximately } 2\% \text{ of the U.S. population)}$$

Remember, the assumption of Hardy-Weinberg equilibria in results in only an approximation; the real number of carriers may be somewhat different. Nevertheless, we can conclude that many harmful recessive alleles at this and other loci are concealed in the human population because they are carried by healthy heterozygotes.

Concept Check 23.1

1. What did Mendel's findings about genetics add to Darwin's theory of evolution by natural selection?
2. Suppose a population of organisms with 500 gene loci is fixed at half of these loci, and has two alleles at each of the other loci. How many alleles are found in its gene pool? Explain.
3. Which term in the Hardy-Weinberg equation ($p^2 + 2pq + q^2 = 1$) corresponds to the frequency of individuals with PKU alleles?

For suggested answers, see Appendix A.

Concept 23.2

Mutation and sexual recombination produce the variation that makes evolution possible

As you have learned, natural selection operates on the heritable differences, often slight ones, among individuals in a population. Two processes, mutation and sexual recombination, produce the variation in gene pools that contributes to these individual differences.

Mutation

New genes and new alleles originate only by mutations (Figure 23.6), which are changes in the nucleotide sequence of DNA. A mutation is like a shot in the dark—it is not possible to predict how it will alter DNA and what its effects will be. Most mutations occur in somatic cells and are lost when the individual dies. Only mutations in cell lines that produce gametes can be passed to offspring, and only a small fraction of these spread through populations.

Point Mutations

A change of as little as one base in a gene—a "point mutation"—can have a significant impact on phenotype, as in sickle-cell disease (see Figure 5.21). But most point mutations are probably harmless. One reason is that much of the DNA in eukaryotic genomes does not code for protein products. And because the genetic code is redundant, even point mutations in genes that code for protein may have little effect because they do not alter the protein's amino acid composition (see

Figure 23.6 Mutations are the source of all heritable variation. The diverse coat colors of these wild mustangs are the products of past mutations over many generations.

Figure 17.24). However, some noncoding regions of DNA do regulate the expression of genes. Changes in these regulatory regions of DNA can have profound effects.

Organisms reflect thousands of generations of past selection, and a single mutational change is about as likely to improve the genome as blindly firing a gunshot through the hood of a car is likely to improve engine performance. On rare occasions, however, a mutant allele may actually make its bearer better suited to the environment, enhancing reproductive success. This is more likely when the environment is changing and mutations that were once selected against become favorable. For example, as you read in Chapter 22, certain mutations that make HIV resistant to particular drugs also slow its reproductive rate. Only after the drugs were introduced were these mutant alleles favored, and natural selection increased their frequency as a result.

Mutations that Alter Gene Number or Sequence

Chromosomal mutations that delete, disrupt, or rearrange many loci at once are almost certain to be harmful. However, when such mutations leave genes intact, their effects on organisms may be neutral. In rare cases, chromosomal rearrangements may even be beneficial. For example, the translocation of part of one chromosome to a different chromosome could link genes that together have some heightened positive effect.

Gene duplication is an important source of variation. Duplications of chromosome segments, like other chromosomal mutations, are nearly always harmful. But smaller pieces of DNA are often introduced into a genome through the activity of transposable elements (see Chapter 19). If such a duplicated segment does not have severe effects, it can persist over generations, providing an expanded genome with new loci that may take on new functions by further mutations and subsequent selection. New genes may also arise when the coding portions of genes (exons) are shuffled within the genome.

Such beneficial increases in gene number appear to have played a major role in evolution. For example, the remote ancestors of mammals carried a single gene for detecting odors that has been duplicated through a variety of mutational mechanisms. As a result, modern humans have close to 1,000 olfactory receptor genes, and mice have 1,300. About 60% of human olfactory receptor genes have been inactivated by subsequent mutations, whereas mice have lost only 20% of theirs—a remarkable demonstration that a versatile sense of smell is more important to mice than it is to us!

Mutation Rates

Mutation rates tend to be low in animals and plants, averaging about one mutation in every 100,000 genes per generation. But in microorganisms and viruses with short generation spans, mutations can rapidly generate genetic variation. For instance, the HIV virus has a generation span of about two days and an RNA genome, which has a much higher mutation rate than a typical

DNA genome. For this reason, single-drug treatments will probably never be effective against HIV—mutant forms of the virus that are resistant to a particular drug are likely to appear in relatively short order. Even double-drug treatments rarely work for long, because viruses with double mutations conferring resistance to *both* drugs arise daily. This explains why the most effective AIDS treatments at this time are drug “cocktails” combining several medications. It is less likely that multiple mutations against *all* the drugs will occur in a short time period.

Sexual Recombination

In sexually reproducing populations, sexual recombination is far more important than mutation on a generation-to-generation time scale in producing the variations that make adaptation possible. Nearly all phenotypic variations based on genetic differences result from recombinational shuffling of the existing alleles in the gene pool. (Of course, this allelic variation originated from past mutations.) A population contains myriad possible mating combinations, and fertilization brings together the gametes of individuals that are likely to have different genetic backgrounds. Sexual reproduction rearranges alleles into fresh combinations every generation.

Bacteria and many viruses can also undergo recombination, but they do so less regularly than animals and plants and often in ways that allow them to cross species barriers (see Chapter 18). Many of the genes of the *Escherichia coli* bacterium O157:H7, a frequent culprit in food poisoning cases, are actually “mosaics” of genes from different types of bacteria. The ability of pathogens to evolve rapidly through such extensive recombination, combined with their high mutation rates, makes them especially dangerous adversaries.

Concept Check 23.2

1. Of all the mutations that occur, why do only a small fraction become widespread in a gene pool?
2. How does sexual recombination produce variation?

For suggested answers, see Appendix A.

Concept 23.3

Natural selection, genetic drift, and gene flow can alter a population's genetic composition

Note again on page 458 the five conditions required for a population to be in Hardy-Weinberg equilibrium. A deviation

from any of these conditions is a potential cause of evolution. However, although new mutations can modify allele frequencies, the change from one generation to the next is likely to be small. Recombination reshuffles alleles, but does not change their frequencies. Nonrandom mating can affect the relative frequencies of homozygous and heterozygous genotypes but usually has no effect on allele frequencies. The three major factors that alter allele frequencies and bring about most evolutionary change are natural selection, genetic drift, and gene flow.

Natural Selection

As you read in Chapter 22, Darwin's concept of natural selection is based on differential success in reproduction: Individuals in a population exhibit variations in their heritable traits, and those with variations that are better suited to their environment tend to produce more offspring than those with variations that are less well suited.

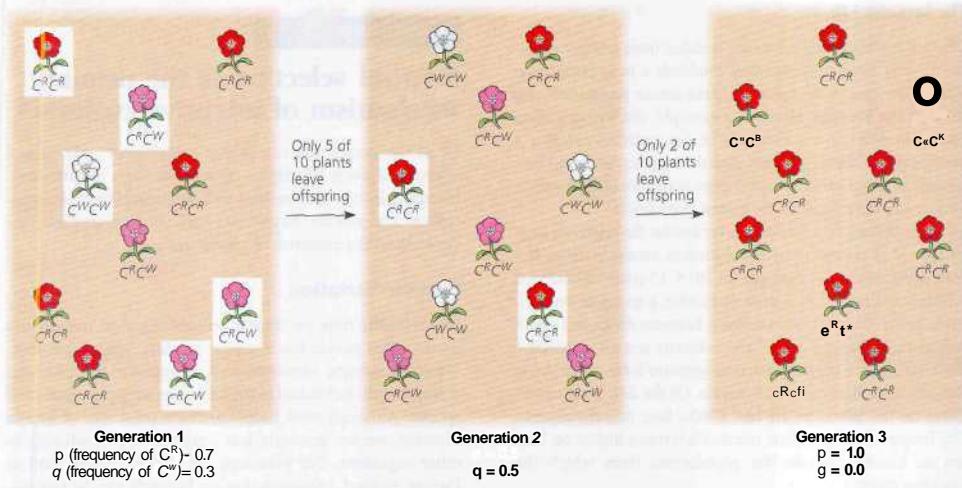

We now know that selection results in alleles being passed to the next generation in proportions different from their relative frequencies in the present generation. For example, in *C*^W imaginary wildflower population, white flowers (*C*^W*C*^W) might be more visible to plant-eating insects, resulting in more white flowers being eaten. And perhaps red flowers (*C*^R*C*^R) are more attractive to pollinators, increasing the opportunity for red flowers to produce offspring. These differences in survival and reproductive success would disturb Hardy-Weinberg equilibrium: The frequency of the *C*^W allele would decline in the gene pool, and the frequency of the *C*^R allele would increase. Later in the chapter, we'll examine the process of natural selection more closely.

