synapses on the same postsynaptic neuron can also add together, an effect called spatial summation (**Figure 48.18c**). Through spatial and temporal summation, several EPSPs can depolarize the membrane at the axon hillock to the threshold, causing the postsynaptic neuron to produce an action potential. Summation also applies to IPSPs: Two or more IPSPs occurring nearly simultaneously or in rapid succession have a larger hyperpolarizing effect than a single IPSP. Through summation, an IPSP can also counter the effect of an EPSP (**Figure 48.18d**).

This interplay between multiple excitatory and inhibitory inputs is the essence of integration in the nervous system. The axon hillock is the neuron's integrating center, the region where the membrane potential at any instant represents the summed effect of all EPSPs and IPSPs. Whenever the membrane potential at the axon hillock reaches the threshold, an action potential is generated and travels along the axon to its synaptic terminals. After the refractory⁷ period, the neuron may produce another action potential if the threshold is reached again at the axon hillock. On the other hand, the summed effect of EPSPs and IPSPs may hold the membrane potential below the threshold, preventing production of action potentials.

Indirect Synaptic Transmission

So far, we have focused on direct synaptic transmission, in which a neurotransmitter binds directly to an ion channel, causing the channel to open. In *indirect synaptic* transmission, a neurotransmitter binds to a receptor that is not part of an ion channel. This activates a signal transduction pathway involving

A Figure 48.18 Summation of postsynaptic potentials. These graphs trace changes in the membrane potential at a postsynaptic neuron's axon hillock. The arrows indicate times when postsynaptic potentials occur at two excitatory synapses E_1 and E_2 , green in the diagrams above the graphs) and at one inhibitory synapse (I , red). Like most EPSPs, those produced at E_1 or E_2 do not reach the threshold at the axon hillock without summation.

a second messenger in the postsynaptic cell (see Chapter 11). Compared to the postsynaptic potentials produced by direct synaptic transmission, the effects of indirect synaptic transmission have a slower onset but last longer (up to several minutes).

A variety of signal transduction pathways play a role in indirect synaptic transmission. One of the best-studied pathways involves cyclic AMP (cAMP) as a second messenger. For example, when the neurotransmitter norepinephrine binds to its receptor, the neurotransmitter-receptor complex activates a G protein, which in turn activates adenylyl cyclase, the enzyme that converts ATP to cAMP (see Chapter 11). Cyclic AMP activates protein kinase A, which phosphorylates specific channel proteins in the postsynaptic membrane, causing them to open or, in some cases, to close. Because of the amplifying effect of the signal transduction pathway, the binding of a neurotransmitter molecule to a single receptor can open or close many channels.

Neurotransmitters

Table 48.1 lists some of the major known neurotransmitters. Each neurotransmitter binds to its own group of receptors; some neurotransmitters have a dozen or more different recep-

tors, which can produce very different effects in postsynaptic cells. Drugs that target specific receptors are powerful tools in the treatment of nervous system diseases.

Acetylcholine

Acetylcholine is one of the most common neurotransmitters in both invertebrates and vertebrates. In the vertebrate CNS, it can be either inhibitory or excitatory, depending on the type of receptor. At the vertebrate neuromuscular junction, the synapse between a motor neuron and a skeletal muscle cell, acetylcholine released by the motor neuron binds to receptors on ligand-gated channels in the muscle cell, producing an EPSP via direct synaptic transmission. The drug nicotine binds to the same receptors, which are also found elsewhere in the PNS and at various sites in the CNS. Nicotine's physiological and psychological effects result from its affinity for this type of acetylcholine receptor. In vertebrate cardiac (heart) muscle, acetylcholine released by parasympathetic neurons (discussed later) activates a signal transduction pathway whose G proteins have two effects: inhibition of adenylyl cyclase and opening of K⁺ channels in the muscle cell membrane. Both effects reduce the strength and rate of contraction of cardiac muscle cells.

Table 48.1 Major Neurotransmitters

| Neurotransmitter | Structure | Functional Class | Secretion Sites |
|---|---|--|---|
| Acetylcholine | | Excitatory to vertebrate skeletal muscles; excitatory or inhibitory at other sites | CNS; PNS; vertebrate neuromuscular junction |
| Biogenic Amines | | | |
| Norepinephrine | | Excitatory or inhibitory | CNS; PNS |
| Dopamine | | Generally excitatory; may be inhibitory at some sites | CNS; PNS |
| Serotonin | | Generally inhibitory | CNS |
| Amino Acids | | | |
| GABA (gamma aminobutyric acid) | H ₂ N—CH ₂ —CH ₂ —COOH | Inhibitory | CNS; invertebrate neuromuscular junction |
| Glycine | H ₂ N—CH ₂ —COOH | Inhibitory | CNS |
| Glutamate | H ₂ N—CH ₂ —CH ₂ —COOH | Excitatory | CNS; invertebrate neuromuscular junction |
| Aspartate | H ₂ N—CH ₂ —CH ₂ —COOH | Excitatory | CNS |
| Neuropeptides (a very diverse group, only two of which are shown) | | | |
| Substance P | Arg—Pro—Lys—Pro—<In—Gin—Phe—Phe—Gly—Leu—Met | Excitatory | CNS; PNS |
| Met-enkephalin (an endorphin) | Tyr—Gly—Gly—Phe—Met | Generally inhibitory | CNS |

Biogenic Amines

Biogenic amines are neurotransmitters derived from amino acids. One group, known as catecholamines, consists of neurotransmitters produced from the amino acid tyrosine. This group includes epinephrine and norepinephrine, which also function as hormones (see Chapter 45), and a closely related compound called dopamine. Another biogenic amine, serotonin, is synthesized from the amino acid tryptophan. The biogenic amines are often involved in indirect synaptic transmission, most commonly in the CNS. However, norepinephrine also functions in a branch of the PNS called the autonomic nervous system, discussed in Concept 48.5.