Genetic Drift

Flip a coin 1,000 times, and a result of 700 heads and 300 tails would make you suspicious about that coin. But flip a coin 10 times, and an outcome of 7 heads and 3 tails would not be surprising. The smaller the sample, the greater the chance of deviation from the predicted result—in this case, an equal number of heads and tails.

Similar deviations from the expected result—which occur because real populations are finite in size rather than infinite—explain how allele frequencies can fluctuate unpredictably from one generation to the next. Such fluctuations are called genetic drift. Consider the example in Figure 23.7. Note that in this example, one of the alleles has been lost by an indiscriminate event; that is, it was a matter of chance that the *C*^W allele rather than the *C*^R allele was lost. Over time, drift tends to reduce genetic variation through such losses of alleles from the gene pool.

Two situations that can increase the likelihood that genetic drift will have a large impact on a population are referred to as the bottleneck effect and the founder effect.

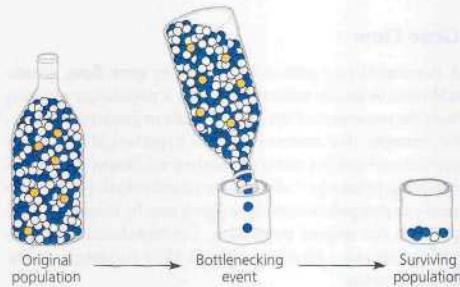

A Figure 23.7 Genetic drift. This small wildflower population has a stable size of ten plants. Only five plants (those in white boxes) of generation 1 produce fertile offspring. By chance, only two plants of generation 2 manage to leave fertile offspring. The C^R allele first increases in generation 2, then falls to zero in generation 3.

The Bottleneck Effect

A disaster caused by a sudden change in the environment may drastically reduce the size of a population. In effect, the few survivors have passed through a restrictive "bottleneck," and their gene pool may no longer be reflective of the original population's gene pool; this is called the **bottleneck effect** (Figure 23.8a). By chance, certain alleles may be overrepresented among the survivors, others may be underrepresented, and some may be eliminated altogether. Genetic drift may continue to substantially change the gene pool for many generations until the population is large enough that chance fluctuations have less effect.

One reason that understanding the bottleneck effect is important is that human actions can sometimes create severe bottlenecks for other species. For example, in the 1890s, hunters reduced the population of northern elephant seals in California to about 20 individuals. Since then, this mammal has become a protected species, and the population has rebounded to over 30,000 (Figure 23.8b). However, in examining 24 gene loci in a representative sample of the seals, researchers found *no* variation: For each of the 24 genes, there was only one allele. In contrast, populations of the southern elephant seal, a closely related species that was not bottlenecked, show abundant genetic variation.

(a) Shaking just a few marbles through the narrow neck of a bottle is analogous to a drastic reduction in the size of a population after some environmental disaster. By chance, blue marbles are overrepresented in the new population and gold marbles are absent.

(b) Similarly, bottlenecking a population of organisms tends to reduce genetic variation, as in these northern elephant seals in California that were once hunted nearly to extinction.

A Figure 23.8 The bottleneck effect.

The Founder Effect

When a few individuals become isolated from a larger population, this smaller group may establish a new population whose gene pool is not reflective of the source population; this is called the founder effect. For example, the founder effect can occur when a few members of a population colonize a new location. These founders pass through an "isolation bottleneck" and represent a distinct gene pool with different allele frequencies from those of the parent population.

The founder effect probably accounts for the relatively high frequency of certain inherited disorders among isolated human populations. For example, in 1814, 15 colonists founded a British settlement on Tristan da Cunha, a group of small islands in the Atlantic Ocean midway between Africa and South America. Apparently, one of the colonists carried a recessive allele for retinitis pigmentosa, a progressive form of blindness that afflicts homozygous individuals. Of the 240 descendants living on the island in the late 1960s, four had the disease. The frequency of this allele remains ten times higher on Tristan da Cunha than in the populations from which the founders came.

Gene Flow

A population may gain or lose alleles by gene flow, genetic additions to and/or subtractions from a population resulting from the movement of fertile individuals or gametes. Suppose, for example, that near our original hypothetical wildflower population there is a newly established wildflower population consisting primarily of white-flowered individuals ($C^W C^W$). Insects carrying pollen from these plants may fly to and pollinate plants in our original population. The introduced C^w alleles will modify our original population's allele frequencies in the next generation.

Gene flow tends to reduce differences between populations. If it is extensive enough, gene flow can amalgamate neighboring populations into a single population with a common gene pool. For example, humans today move much more freely about the world than in the past, and gene flow has become an important agent of evolutionary change in human populations that were previously quite isolated.

Concept Check 23.3

1. In what sense is natural selection more "predictable" than genetic drift?
2. Distinguish genetic drift and gene flow in terms of (a) how they occur and (b) their implications for future genetic variation in a population.

For suggested answers, see Appendix A.

Concept 23.4

Natural selection is the primary mechanism of adaptive evolution

Of all the factors that can change a gene pool, only natural selection is likely to adapt a population to its environment. Natural selection accumulates and maintains favorable genotypes in a population. As you have read, the process of selection depends on the existence of genetic variation.

Genetic Variation

You probably have no trouble recognizing your friends in a crowd. Each person has a unique genome, reflected in individual phenotypic variations such as appearance, voice, and temperament. Individual variation occurs in populations of all species. Although most people are very conscious of human diversity, we are generally less sensitive to individuality in other organisms. But variations are always present, and as Darwin realized, variations that are heritable are the raw material for natural selection. In addition to the differences that we can see or hear, populations have extensive genetic variation, that can only be observed at the molecular level. For example, you cannot identify a person's blood group (A, B, AB, or O) from his or her appearance.

Not all phenotypic variation is heritable (Figure 23.9). Phenotype is the cumulative product of an inherited genotype and a multitude of environmental influences. For example, body-builders alter their phenotypes dramatically but do not pass their huge muscles on to the next generation. It is important to remember that only the genetic component of variation can have evolutionary consequences as a result of natural selection.

(a) Map butterflies that emerge in spring: orange and brown

(b) Map butterflies that emerge in late summer: black and white

A Figure 23.9 Nonheritable variation within a population.

These European map butterflies are seasonal forms of the same species (*Araschnia levana*). Owing to seasonal differences in hormones, (a) individuals that emerge in the spring are orange and brown, while (b) individuals that emerge in the late summer are black and white. These two forms are genetically identical at the loci for coloration. Therefore, if these two forms differ in reproductive success, that in itself would not lead to any change in the ability of the butterflies to develop in these two different ways.

Variation Within a Population

Both discrete and quantitative characters contribute to variation within a population. *Discrete characters*, such as the red, pink, and white colors of our hypothetical wildflower population, can be classified on an either-or basis (each plant has flowers that are all either red or pink or white). Discrete characters often are determined by a single gene locus with different alleles that produce distinct phenotypes. However, as discussed in Chapter 22, most heritable variation consists of *quantitative characters* that vary along a continuum within a population. Heritable quantitative variation results from the influence of two or more genes on a single phenotypic character.

Polymorphism. When individuals differ in a discrete character, the different forms are called *morphs*. A population is said to display phenotypic polymorphism for a character if two or more distinct morphs are each represented in high enough frequencies to be readily noticeable. (Obviously, the definition of "readily noticeable" is somewhat subjective, but a population is not considered polymorphic if it consists primarily of a single morph and other morphs are extremely rare.)

In contrast, height variation in the human population does not show phenotypic polymorphism because it does not consist of distinct and separate morphs—heights vary along a continuum. Nonetheless, polymorphisms play a role in such characters at the genetic level. The heritable component of height is the result of such genetic polymorphisms for alleles at the several loci that influence height.

Measuring Genetic Variation. Population geneticists measure the number of polymorphisms in a population by determining the amount of heterozygosity at both the level of whole genes (gene variability) and the molecular level of DNA (nucleotide variability). To see how this works, consider a population of fruit flies (*Drosophila*). The genome of a fruit fly has about 13,000 loci. The average heterozygosity of *Drosophila* is measured as the average percent of these loci that are heterozygous. On average, a fruit fly is heterozygous (has two different alleles) at about 14% of its loci. You can therefore say that the fly population has an average heterozygosity of 14%, meaning that a typical fruit fly is heterozygous at about 1,800 of its 13,000 gene loci and homozygous at all the rest.

Nucleotide variability is measured by comparing the nucleotide sequences of DNA samples from two individuals and then averaging the data from many such comparisons. The fruit fly genome has about 180 million nucleotides, and the sequences of any two flies differ on average by approximately 1%.

Why does average heterozygosity tend to be greater than nucleotide variability? This occurs because a gene can consist of thousands of bases of DNA. A difference at only one of these bases is sufficient to make two alleles of that gene different and count toward average heterozygosity.

Based on measurements of nucleotide variability, humans have relatively little genetic variation compared to most species. Two humans differ by only about 0.1% of their bases, a tenth of the nucleotide variability found within *Drosophila* populations. Clearly, we humans are all far more genetically alike than we are different. Still, this 0.1% nucleotide variability encompasses the entire heritable component of the many different ways that people look, sound, and act, along with their biochemical differences, such as ABO blood group, that are not outwardly visible.

Variation Between Populations

Most species exhibit geographic variation, differences between the gene pools of separate populations or population subgroups. **Figure 23.10** illustrates an example of geographic variation observed in isolated populations of house mice (*Mus musculus*) that were inadvertently introduced to the Atlantic island of Madeira by Portuguese settlers in the 15th century.

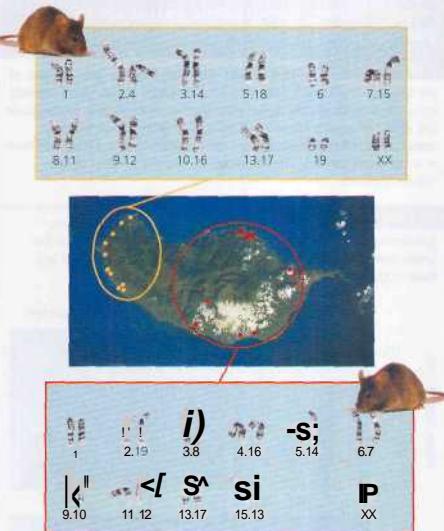

Figure 23.10 Geographic variation in chromosomal mutations. Separated by mountains, several populations of house mice on the island of Madeira have evolved isolation from one another. Researchers have observed differences in the karyotypes (chromosome sets) of these isolated populations. In some of the populations, the original chromosomes have become fused. For example, "2.4" indicates fusion of chromosome 2 and chromosome 4. However, the patterns of fused chromosomes differ from one mouse population to another. Mice in the areas indicated by the gold dots have the set of fused chromosomes in the gold box; mice in the locales with the red dots have the different pattern of fusions in the red box. Because these mutations leave genes intact, their effects on the mice appear to be neutral.

Because environmental factors are likely to differ from one place to another, natural selection can contribute to geographic variation. For example, one population of our hypothetical wildflower species might have a higher frequency of C^W alleles than other populations because local pollinators prefer white flowers. Genetic drift can also produce allele frequency differences between populations through the cumulative effect of random fluctuations in frequencies rather than natural selection.

Some examples of geographic variation occur as acline, a graded change in a trait along a geographic axis. In some cases, a cline may represent a graded region of overlap where individuals of neighboring populations are interbreeding. In other cases, a gradation in some environmental variable may produce a cline. For example, the average body size of many North American species of birds and mammals increases gradually with increasing latitude. Presumably, the reduced ratio of surface area to volume that accompanies larger size is an

adaptation that helps animals conserve body heat in cold environments. Experimental studies of many clines have confirmed that both genetic variation and environment play a role in the geographic differences of phenotype (Figure 23.11).

A Closer Look at Natural Selection

From the range of available variations in a population, natural selection increases the frequencies of certain genotypes, fitting organisms to their environment over generations. This section takes a closer look at natural selection as a mechanism of evolutionary adaptation.

Evolutionary Fitness

The phrases "struggle for existence" and "survival of the fittest" are commonly used to describe natural selection, yet these expressions are misleading if taken to mean direct competitive contests among individuals. There are animal species in which individuals, usually the males, lock horns or otherwise do combat to determine mating privilege. But reproductive success is generally subtler and depends on many factors besides outright battles for mates. For example, a barnacle may produce more eggs than its neighbors because it is more efficient at collecting food from the water. A moth may have more offspring than other moths in the same population because its body colors more effectively conceal it from predators. Wildflowers may differ in reproductive success because some attract more pollinators owing to slight variations in color, shape, or fragrance. These are all examples of adaptive advantage, and they are all components of what we call fitness: the contribution an individual makes to the gene pool of the next generation, relative to the contributions of other individuals.

In a more quantitative approach to natural selection, population geneticists define relative fitness as the contribution of a genotype to the next generation compared to the contributions of alternative genotypes for the same locus. Consider our wildflower population once again. Let's assume that, on average, individuals with red flowers produce fewer offspring than those with white or pink flowers, which produce equal numbers of offspring. The relative fitness of the most reproductively successful variants is set at 1 as a basis for comparison, so the relative fitness of a white-flowered or pink-flowered plant is 1. If plants with red flowers average only 80% as many offspring, their relative fitness is 0.8.

Although population geneticists often refer to the relative fitness of a genotype, it is important to remember that natural selection acts on phenotypes, not genotypes. The entity that is subjected to natural selection is the whole organism. Thus, the relative fitness of a particular allele depends on the entire genetic and environmental context in which it is expressed. For example, alleles that enhance the growth of a tree's trunk and limbs may be useless or even detrimental in the absence of alleles at other loci that enhance the growth of roots necessary

Figure 23.11

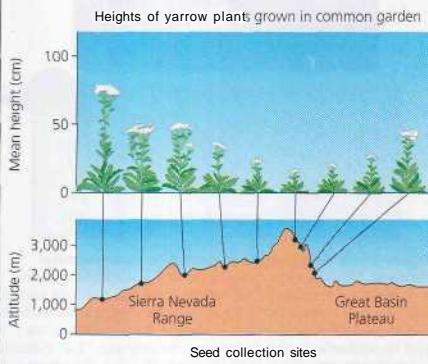

Inquiry Does geographic variation in yarrow plants have a genetic component?

EXPERIMENT

Researchers observed that the average size of yarrow plants (*Achillea*) growing on the slopes of the Sierra Nevada mountains gradually decreases with increasing elevation. To eliminate the effect of environmental differences at different elevations, researchers collected seeds from various altitudes and planted them in a common garden. They then measured the heights of the resulting plants.

RESULTS

The average plant sizes in the common garden were inversely correlated with the altitudes at which the seeds were collected, although the height differences were less than in the plants' natural environments.

CONCLUSION

The lesser but still measurable clinal variation in yarrow plants grown at a common elevation demonstrates the role of genetic as well as environmental differences.

to support the tree. On the other hand, alleles or other pieces of DNA that contribute nothing to an organism's success (or that may even be slightly maladaptive) may be perpetuated in individuals whose overall fitness is high. In this way, thousands of pieces of old retroviruses and transposable elements have accumulated and continue to accumulate in our genomes. These functionless bits of DNA are carried along from one generation to the next because they do no harm.