Dopamine and serotonin are released at many sites in the brain and affect sleep, mood, attention, and learning. Imbalances of these neurotransmitters are associated with several disorders. For example, the degenerative illness Parkinson's disease is associated with a lack of dopamine in the brain (see Concept 48.7). Some psychoactive drugs, including LSD and mescaline, apparently produce their hallucinatory effects by binding to brain receptors for serotonin and dopamine. Depression is often treated with drugs that increase the brain concentrations of biogenic amines such as norepinephrine or serotonin. Prozac, for instance, elevates the concentration of serotonin by inhibiting its uptake after release.

Amino Acids and Peptides

Four amino acids are known to function as neurotransmitters in the CNS: gamma aminobutyric acid (GABA), glycine, glutamate, and aspartate. GABA, believed to be the neurotransmitter in most inhibitory synapses in the brain, produces EPSPs by increasing the permeability of the postsynaptic membrane to Cl^- . Several neuropeptides, relatively short chains of amino acids, serve as neurotransmitters. Most neurons release one or more neuropeptides as well as a nonpeptide neurotransmitter. Many neuropeptides are produced by post-translational modification of much larger protein precursors. For example, cleavage of the 267-amino-acid precursor proenkephalin yields four copies of the pentapeptide met-enkephalin as well as other peptides. In common with the biogenic amines, neuropeptides often operate via signal transduction pathways.

The neuropeptide substance P is a key excitatory neurotransmitter that mediates our perception of pain, while other neuropeptides, called endorphins, function as natural analgesics, decreasing pain perception. Neurochemists Candace Pert and Solomon Snyder, of Johns Hopkins University discovered endorphins in the 1970s when they found specific receptors for the opiates morphine and heroin on brain neurons. Further research showed that opiates bind to these receptors by mimicking endorphins (see Figure 2.17), which are produced in the brain during times of physical or emotional stress, such as childbirth. In addition to relieving pain,

endorphins also decrease urine output by stimulating ADH secretion (see Chapter 45), depress respiration, produce euphoria, and have other emotional effects. An endorphin released from the anterior pituitary gland as a hormone also affects specific regions of the brain, providing an example of the overlap between endocrine and nervous system control.

Gases

In common with many other types of cells, some neurons of the vertebrate PNS and CNS release dissolved gases, notably nitric oxide (NO; see Chapter 45) and carbon monoxide (CO), as local regulators. For example, during sexual arousal of human males, certain neurons release NO into the erectile tissue of the penis. In response, smooth muscle cells in the blood vessel walls of the erectile tissue relax, which causes the blood vessels to dilate and fill the spongy erectile tissue with blood, producing an erection. As you read in Chapter 45, the male impotence drug Viagra increases the ability to achieve and maintain an erection by inhibiting an enzyme that slows the muscle-relaxing effects of NO.

Carbon monoxide is synthesized by the enzyme heme oxygenase, one form of which is localized to certain populations of neurons in the brain and the PNS. In the brain, CO regulates the release of hypothalamic hormones. In the PNS, it acts as an inhibitory neurotransmitter that hyperpolarizes intestinal smooth muscle cells.

Unlike typical neurotransmitters, NO and CO are not stored in cytoplasmic vesicles; cells synthesize them on demand. These substances diffuse into neighboring target cells, produce a change, and are broken down—all within a few seconds. In many of its targets, including smooth muscle cells, NO works like many hormones, stimulating a membrane-bound enzyme to synthesize a second messenger that directly affects cellular metabolism.

In the rest of this chapter we will consider how the cellular and biochemical mechanisms we have discussed so far contribute to neural function on the system level.

Concept Check 48.4

1. Cone snails produce a toxin that blocks voltage-gated calcium channels. Which of the two main types of synapses would be most affected by the toxin? Why?
2. Organophosphate pesticides work by inhibiting acetylcholinesterase, the enzyme that breaks down the neurotransmitter acetylcholine. Explain how these toxins would affect EPSPs produced by acetylcholine.
3. How is it possible for a given neurotransmitter to produce opposite effects in different tissues?

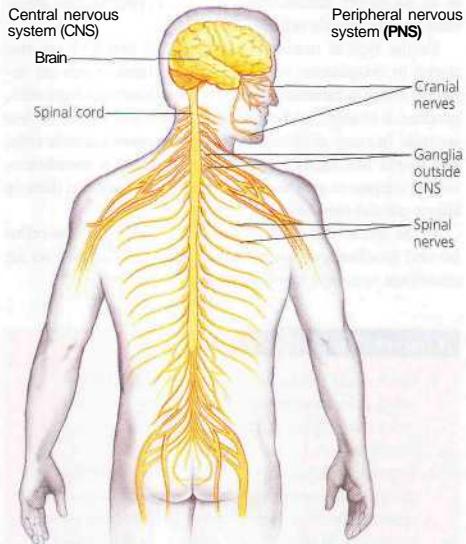

For suggested answers, see Appendix A.

Concept 48.5

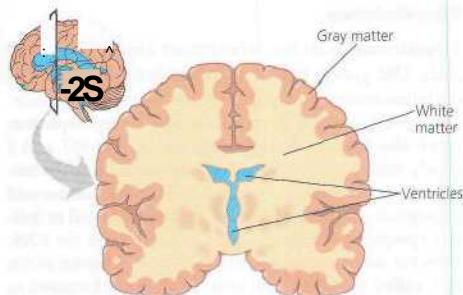

The vertebrate nervous system is regionally specialized

In all vertebrates, the nervous system shows cephalization and distinct CNS and PNS components (Figure 48.19). The brain provides the integrative power that underlies the complex behavior of vertebrates. The spinal cord, which runs lengthwise inside the vertebral column (spine), integrates simple responses to certain kinds of stimuli (such as the knee-jerk reflex) and conveys information to and from the brain. Unlike the ventral nerve cord of many invertebrates, the vertebrate spinal cord runs along the dorsal side of the body and does not contain segmental ganglia. However, there are segmental ganglia just outside the spinal cord (see Figures 48.2h and 48.19), and the arrangement of neurons within the spinal cord clearly shows an underlying segmental organization.