Survival alone does not guarantee reproductive success. Relative fitness is zero for a sterile plant or animal, even if it is robust and outlives other members of the population. But survival is necessary for reproduction, and longevity increases fitness if it means that long-lived individuals leave more descendants than those that die sooner. On the other hand, an individual that matures quickly and becomes fertile at an early age even if it only lives for a short time, may have more offspring than an individual that lives longer but matures late. Thus, many factors affect both survival and fertility and contribute to evolutionary fitness.

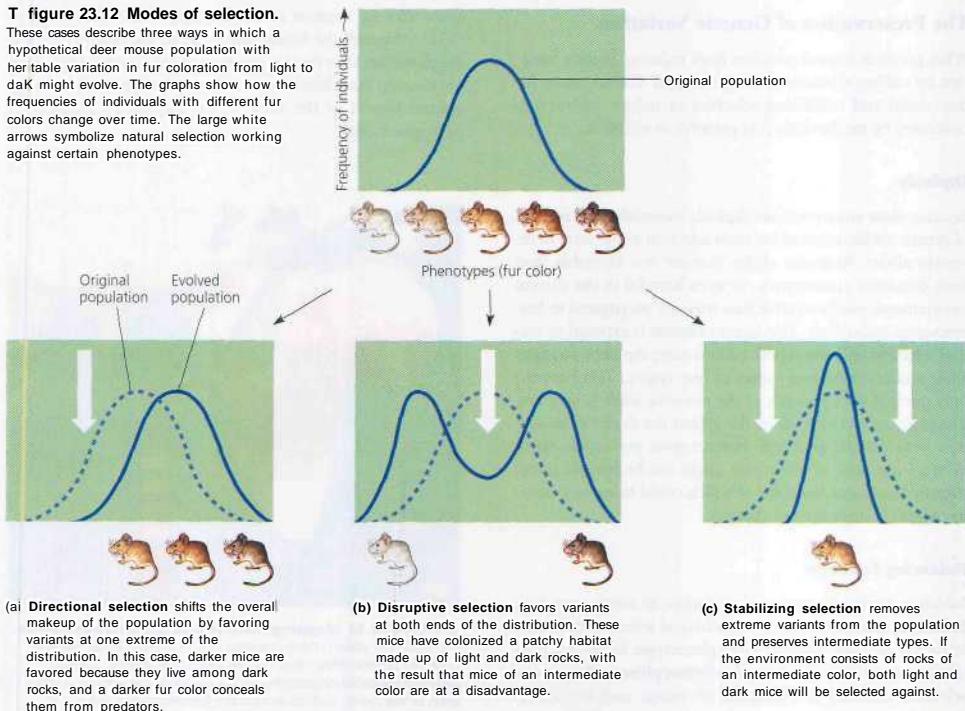

Directional, Disruptive, and Stabilizing Selection

Natural selection can alter the frequency distribution of heritable traits in three ways, depending on which phenotypes in a population are favored. These three modes of selection are called directional selection, disruptive selection, and stabilizing selection.

Directional selection (Figure 23.12a) is most common when a population's environment changes or when members of a population migrate to a new habitat with different environmental conditions than their former one. Directional selection shifts the frequency curve for some phenotypic character in one direction or the other by favoring individuals that deviate from the average. For instance, fossil evidence indicates that the average size of black bears in Europe increased with each glacial period, only to decrease again during the warmer interglacial periods. Larger bears, with a smaller surface-to-volume ratio, are better at conserving body heat and surviving periods of extreme cold.

T figure 23.12 Modes of selection.

These cases describe three ways in which a hypothetical deer mouse population with heritable variation in fur coloration from light to dark might evolve. The graphs show how the frequencies of individuals with different fur colors change over time. The large white arrows symbolize natural selection working against certain phenotypes.

Disruptive selection (Figure 23.12b) occurs when environmental conditions favor individuals on both extremes of a phenotypic range over intermediate phenotypes. For example, a population of black-bellied seedcracker finches in Cameroon displays two distinctly different beak sizes. Small-billed individuals feed mainly on soft seeds, whereas large-billed birds specialize in cracking hard seeds. It appears that birds with intermediate-sized bills are relatively inefficient at cracking both types of seeds, and thus have lower relative fitness. As you will read in the next chapter, disruptive selection can be important in the early stages of speciation.

Stabilizing selection (Figure 23.12c) acts against extreme phenotypes and favors intermediate variants. This mode of selection reduces variation and maintains the status quo for a particular phenotypic character. For example, the birth weights of most human babies lie in the range of 3–4 kg; babies who are much smaller or larger suffer higher rates of mortality.

Regardless of the mode of selection, however, the basic mechanism remains the same. Selection favors certain heritable traits through differential reproductive success.

The Preservation of Genetic Variation

What prevents natural selection from reducing genetic variation by culling all unfavorable genotypes? The tendency for directional and stabilizing selection to reduce variation is countered by mechanisms that preserve or restore it.

Diploidy

Because most eukaryotes are diploid, a considerable amount of genetic variation is hidden from selection in the form of recessive alleles. Recessive alleles that are less favorable than their dominant counterparts, or even harmful in the current environment, can persist because they are propagated in heterozygous individuals. This latent variation is exposed to natural selection only when both parents carry the same recessive allele and combine two copies in one zygote. This happens only rarely if the frequency of the recessive allele is very low. The rarer the recessive allele, the greater the degree of protection from natural selection. Heterozygote protection maintains a huge pool of alleles that might not be favored under present conditions but some of which could bring new benefits when the environment changes.

Balancing Selection

Selection itself may preserve variation at some gene loci. Balancing selection occurs when natural selection maintains stable frequencies of two or more phenotypic forms in a population, a state called balanced polymorphism. This type of selection includes heterozygote advantage and frequency-dependent selection.

Heterozygote Advantage, if individuals who are heterozygous at a particular gene locus have greater fitness than the homozygotes, natural selection will tend to maintain two or more alleles at that locus. An example of this heterozygote advantage occurs at the locus in humans that codes for one of the peptide subunits in hemoglobin, the oxygen-carrying protein of red blood cells. In homozygous individuals, a recessive allele at that locus causes sickle-cell disease (see Figures 5.21 and 17.23). However, heterozygotes are protected against the severest effects of malaria (although they are not resistant to malarial infection). This protection is an important advantage in tropical regions where malaria is a major killer. The environment in these areas favors heterozygotes over homozygous dominant individuals, who are more susceptible to malaria, and also over homozygous recessive individuals, who develop sickle-cell disease. The frequency of the sickle-cell allele in Africa is generally highest in areas where the malaria parasite is most common (Figure 23.13). In some tribes, it accounts for 20% of the hemoglobin alleles in the gene pool, a very high frequency for such a harmful allele. But even at this high frequency ($q = 0.2$), only 4% of the population suffers from sickle-cell disease ($q^2 = 0.04$). There are far more heterozygotes who are resistant to malaria ($2pq = 2 \times 0.8 \times 0.2 = 0.32$). Although the fitness advantage to the heterozygotes is much smaller than the disadvantage to the homozygotes, there are so many more heterozygotes than homozygotes that the aggregate benefit of the allele in the population *balances* its aggregate harm.

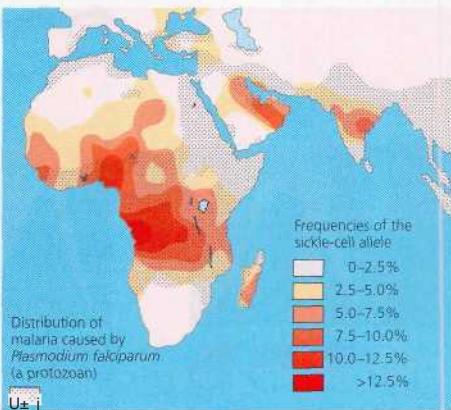

Figure 23.13 Mapping malaria and the sickle-cell allele. The sickle-cell allele is most common in Africa, but it is not the only balanced polymorphism that confers protection against malaria. Different balanced polymorphisms are found in populations in other parts of the world, such as around the Mediterranean Sea and in Southeast Asia, where malaria is widespread.

Figure 23.14

Research Meilheci Using a Virtual Population to Study the Effects of Selection

APPLICATION

Using virtual organisms that can "reproduce" and pass on characteristics to their offspring, biologists can model the effects of selection over many generations in a compressed period

of time. This method also enables researchers to isolate the effect of the study variable by controlling for other influences on the population's evolution—a nearly impossible goal in nature.

TECHNIQUE

Studies involving virtual populations are most meaningful when based on a natural system. For example, Alan Bond and Alan Kamil of the University of Nebraska created a "virtual ecology" based on the well-studied predator-prey relationship between the North American blue jay and the woodland moth. First, the researchers converted gray-scale photographs of moths into digital moths. The wing patterns were determined by a complex computerized genome based on real moth genetics, including polygenic inheritance, crossing-over events, and mutation. These moths can be "mated" and the genotypes and phenotypes of the offspring determined by various mathematical models.

Bond and Kamil trained captive blue jays to "hunt" digital moths displayed against patterned backgrounds, as the birds would hunt moths hidden on tree trunks in the wild. To model the effects of blue jay predation on the moth population, the researchers presented each moth to a jay and measured the detection time (or lack of detection). The researchers used a statistical model to calculate each moth's likelihood of breeding, producing the next generation of potential prey. They repeated this process for 100 generations each for the

experimental group (exposed to frequency-dependent selection by jays) and two control groups. In one control (no selection by jays), the researchers randomly recombined the genotypes in each generation. In the other control (frequency-independent selection), jays selected moths, but a computer program eliminated the "search image" effect.

On pecking a moth image the blue jay receives a food reward. If the bird does not detect a moth on either screen, it pecks the green circle to continue to a new set of images (a new feeding opportunity).

RESEARCHERS' PERSPECTIVE Using a virtual prey population enabled the researchers to model the long-term evolutionary impact of selection

Parental population sample

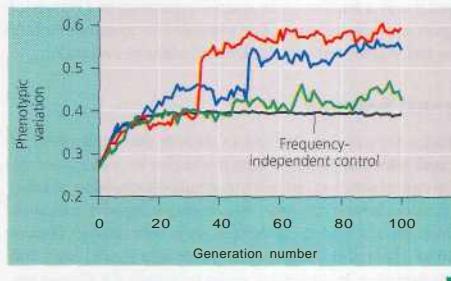

Experimental group sample

Plain background

Patterned background

by real predators. In this study, the experimental moth population became more difficult to detect against the patterned backgrounds compared to the nonselected control (as did the frequency-independent control). But as shown in the graph below, in three trials, the experimental group (colored lines) showed much greater phenotypic variation than the frequency-independent control group (black line). This result supports Bond and Kamit's hypothesis that frequency-dependent selection by visual predators promotes polymorphism in a prey population.

Frequency-Dependent Selection. In frequency-dependent selection, the fitness of any one morph declines if it becomes too common in the population. **Figure 23.14** illustrates an experiment that simulates frequency-dependent selection. In the wild, blue jays locate and eat moths that sit motionless on tree trunks during the day. Captive jays can be trained to find virtual prey on a computer screen. These jays were presented with a series of screens that showed a speckled background,

sometimes including an image of a moth. When a jay pecked at a moth image, it was rewarded with a small piece of food. The jays soon learned a "search image"—a quick way to recognize the most common type of moth. As their skill grew, the computer program adjusted the frequencies of the virtual prey, making the common type rare and formerly rare types common, just as natural selection would do. The researchers also programmed "mutations" that introduced new moth patterns.

Whenever a type of moth became common, the jays rapidly learned a new search image and targeted it. Frequency-dependent selection preserved polymorphism in this population: Rare moths of any pattern were at an advantage and common moths of any pattern were at a disadvantage because the jays learned to find the common moths more easily than the rare ones. Similar frequency-dependent selection has been observed in a number of predator-prey interactions in the wild.

Neutral Variation

Some of the genetic variation in populations probably has little or no impact on reproductive success, and thus natural selection does not affect these alleles. For example, most of the DNA base differences between humans that are found in untranslated parts of the genome appear to confer no selective advantage and therefore are considered neutral variation. And in pseudogenes, genes that have become inactivated by mutations, genetic "noise" is free to accumulate in all parts of the gene. The relative frequencies of neutral variations are not affected by natural selection; over time, some neutral alleles increase in frequency and others decrease through genetic drift. Even mutational changes that alter proteins can be neutral. For example, data from *Drosophila* suggest that roughly half of the amino-acid-changing mutations that arise and subsequently become fixed have no selective effect—that is, they do not affect protein function.

Of course, it is possible that genetic differences that appear to be neutral may actually influence survival and reproductive success in ways that are difficult to measure. Furthermore, a variant allele may be neutral in one environment but not in another. The debate over the extent of neutral variation continues (as you will read further in Chapter 25), but one thing is clear: Even if only a fraction of the extensive variation in a gene pool significantly affects fitness, that is still an enormous reservoir of raw material for natural selection and adaptive evolution.

Sexual Selection

Charles Darwin was the first to explore the implications of sexual selection, which is natural selection for mating success. This type of selection can result in sexual dimorphism, marked differences between the sexes in secondary sexual characteristics, which are not directly associated with reproduction (**Figure 23.15**). These distinctions include differences in size, color and ornamentation. In vertebrates, males are usually the showier sex.

It is important to distinguish between intrasexual and intersexual selection. Intrasexual selection, meaning selection "within the same sex" is a direct competition among individuals of one sex for mates of the opposite sex. Intrasexual selection is usually most obvious in males. For example, in many species a single male patrols a group of females and prevents other males from mating with them. The patrolling male may defend his status by defeating smaller, weaker, or less fierce males in combat; more often, he is the psychological

A Figure 23.15 Sexual dimorphism and sexual selection. Peacocks and peahens show extreme sexual dimorphism. There is intrasexual selection between competing males followed by intersexual selection when the females choose among the showiest males.

victor in ritualized displays that discourage would-be competitors but do not risk **injury** that would reduce his own fitness (see Chapter 51). But evidence is growing that intrasexual selection can take place between females as well. In ring-tailed lemurs, for example, females dominate males and also establish hierarchies of dominance among themselves.

In intersexual selection, also called mate choice, individuals of one sex (usually females) are choosy in selecting their mates from the other sex. In many cases, the female's choice depends on the showiness of the male's appearance or behavior (see Figure 23.15). However, because females have fewer chances to mate than males, a female only gains an advantage over other females if she chooses a mate that enables her to produce more fit offspring.

What intrigued Darwin about mate choice is that some of the male showiness does not seem to be adaptive in any other way and may in fact pose some risk. For example, bright plumage may make male birds more visible to predators. But if such secondary sexual characteristics help a male gain a mate, and this benefit outweighs the risk from predation, then both the bright plumage and the female preference for it will be reinforced for the most Darwinian of reasons—because they enhance reproductive success. Every time a female chooses a mate based on a certain appearance or behavior, she perpetuates the alleles that influenced her to make that choice, allowing a male with an especially showy phenotype to pass on his alleles to offspring.

How do female preferences for certain male characteristics evolve? Could there be fitness benefits to showy traits? Several researchers are testing the hypothesis that these sexual advertisements reflect overall health. For example, male birds with serious parasitic infections may have dull, disheveled plumage. They don't usually win many females. If the female chooses a showy male, she may be choosing a healthy one as well, and the benefit will be a greater chance of healthy offspring.