The vertebrate CNS is derived from the dorsal embryonic nerve cord, which is hollow—one of the phylogenetic hallmarks of chordates (see Chapter 34). In the adult, this feature persists as the narrow central canal of the spinal cord and the

A Figure 48.19 The vertebrate nervous system. The central nervous system consists of the brain and spinal cord. Cranial nerves, spinal nerves, and ganglia outside the central nervous system make up the peripheral nervous system.

A Figure 48.20 Ventricles, gray matter, and white matter. Ventricles deep in the interior of the brain contain cerebrospinal fluid. Most of the gray matter is on the surface of the brain, surrounding the white matter.

four ventricles of the brain (Figure 48.20). Both the central canal and the ventricles are filled with cerebrospinal fluid, which is formed in the brain by filtration of the blood. The cerebrospinal fluid circulates slowly through the central canal and ventricles and then drains into the veins, assisting in the supply of nutrients and hormones to different parts of the brain and in the removal of wastes. In mammals, the cerebrospinal fluid also cushions the brain and spinal cord by circulating between two of the meninges, layers of connective tissue that surround the CNS.

Axons within the CNS are often found in well-defined bundles, or tracts, whose myelin sheaths give them a whitish appearance. In cross sections of the brain and spinal cord, this white matter is clearly distinguishable from gray matter, which consists mainly of dendrites, unmyelinated axons, and neuron cell bodies (see Figures 48.4 and 48.20).

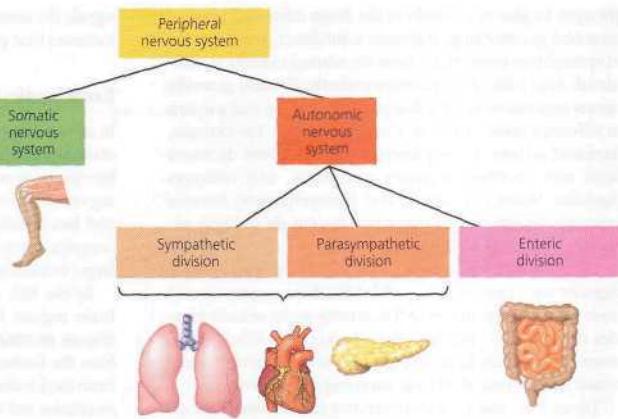

The Peripheral Nervous System

The PNS transmits information to and from the CNS and plays a large role in regulating a vertebrate's movement and internal environment. Structurally, the vertebrate PNS consists of left-right pairs of cranial and spinal nerves and their associated ganglia (see Figure 48.19). The cranial nerves originate in the brain and terminate mostly in organs of the head and upper body. The spinal nerves originate in the spinal cord and extend to parts of the body below the head. Mammals have 12 pairs of cranial nerves and 31 pairs of spinal nerves. Most of the cranial nerves and all of the spinal nerves contain axons of both sensory and motor neurons; a few of the cranial nerves (the olfactory and optic nerves, for example) are sensory only.

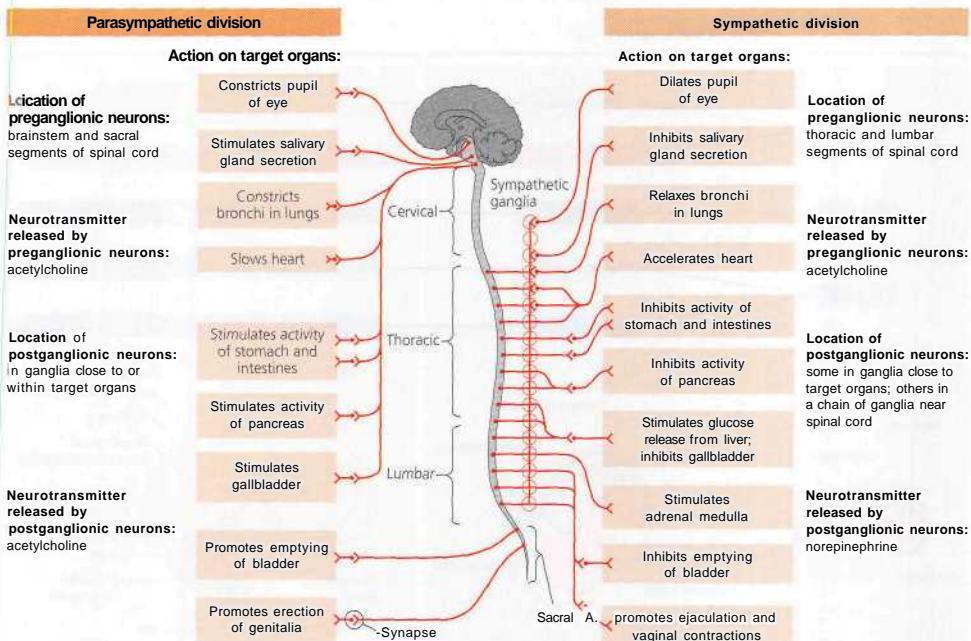

The PNS can be divided into two functional components: the somatic nervous system and the autonomic nervous system (Figure 48.21). The somatic nervous system carries signals to and from skeletal muscles, mainly in response to *external* stimuli. It is often considered voluntary because U is

subject to conscious control, but much skeletal muscle activity is actually controlled by reflexes mediated by the spinal cord or a part of the brain called the brain-stem. The **autonomic nervous system** regulates the *internal* environment by controlling smooth and cardiac muscles and the organs of the digestive, cardiovascular, excretory, and endocrine systems. This control is generally involuntary. Three divisions—sympathetic, parasympathetic, and enteric—together make up the autonomic nervous system.

Figure 48.22 compares the organization and actions of the sympathetic and parasympathetic divisions. Activation of the **sympathetic division** corresponds to arousal and energy generation (the "fight-or-flight" response). For example, the heart beats faster, the liver converts

A **Figure 48.21** Functional hierarchy of the vertebrate peripheral nervous system.

▲ Figure 48.22 The parasympathetic and sympathetic divisions of the autonomic nervous system. Most pathways in each division consist of preganglionic neurons (with cell bodies in the CNS) and postganglionic neurons (with cell bodies in ganglia in the PNS).

glycogen to glucose, bronchi of the lungs dilate and support increased gas exchange, digestion is inhibited, and secretion of epinephrine (adrenaline) from the adrenal medulla is stimulated. Activation of the **parasympathetic division** generally causes opposite responses that promote calming and a return to self-maintenance functions ("rest and digest"). For example, increased activity in the parasympathetic division decreases heart rate, increases glycogen production, and enhances digestion. When sympathetic and parasympathetic neurons innervate the same organ, they often (but not always) have antagonistic (opposite) effects.

The **enteric division** consists of networks of neurons in the digestive tract, pancreas, and gallbladder; these neurons control these organs' secretions as well as activity in the smooth muscles that produce peristalsis (see Chapter 41). Although the enteric division can function independently, it is normally regulated by the sympathetic and parasympathetic divisions.

The somatic and autonomic nervous systems often cooperate in maintaining homeostasis. In response to a drop in body temperature, for example, the hypothalamus signals the autonomic nervous system to constrict surface blood vessels, which reduces heat loss. At the same time, the hypothalamus

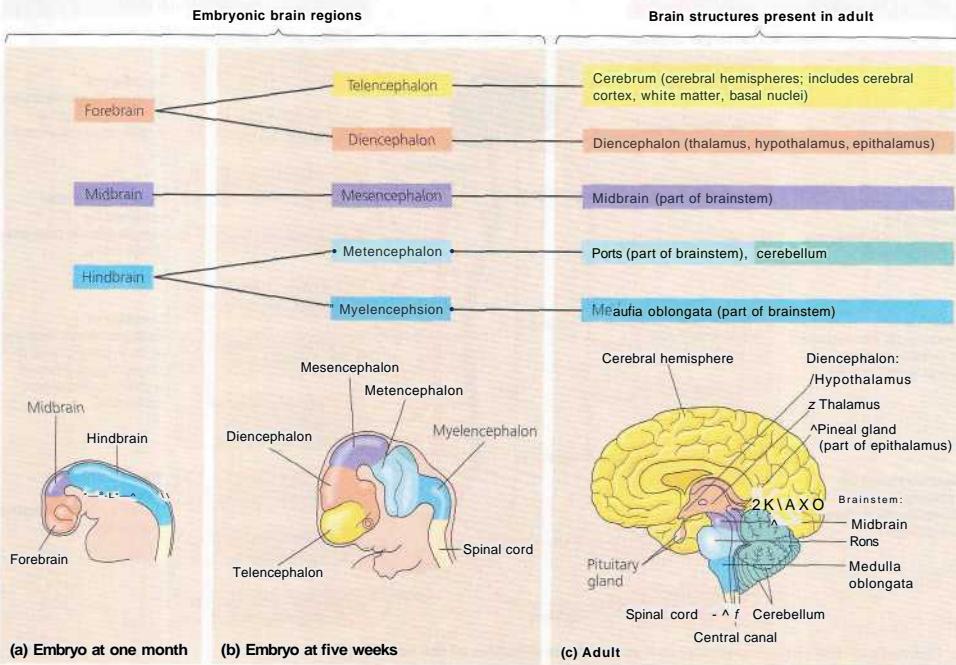

signals the somatic nervous system to cause shivering, which increases heat production.

Embryonic Development of the Brain

In all vertebrates, three bilaterally symmetrical, anterior bulges of the neural tube—the **forebrain**, **midbrain**, and **hindbrain**—become evident as the embryo develops (Figure 48.23a). During vertebrate evolution, the brain further divided structurally and functionally. This regionalization increased capacity for complex integration, with the forebrain becoming much larger in birds and mammals than in other vertebrates.

By the fifth week of human embryonic development, five brain regions have formed from the three primary bulges (Figure 48.23b): The **telencephalon** and **diencephalon** develop from the forebrain; the **mesencephalon** develops from the midbrain (and is also called the midbrain in the adult); and the **metencephalon** and **myelencephalon** develop from the hindbrain. I

As a human brain develops further the most profound changes occur in the telencephalon, the region of the forebrain that gives rise to the **cerebrum** (Figure 48.23c). Rapid, expansive growth of the telencephalon during the second

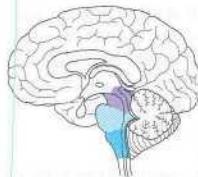

A Figure 48.23 Development of the human brain.

and third months causes the outer portion of the cerebrum, called the **cerebral cortex**, to extend over and around much of the rest of the brain. Major centers that develop from the diencephalon—the forebrain division that evolved earliest in vertebrate history—are the thalamus, hypothalamus, and epithalamus.

The three regions derived from the midbrain and hindbrain give rise to the brainstem, a set of structures deep within the brain. The adult **brainstem** consists of the midbrain (derived from the metencephalon), the pons (derived from the metencephalon), and the medulla oblongata (derived from the myelencephalon). The metencephalon also gives rise to another major brain center, the cerebellum, which is not part of the brainstem.