The Evolutionary Enigma of Sexual Reproduction

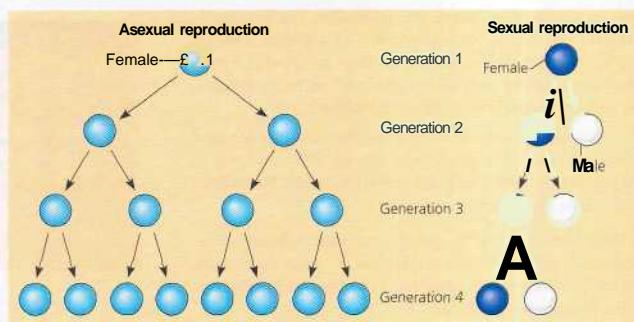

Ever as biologists study the mechanisms of sexual selection, they continue to wonder about the evolution of sex itself. As a mechanism of rapid population expansion, it is far inferior to asexual reproduction. Consider, for example, a population of insects in which half the females reproduce only sexually and half reproduce only asexually. Even if both types of females produced the same number of offspring each generation, the asexual condition would increase in frequency because all of the females' offspring would be daughters that are able to give

birth to more reproductive daughters in turn. In contrast, half of the sexual females' offspring would be males, which would be required for reproduction but would themselves be unable to give birth. **Figure 23.16** diagrams this "reproductive handicap" of sex.

Nonetheless, sex is maintained in the vast majority of eukaryotic species, even in those that can also reproduce asexually. It must enhance reproductive success somehow, for otherwise natural selection would act in favor of asexual reproduction. But what advantage does sex provide?

One explanation is that the processes of meiotic recombination and fertilization generate the genetic variation on which natural selection acts. The assumption is that natural selection sustains sex, in spite of its reproductive drawbacks, because genetic variation enables future adaptation to an ever-changing environment. But this assumption is difficult to defend. Natural selection always acts in the here and now, favoring the success of those individuals that reproduce best in the current environment.

So instead, consider how the genetic variation that results from sex might benefit sexually reproducing individuals over the short term—on a generation-to-generation time scale. One hypothesis emphasizes the importance of genetic variation in resistance to disease. Many bacterial and viral pathogens recognize and infect a host by attaching to receptor molecules on the host's cells. There should be an advantage in producing offspring that vary in their resistance to different diseases. For example, one offspring may have cellular markers that make it resistant to virus A, while another may be resistant to virus B. This hypothesis predicts that gene loci that code for the receptors to which pathogens attach should have many alleles. And that seems to be the case. In humans, for example, there are hundreds of alleles for each of two gene loci coding for the proteins that give cell surfaces their molecular fingerprints (you'll read more about these cellular markers in Chapter 43). Of course, because most pathogens evolve rapidly in their ability to key on specific host receptors, resistance of a particular genotype to a given disease is not permanent. But sex provides a mechanism for "changing the locks" and varying them among offspring.

A Figure 23.16 The "reproductive handicap" of sex. These diagrams contrast the reproductive output of females (blue circles) over four generations for asexual versus sexual reproduction. The scenarios assume two surviving offspring per female. The asexual population rapidly outgrows the sexual one.

Such an example of coevolution, in which host and parasite must evolve quickly to keep up with each other, is sometimes described as a "Red Queen race," after the Red Queen in Lewis Carroll's *Through the Looking Glass*, who advised Alice to run as fast as she could just to stay in the same place.

Why Natural Selection Cannot Fashion Perfect Organisms

As we noted in Chapter 22, nature abounds with examples of organisms that seem to be less than ideally "engineered" for their lifestyles, for several reasons.

f. Evolution is limited by historical constraints. Each species has a legacy of descent with modification from a long line of ancestral forms. Evolution does not scrap ancestral anatomy and build each new complex structure from scratch; it co-opts existing structures and adapts them to new situations. For example, we could imagine how some bird species might benefit by having wings for flight as well as *four* legs for speedy, maneuverable running, instead of just two legs. But birds descended from reptiles that had only two pairs of limbs, and co-opting the forelimbs for flight left only the two hind limbs for moving around on the ground.

2. Adaptations are often compromises. Each organism must do many different things. A seal spends part of its time on rocks; it could probably walk better if it had legs instead of flippers, but it would not swim nearly as well. We humans owe much of our versatility and athleticism to our prehensile hands and flexible limbs, which also make us prone to sprains, torn ligaments, and dislocations. Structural reinforcement has been compromised for agility.

3. Chance and natural selection interact. Chance events affect the subsequent evolutionary history of populations. For instance, when a storm blows insects or birds hundreds of miles

over an ocean to an island, the wind does not necessarily transport the species, or the members of a species, that are best suited to the new environment. Thus, not all alkies present in the founding population's gene pool are better suited to the new environment than alleles "left behind."

4. *Selection can only edit existing variations.* Natural selection favors only the fittest phenotypes among those currently in the population, which may not be the ideal traits. New alleles do not arise on demand.

With these constraints, evolution cannot craft perfect organisms. Natural selection operates on a "better than" basis. We can see evidence for evolution in the many imperfections of the organisms it produces.

Concept Check 23.4

1. Does nucleotide variability in a population always correspond to phenotypic polymorphism? Why or why not?
2. What is the relative fitness of a sterile mule? Explain.
3. How does sexual selection lead to sexual dimorphism?
4. Explain what is meant by the "reproductive handicap" of sex.

For suggested answers, see Appendix A.

Chapter 23 Review

SUMMARY OF KEY CONCEPTS

Concept 23.1

Population genetics provides a foundation for studying evolution

- **The Modern Synthesis** (p. 455) The modern synthesis integrates Mendelian genetics with the Darwinian theory of evolution by natural selection and focuses on populations as the basic unit of evolution.
- **Gene Pools and Allele Frequencies** (pp. 455–456) A population, a localized group of organisms that all belong to the same species, is united by its gene pool, the aggregate of all alleles in the population.
- **The Hardy-Weinberg Theorem** (pp. 456–458) The Hardy-Weinberg theorem states that the frequencies of alleles and genotypes in a population will remain constant if Mendelian segregation and random mating are the only processes that affect the gene pool. If p and q represent the relative frequencies of the only two possible alleles at a particular locus, then $p^2 + 2pq + q^2 = 1$, where p^2 and q^2 are the frequencies of the homozygous genotypes and $2pq$ is the frequency of the heterozygous genotype. Although many populations approximate Hardy-Weinberg equilibrium, the equilibrium in its strictest sense applies only if the population is large, mating is random, mutation is negligible, there is no gene flow from other populations, and all individuals have equal reproductive success.

Investigation *How Can Frequency of Alleles Be Calculated?*

Concept 23.2

Mutation and sexual recombination produce the variation that makes evolution possible

- **Mutation** (pp. 459–460) New genes and new alleles originate only by mutation. Most mutations have no effect or are harmful, but a few increase adaptation.
- **Sexual Recombination** (p. 460) Genetic recombination between sexually reproducing organisms produces most of the variation in traits that makes adaptation possible.

Activity *Genetic Variation from Sexual Recombination*

Concept 23.3

Natural selection, genetic drift, and gene flow can alter a population's genetic composition

- **Natural Selection** (p. 460) Differential success in reproduction results in certain alleles being passed to the next generation in greater proportions than others.
- **Genetic Drift** (pp. 460–462) Chance fluctuations in allele frequencies from generation to generation tend to reduce genetic variation in populations.
- **Gene Flow** (p. 462) Genetic exchange between populations tends to reduce differences between populations over time. *Biology Labs On-Line Population Genetics Lab Activity Causes of Evolutionary Change*

Concept 23.4

Natural selection is the primary mechanism of adaptive evolution

- **Genetic Variation** (pp. 462–464) Genetic variation includes variation among individuals within a population in discrete and quantitative characters, as well as geographic variation between populations.
- **A Closer Look at Natural Selection** (pp. 464–466) One organism has a greater relative fitness than another if it leaves more descendants. Selection favors certain genotypes in a population by acting on the phenotypes of individual organisms. Natural selection can favor relatively rare individuals at one end of the phenotype range (directional selection), can favor individuals at both extremes of the range rather than intermediate phenotypes (disruptive selection), or can act against extreme phenotypes (stabilizing selection).
- **The Preservation of Genetic Variation** (pp. 466–468) Diploidy maintains a reservoir of concealed recessive variation in heterozygotes. Balanced polymorphism may maintain variation at some gene loci as a result of heterozygote advantage or frequency-dependent selection.
- **Sexual Selection** (p. 468) Sexual selection leads to the evolution of secondary sex characteristics, which can give individuals an advantage in mating.
- **The Evolutionary Enigma of Sexual Reproduction** (p. 469) Enhanced disease resistance based on genetic variation is one possible explanation for the persistence of sexual reproduction despite its lesser reproductive output compared to asexual reproduction.