The Brainstem

The brainstem is one of the evolutionary older parts of the vertebrate brain. Sometimes called the "lower brain," it consists of a stalk with caplike swellings at the anterior end of the spinal cord. The three parts of the brainstem—the medulla oblongata, the pons, and the midbrain—function in homeostasis, coordination of movement, and conduction of information to higher brain centers.

Several centers in the brainstem contain neuron cell bodies that send axons to many areas of the cerebral cortex and cerebellum, releasing neurotransmitters such as norepinephrine, dopamine, serotonin, and acetylcholine. Signals in these pathways cause changes in attention, alertness, appetite, and motivation. The **medulla oblongata** (commonly called the **medulla**) contains centers that control several visceral (automatic, homeostatic) functions, including breathing, heart and blood vessel activity, swallowing, vomiting, and digestion. The **pons** also participates in some of these activities; for example, it regulates the breathing centers in the medulla.

All axons carrying sensory information to and motor instructions from higher brain regions pass through the brainstem, making information transmission one of the most important functions of the medulla and pons. These two regions also help coordinate large-scale body movements, such as walking. Most of the axons carrying instructions about movement from the midbrain and forebrain to the spinal cord cross from one side of the CNS to the other in the medulla. As a result, the right side of the brain controls much of the movement of the left side of the body, and vice versa.

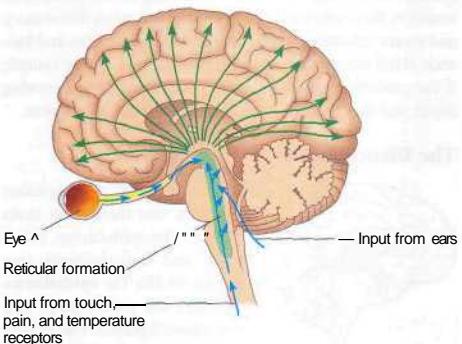

The midbrain contains centers for the receipt and integration of several types of sensory information. It also sends coded sensory information along neurons to specific regions of the forebrain. Prominent centers of the midbrain are the inferior and superior colliculi, which are part of the auditory

and visual systems, respectively. All sensory axons involved in hearing either terminate in or pass through the inferior colliculi on their way to the cerebrum. In nonmammalian vertebrates, the superior colliculi take the form of prominent optic lobes and may be the only visual centers. In mammals, vision is integrated in the cerebrum, leaving the superior colliculi to coordinate visual reflexes, such as automatically turning your head when your peripheral vision picks up something moving toward you from the side.

Arousal and Sleep

As anyone who has sat through a lecture on a warm spring afternoon knows, attentiveness and mental alertness vary from moment to moment. Arousal is a state of awareness of the external world. The counterpart of arousal is sleep, when an individual continues to receive external stimuli but is not conscious of them. Arousal and sleep are controlled by several centers in the brainstem and cerebrum.

A diffuse network of neurons called the **reticular formation**, containing over 90 separate clusters of cell bodies, is present in the core of the brainstem (Figure 48.24). A part of the reticular formation, the reticular activating system (RAS), regulates sleep and arousal. Acting as a sensory filter, the RAS selects which information reaches the cerebral cortex, and the more information the cortex receives, the more alert and aware a person is. But arousal is not just a generalized phenomenon; certain stimuli can be ignored while the brain is actively processing other input. Also, sleep and wakefulness are regulated by specific parts of the brainstem: The pons and medulla contain centers that cause sleep when stimulated, and the midbrain has a center that causes arousal. Serotonin may be the neurotransmitter of the sleep-producing centers. Drinking

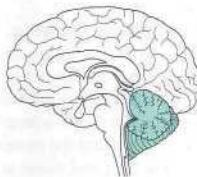

A Figure 48.24 The reticular formation. This system of neurons distributed throughout the brainstem filters sensory input (blue arrows), blocking familiar and repetitive information that constantly enters the nervous system. It sends the filtered input to the cerebral cortex (green arrows).

milk before bedtime may induce sleep because milk contains large amounts of tryptophan, the amino acid from which serotonin is synthesized.

All birds and mammals show characteristic sleep/wake cycles, and melatonin, a hormone produced by the pineal gland, also appears to play an important role in these cycles. As explained in Chapter 45, peak melatonin secretion occurs at night. Melatonin has been promoted as a dietary supplement to treat sleep disturbances, such as those associated with jet lag, insomnia, seasonal affective disorder, and depression.

Understanding the function of sleep remains a compelling research topic. One hypothesis is that sleep is involved in the consolidation of learning and memory, and experiments show that regions of the brain activated during a learning task can become active again during sleep.

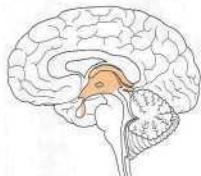

The Cerebellum

The cerebellum develops from part of the metencephalon (see Figure 48.23). It is important for coordination and error checking during motor, perceptual, and cognitive functions. (Cognitive functions include learning, decision making, consciousness, and

an integrated sensory awareness of the surroundings.) The cerebellum is likely involved in learning and remembering motor skills, such as those involved in riding a bicycle, because such learning can be blocked by damage to one of its major subdivisions. The cerebellum receives sensory information about the position of the joints and the length of the muscles, as well as information from the auditory and visual systems. It also receives input concerning motor commands issued by the cerebrum. The cerebellum integrates this sensory and motor information as it coordinates movements and balance. Hand-eye coordination is an example of cerebellar control; if the cerebellum is damaged, the eyes can follow a moving object, but they will not stop at the same place as the object.