► Why Natural Selection Cannot Fashion Perfect

Organisms (pp. 469-470) Structures result from modified ancestral anatomy; adaptations are often compromises; the gene pool can be affected by genetic drift; and natural selection can act only on available variation.

TESTING YOUR KNOWLEDGE

Evolution Connection

How is the process of evolution revealed by the imperfections of living organisms?

Scientific Inquiry

In the population of wildflowers we used to test the Hardy-Weinberg theorem, the frequency of C^R is 0.8 and the frequency of C^W is 0.2. In a different population of these flowers, the frequencies of genotypes do not conform to Hardy-Weinberg equilibrium: 60% of the plants are $C^R C^R$ and 40% are $C^W C^W$. Assuming that all Hardy-Weinberg conditions are met, show that genotypes will reach equilibrium in the next generation. Suppose instead that the plants mate only with themselves (self-fertilize). What will the allele and genotype frequencies be in the next generation?

The Origin of Species

A. **Figure 24.1** The flightless cormorant (*Nannopterum harrisi*), one of many new species that have originated on the isolated Galápagos Islands.

Key Concepts

- 24.1 The biological species concept emphasizes reproductive isolation
- 24.2 Speciation can take place with or without geographic separation
- 24.3 Macroevolutionary changes can accumulate through many speciation events

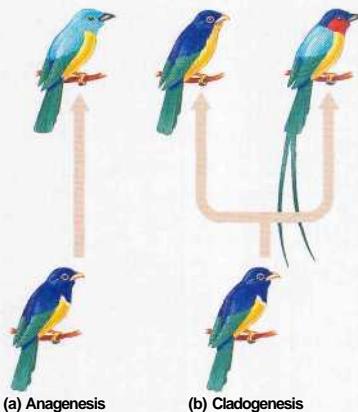

Overview

That "Mystery of Mysteries"

Darwin came to the Galápagos Islands eager to explore landforms newly emerged from the sea. He noted that these volcanic islands, despite their geologic youth, were filled with plants and animals known nowhere else in the world, and later realized that these species, like the islands, were new (Figure 24.1). He wrote in his diary: "Both in space and time, we seem to be brought somewhat near to that great fact—that mystery of mysteries—the first appearance of new beings on this Earth."

The origin of new species, or **speciation**, is at the focal point of evolutionary theory, because the appearance of new species is the source of biological diversity. It is not enough to explain how adaptations evolve in a population (the topic covered in Chapter 23; such changes, confined to a single gene pool, are described as **microevolution**). Evolutionary theory must also explain how new species originate and develop through the subdivision and subsequent divergence of gene pools. The fossil record reveals the cumulative effects of speciation over vast tracts of time. The term **macroevolution** refers to such evolutionary change above the species level—for example, the appearance of feathers during the evolution of birds from one group of dinosaurs, and other such "evolutionary novelties" that can be used to define higher taxa.

We can distinguish two basic patterns of evolutionary change: anagenesis and cladogenesis (Figure 24.2). Anagenesis (from the Greek *ana*, new, and *genos*, race), also called phyletic evolution, is the accumulation of changes that gradually transform a given species into a species with different characteristics. Cladogenesis (from the Greek *klados*, branch), also called branching evolution, is the splitting of a gene pool into two or more separate pools, which each give rise to one or more new species. Only cladogenesis can promote biological diversity by increasing the number of species.

A **Figure 24.2** Two patterns of evolutionary change. (a) Anagenesis is the accumulation of heritable changes, altering the characteristics of a species. (b) Cladogenesis is branching evolution, in which a new species arises from a population that buds from a parent species. (Note that the "parent" species may change as well.) Cladogenesis is the basis for biological diversity.

In this chapter, we will explore the mechanisms by which species arise. We will also examine the possible origins of some novel features that define higher taxonomic groups. But first, let's consider what we really mean when we refer to a "species."

Concept 24.1

The biological species concept emphasizes reproductive isolation

Species is a Latin word meaning "kind" or "appearance." We distinguish between various "kinds" of plants or animals—between dogs and cats, for instance—from differences in their appearance. But are organisms truly divided into the discrete units we call species, or is this classification an arbitrary attempt to impose order on the natural world? To answer this question, biologists have compared not only the morphology (body form) of different groups of organisms but also less obvious differences in physiology, biochemistry, and DNA sequences. The results generally confirm that morphologically distinct species are indeed discrete groups, with many differences in addition to morphological ones.

The Biological Species Concept

The primary definition of species used most frequently in this textbook was proposed in 1942 by biologist Ernst Mayr. This biological species concept defines a species as a population or group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring, but are unable to produce viable, fertile offspring with members of other populations (**Figure 24.3**). In other words, the members of a biological species are united by being reproductively compatible, at least potentially. All humans, for example, belong to the same biological species. A businesswoman in Manhattan may be unlikely to meet a dairy farmer in Mongolia, but if the two should happen to get together, they could have viable babies that develop into fertile adults. In contrast, humans and chimpanzees remain distinct biological species even where they share territory, because many factors keep them from interbreeding and producing fertile offspring.

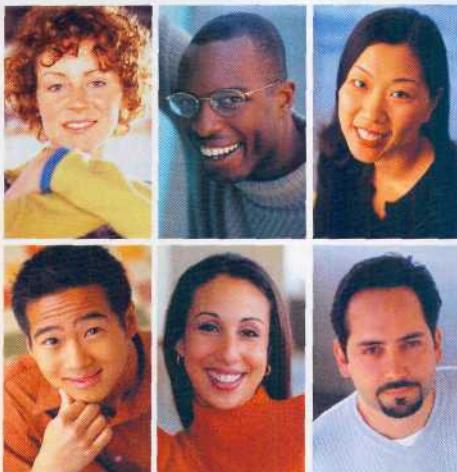

Reproductive Isolation

Because biological species are distinguished based on reproductive incompatibility, the concept hinges on reproductive isolation—the existence of biological factors (barriers) that impede members of two species from producing viable, fertile hybrids. Although a single barrier may not block all genetic exchange between species, a combination of several barriers can effectively isolate a species' gene pool.

Clearly, a fly cannot mate with a frog or a fern, but the reproductive barriers between more closely related species are

(a) Similarity between different species. The eastern meadowlark (*Sturnella magna*, left) and the western meadowlark (*Sturnella neglecta*, right) have similar body shapes and colorations. Nevertheless, they are distinct biological species because their songs and other behaviors are different enough to prevent interbreeding should they meet in the wild.

(b) Diversity within a species. As diverse as we may be in appearance, all humans belong to a single biological species (*Homo sapiens*), defined by our capacity to interbreed.

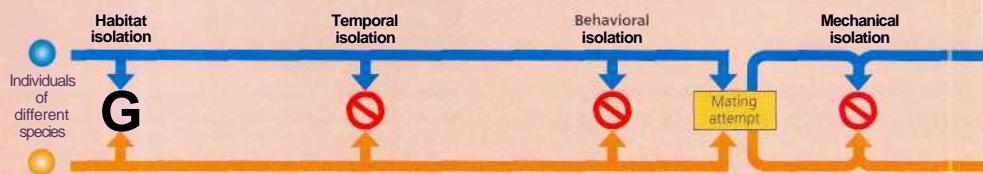

A Figure 24.3 The biological species concept is based on the potential to interbreed rather than on physical similarity.

not so obvious. These barriers can be classified according to whether they contribute to reproductive isolation before or after fertilization. Prezygotic barriers ("before the zygote") impede mating between species or hinder the fertilization of ova if members of different species attempt to mate. If a sperm cell from one species does overcome prezygotic barriers and fertilizes an ovum from another species, postzygotic barriers ("after the zygote") often prevent the hybrid zygote from developing into a viable, fertile adult. **Figure 24.4**, on the next two pages, describes various prezygotic and postzygotic barriers.