The Diencephalon

The embryonic diencephalon develops into three adult brain regions: the epithalamus, thalamus, and hypothalamus (see Figure 48.23). The epithalamus includes the pineal gland and the choroid plexus, one of several clusters of capillaries that

produce cerebrospinal fluid from blood. The thalamus and hypothalamus are major integrating centers.

The thalamus is the main input center for sensory information going to the cerebrum and the main output center for

motor information leaving the cerebrum. Incoming information from all the senses is sorted in the thalamus and sent to the appropriate cerebral centers for further processing. The thalamus also receives input from the cerebrum and other parts of the brain that regulate emotion and arousal.

Although it weighs only a few grams, the hypothalamus is one of the most important brain regions for homeostatic regulation. We saw in Chapter 45 that the hypothalamus is the source of two sets of hormones, posterior pituitary hormones and releasing hormones that act on the anterior pituitary (see Figure 45.8). The hypothalamus also contains the body's thermostat, as well as centers for regulating hunger, thirst, and many other basic survival mechanisms. Hypothalamic centers also play a role in sexual and mating behaviors, the fight-or-flight response, and pleasure. Stimulation of specific centers can cause what are known as "pure" behaviors. For example, rats placed in an experimental situation where they can press a lever to stimulate a "pleasure" center will do so to the exclusion of eating and drinking. Stimulation of another hypothalamic area can produce rage.

Circadian Rhythms

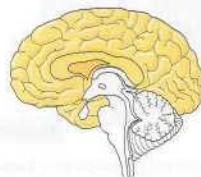

We have already discussed circadian (daily) rhythms in plants (see Chapter 39). Animals also exhibit circadian rhythms, one example being the sleep/wake cycle. Numerous studies have shown that animals usually have an internal timekeeper, known as a biological clock, that is involved in maintaining circadian rhythms. Biological clocks regulate a variety of physiological phenomena, including hormone release, hunger, and heightened sensitivity to external stimuli. In mammals, the biological clock is a pair of hypothalamic structures called the suprachiasmatic nuclei (SCN). (Some clusters of neurons in the CNS are referred to as "nuclei.") In contrast, fruit flies (*Drosophila*) appear to have many biological clocks in various parts of their body, such as the outer edges of their wings.

Biological clocks usually require external cues to remain synchronized with environmental cycles. For example, visual information about light intensity transmitted to the SCN synchronizes the mammalian clock with the natural cycles of day length and darkness (Figure 48.25). Experiments with rodents have revealed that cells in the SCN produce specific proteins in response to changing light/dark cycles.

Human circadian rhythms have been the subject of particularly intense study because upsetting them can cause sleep disorders. In a famous series of experiments in the 1970s, researchers housed subjects in comfortable rooms deep underground, where the subjects could set their own schedules without external cues. Those experiments suggested that the human biological clock has a cycle length of about 25 hours, with much individual variation. In the late 1990s, however, a research team at Harvard University challenged those findings, pointing out that even indoor lighting can influence circadian rhythms.

cadian rhythms. Using more rigorous experimental conditions, the Harvard scientists found that the human biological clock has a cycle length of 24 hours and 11 minutes, with very little variation between individuals.

The Cerebrum

The cerebrum develops from the embryonic telencephalon, an outgrowth of the forebrain that arose early in vertebrate evolution as a region supporting olfactory reception as well as auditory and visual processing. The cerebrum is divided into right and left **cerebral hemispheres**. Each hemisphere consists of an outer covering of gray matter, the cerebral cortex; internal white matter; and groups of neurons collectively called **basal nuclei** located deep within the white matter (Figure 48.26). The basal nuclei are important centers for planning and learning movement sequences. Damage in this region can prevent motor commands from being sent to the muscles, rendering a person passive and immobile.

In humans, the largest and most complex part of the brain is the cerebral cortex. It is here that sensory information is analyzed, motor commands are issued, and language is generated. The cerebral cortex underwent a dramatic expansion when the ancestors of mammals diverged from reptiles. Most significantly, mammals have a region of the cerebral cortex known as the neocortex. The neocortex forms the outermost part of the mammalian cerebrum, consisting of six parallel layers of neurons running tangential to the brain surface. Whereas the neocortex of a rat is relatively smooth, the human neocortex is highly convoluted (see Figure 48.26). The convolutions allow the neocortex to have a large surface area and still fit inside the skull. Although less than 5 mm thick, the human neocortex has a surface area of about 0.5 m^2 and accounts for about 80% of total brain mass. Nonhuman primates and cetaceans (whales and porpoises, for example) also have exceptionally large, convoluted neocortices. In fact, the surface area (relative to body size)

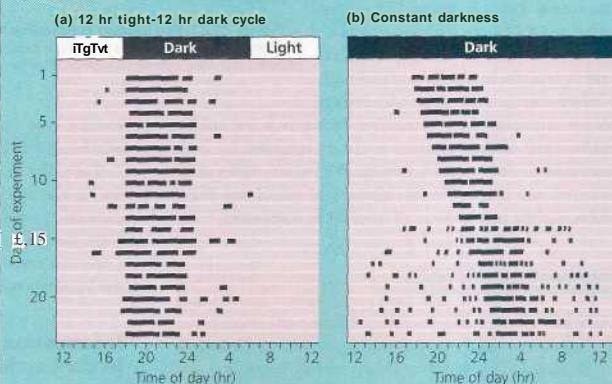

Figure 48.25
Inquiry Are mammalian biological clocks influenced by external cues?

EXPERIMENT

In the northern flying squirrel (*Glaucomys sabrinus*), activity normally begins with the onset of darkness and ends at dawn, which suggests that light is an important external cue for the squirrel. To test this idea, researchers monitored the activity of captive squirrels for 23 days under two sets of conditions: (a) a regular cycle of 12 hours of light and 12 hours of darkness and (b) constant darkness. The squirrels were given free access to an exercise wheel and a rest cage. A recorder automatically noted when the wheel was rotating and when it was still.