Figure 24.4

Exploring | Reproductive Barriers

Prezygotic barriers impede mating or hinder fertilization if mating does occur

HABITAT ISOLATION

Two species that occupy different habitats within the same area may encounter each other rarely, if at all, even though they are not isolated by obvious physical barriers such as mountain ranges.

Example: Two species of garter snakes in the genus *Thamnophis* occur in the same arid, riparian areas, but one lives mainly in water (a) while the other is primarily terrestrial (b).

(a)

TEMPORAL ISOLATION

Species that breed during different times of the day, different seasons, or different years cannot mix their gametes.

Example: In North America, the geographic ranges of the eastern spotted skunk (*Spilogale putorius*) (c) and the western spotted skunk (*Spilogale occidentalis*) (d) overlap, but *S. putorius* mates in late winter and *S. gracilis* mates in late summer.

(c)

(d)

BEHAVIORAL ISOLATION

Courtship rituals that attract mates and other behaviors unique to a species are effective reproductive barriers, even between closely related species.

Example: Blue-footed boobies, inhabitants of the Galapagos, mate only after a courtship display unique to their species. Part of the "script" calls for the male to high-step, a behavior that calls the female's attention to his bright blue feet (e).

(e)

(g)

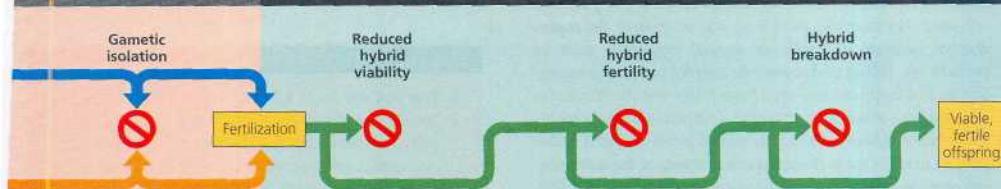

(f)

MECHANICAL ISOLATION

Morphological differences can prevent successful mating.

Example: Even in closely related species of plants, the flowers often have distinct appearances that attract different pollinators. These two species of monkey flower (*Mimulus*) differ greatly in the shapes and colors of their blossoms (f, g). Thus, cross-pollination between the plants does not occur.

Postzygotic barriers prevent a hybrid zygote from developing into a viable, fertile adult

GAMETIC ISOLATION

Sperm of one species may not be able to fertilize the eggs of other species. Many mechanisms can produce this isolation. For instance, sperm, may not be able to survive in the reproductive tract of females of the other species, or biochemical mechanisms may prevent the sperm from penetrating the membrane surrounding the other species' eggs.

Example: Gametic isolation separates certain closely related species? of aquatic animals such as sea urchins (h). The sea urchins release their sperm and eggs into the surrounding water, where they fuse and form zygotes. Gametes of different species, like the red and purple urchins shown here, are unable to fuse.

(h)

REDUCED HYBRID VIABILITY

The genes of different parent species may interact, and impair the hybrid's development.

Example: Some salamander subspecies of the genus *Ensatina* live in the same regions and habitats, where they may occasionally hybridize. But most of the hybrids do not complete development, and those that do are frail (i).

(i)

REDUCED HYBRID FERTILITY

Even if hybrids are vigorous, they may be sterile. If chromosomes of the two parent species differ in number or structure, meiosis in the hybrids may fail to produce normal gametes. Since the "infertile hybrid" cannot produce offspring when they mate with either parental species, genes cannot flow freely between the species.

Example: The hybrid offspring of a donkey (j) and a horse (k), a mule (l), is robust but sterile.

(k)

(l)

HYBRID BREAKDOWN

Some first-generation hybrids are viable and fertile, but when they mate with one another or with either parent species, offspring of the next generation are feeble or sterile.

Example: Strains of cultivated rice have accumulated different mutant recessive alleles at two loci in the course of their divergence from a common ancestor. Hybrids between them are vigorous and fertile (m, left and right), but plants in the next generation that carry too many of these recessive alleles are small and sterile (m, center). Although these rice strains are not yet considered different species, they have already begun to be separated by postzygotic barriers.

(m)

Limitations of the Biological Species Concept

While the biological species concept's emphasis on reproductive isolation has greatly influenced evolutionary theory, the number of species to which this concept can be usefully applied is limited. For example, there is no way to evaluate the reproductive isolation of fossils or asexual organisms such as prokaryotes. (Many prokaryotes do transfer genes by conjugation and other processes—see Chapter 18—but this transfer is different from sexual recombination. Furthermore, genes are often transferred between distantly related prokaryotes.) It is also difficult to apply the biological species concept to the many sexual organisms about which little is known regarding their ability to mate with different kinds of organisms. For such reasons, alternative species concepts are useful in certain situations.

Other Definitions of Species

While the biological species concept emphasizes the *separateness* of species from one another due to reproductive barriers, several other definitions emphasize the *unity* within a species. For example, the morphological species concept characterizes a species by its body shape, size, and other structural features. The morphological species concept has advantages: It can be applied to asexual and sexual organisms, and it can be useful even without information on the extent of gene flow, in practice, this is how scientists distinguish most species. One disadvantage, however, is that this definition relies on subjective criteria; researchers may disagree on which structural features distinguish a species.

The paleontological species concept focuses on morphologically discrete species known only from the fossil record. We are forced to distinguish many species in this way because there is little or no information about their mating capability.

The ecological species concept views a species in terms of its ecological niche, its role in a biological community (see Chapter 53). For example, two species of Galapagos finches may be similar in appearance but distinguishable based on what they eat. Unlike the biological species concept, this definition can accommodate asexual as well as sexual species.

The phylogenetic species concept defines a species as a set of organisms with a unique genetic history—that is, as one branch on the tree of life. Biologists trace the phylogenetic history of a species by comparing its physical characteristics or its molecular sequences with those of other organisms. Such analysis can distinguish groups of individuals that are sufficiently different to be considered separate species. (Of course, the difficulty is in determining the degree of difference required to indicate separate species.) Phylogenetic information sometimes reveals the existence of "sibling species": species that appear so similar that they cannot be distinguished on morphological grounds. Scientists can then apply the biological species concept to determine if the phylogenetic distinction is confirmed by reproductive incompatibility.

The usefulness of each of these definitions depends on the situation and the questions we are asking. The biological species concept, with its focus on reproductive barriers, is particularly valuable for studying how species originate.

Concept Check 24.1

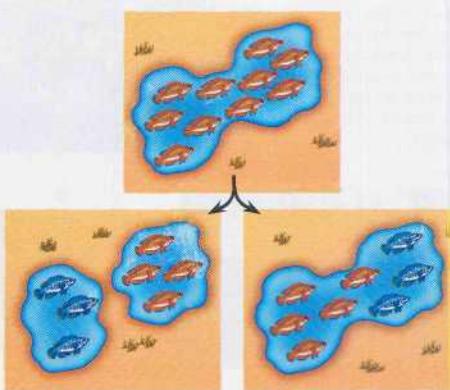

1. Two bird species in a forest are not known to interbreed. One species feeds and mates in the treetops and the other on the ground. But in captivity, the two species can interbreed and produce viable, fertile offspring. What type of reproductive barrier most likely keeps these species separate? Explain.
2. a. Which species concept can be used for both asexual and sexual species? b. Which can only be applied to sexual species? c. Which would be most useful for identifying species in the field?

For suggested answers, see Appendix A.

Concept 24.2

Speciation can take place with or without geographic separation

Speciation can occur in two main ways, depending on how gene flow between the populations is interrupted (Figure 24.5).

(a) Allopatric speciation. A population forms a new species while geographically isolated from its parent population.

(b) Sympatric speciation. A small population becomes a new species without geographic separation.

A Figure 24.5 Two main modes of speciation.

Allopatric ("Other Country") Speciation