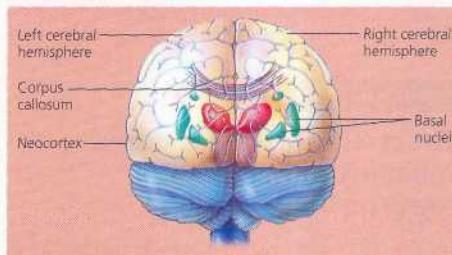

RESULTS

When the squirrels were exposed to a regular light/dark cycle, their wheel-turning activity (indicated by the dark bars) occurred at roughly the same time every day. However, when they were kept in constant darkness, their activity phase began about 21 minutes later each day.

CONCLUSION

The northern flying squirrel's internal clock can run in constant darkness, but it does so on its own cycle, which lasts about 24 hours and 21 minutes. External (light) cues keep the clock running on a 24-hour cycle.

A Figure 48.26 The human cerebrum viewed from the rear. The corpus callosum and basal nuclei are not visible from the surface because they are completely covered by the left and right cerebral hemispheres.

of a porpoise's neocortex is second only to that of a human.

Like the rest of the cerebrum, the cerebral cortex is divided into right and left sides, each of which is responsible for the opposite half of the body. The left side of the cortex receives information from, and controls the movement of, the right side of the body, and vice versa. A thick band of axons known as the **corpus callosum** enables communication between the right and left cerebral cortices (see Figure 48.26).

Damage to one area of the cerebrum early in development can frequently cause redirection of its normal functions to other areas. Perhaps the most dramatic example of this phenomenon occurs after an entire cerebral hemisphere is removed in infants as a treatment for severe epilepsy. Amazingly, the remaining hemisphere eventually assumes most of the functions normally provided by both hemispheres. Even in adults, damage to a portion of the cerebral cortex can trigger the development or use of new brain circuits, leading to a recovery of function in some cases.

Concept Check 48.5

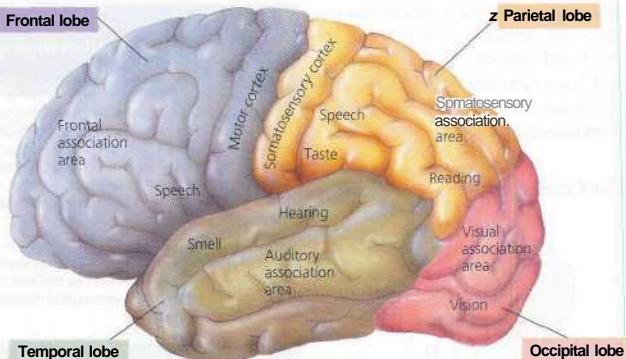

- Which division of your autonomic nervous system would most likely be activated if you were to come to class and learn that an exam you had forgotten about were scheduled for that day? Explain.
- List at least three functions of the medulla oblongata.
- Compare the roles of the reticular formation and thalamus in the transmission of sensory information to the cerebrum.

For suggested answers, see Appendix A.

Concept 48.6

The cerebral cortex controls voluntary movement and cognitive functions

Each side of the cerebral cortex is customarily described as having four lobes, called the frontal, temporal, occipital, and parietal lobes. Researchers have identified a number of functional areas within each lobe (Figure 48.27). These areas include *primary sensory areas*, each of which receives and processes a

A Figure 48.27 The human cerebral cortex. Each side of the cerebral cortex is divided into four lobes, and each lobe has specialized functions. Some of the association areas on the left side (shown here) have different functions than those on the right side.

specific type of sensory information, and *association areas* which integrate the information from various parts of the brain!

The major increase in the size of the neocortex that occurred during mammalian evolution was mostly an expansion of the! association areas that integrate higher cognitive functions and make more complex behavior and learning possible. Whereas a rats neocortex is occupied mainly by primary sensory areas, the human neocortex consists largely of association areas.

Information Processing in the Cerebral Cortex

Most sensory information coming into the cortex is directed via the thalamus to primary sensory areas within the lobes: visual information to the occipital lobe; auditory input to the temporal lobe; and somatosensory information about touch, pain, pressure, temperature, and the position of muscles and limbs to the parietal lobe (see Figure 48.27). Information about taste goes to a separate sensory region of the parietal lobe. Olfactory information is sent first to "primitive" regions of the cortex (that is, regions that are similar in mammals and reptiles) and then via the thalamus to an interior part of the frontal lobe.

The primary sensory areas send information to nearby association areas that can process particular features in the sensory input. In the primary visual cortex, for example, some neurons are sensitive to bars of light that have a certain width and orientation. Information related to such features is combined in association areas dedicated to recognizing complex images, such as faces.

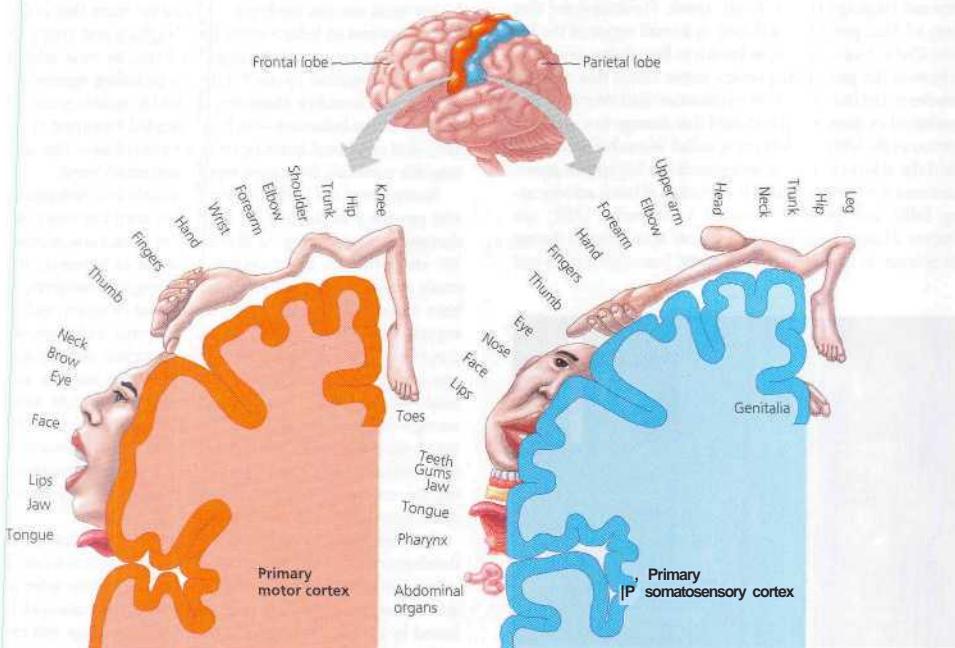

Based on the integrated sensory information, the cerebral cortex may generate motor commands that cause specific behaviors—moving a limb or saying hello, for example. These commands consist of action potentials produced by neurons

in the primary motor cortex, which lies at the rear of the frontal lobe, adjacent to the primary somatosensory cortex (see Figure 48.27). The action potentials travel along axons to the brainstem and spinal cord, where they excite motor neurons, which in turn excite skeletal muscle cells.

In both the somatosensory cortex and the motor cortex, neurons are distributed in an orderly fashion according to the part of the body that generates the sensory input or receives the motor commands (**Figure 48.28**). For example, neurons that process sensory information from the legs and feet are located in the region of the somatosensory cortex that lies closest to the midline. Neurons that control muscles in the legs and feet are located in the corresponding region of the motor cortex. Notice in **Figure 48.28** that the cortical surface area devoted to each body part is not related to the size of that part. Instead, it is related to the number of sensory neurons that innervate that part (for the somatosensory cortex) or to the amount of skill needed to control muscles in that part (for the motor cortex). Thus, the surface area devoted to the face is much larger than that devoted to the trunk.

Lateralization of Cortical Function

During brain development after birth, competing functions segregate and displace each other in the cortex of the left and right cerebral hemispheres, resulting in **lateralization** of functions. The left hemisphere becomes more adept at language, math, logical operations, and the serial processing of sequences of information. It has a bias for the detailed, speed-optimized activities required for skeletal muscle control and the processing of fine visual and auditory details. The right hemisphere is stronger at pattern recognition, face recognition, spatial relations, nonverbal thinking, emotional processing in general, and the simultaneous processing of many kinds of information. Understanding and generating the stress and intonation patterns of speech that convey its emotional content emphasize right-hemisphere function, as does music. The right hemisphere appears to specialize in perceiving the relationship between images and the whole context in which they occur, whereas the left hemisphere is better at focused perception. Most right-handed people use their left hand

A. Figure 48.28 Body representations in the primary motor and primary somatosensory cortices. In these cross-sectional maps of the cortices, the cortical surface area devoted to each body part is represented by the relative size of that part in the cartoons.

(controlled by the right hemisphere) for context or holding and use their right hand (controlled by the left hemisphere) for fine, detailed movement.

The two hemispheres normally work together harmoniously, trading information back and forth through the fibers of the corpus callosum. The importance of this exchange is revealed in patients who have had their corpus callosum severed to control their epileptic seizures. When such "split-brain" patients see a familiar word in their left field of vision, they cannot read the word because the sensory information that travels from the left field of vision to the right hemisphere cannot reach the language centers in the left hemisphere. Each hemisphere in these patients functions independently of the other.

Language and Speech

The systematic mapping of higher cognitive functions to specific brain areas began in the 19th century when physicians learned that damage to particular regions of the cortex by injuries, strokes, or tumors can produce distinctive changes in a person's behavior. The French physician Pierre Broca conducted postmortem examinations of patients who could understand language but could not speak. He discovered that many of these patients had defects in a small region of the left frontal lobe. That region, now known as *Broca's area*, is located in front of the part of the primary motor cortex that controls muscles in the face. The German physician Karl Wernicke also conducted examinations and found that damage to a posterior portion of the temporal lobe, now called *Wernicke's area*, abolished the ability to comprehend speech but left speech generation intact. Over a century later, studies of brain activity using fMRI and positron-emission tomography (PET; see Chapter 2) have confirmed that Broca's area is active during the generation of speech (Figure 48.29, lower left image) and

that Wernicke's area is active when speech is heard (Figure 48.29, upper left image).

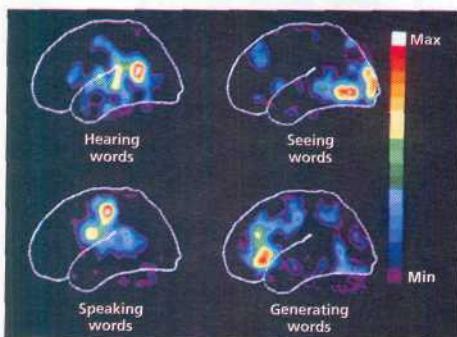

Broca's area and Wernicke's area are part of a much larger network of brain regions involved in language. Reading a printed word without speaking activates the visual cortex (Figure 48.29, upper right image), whereas reading a printed word out loud activates both the visual cortex and Broca's area. Frontal and temporal areas become active when meaning must be attached to words, such as when a person generates verbs to go with nouns or groups related words or concepts (Figure 48.29, lower right image).

Emotions

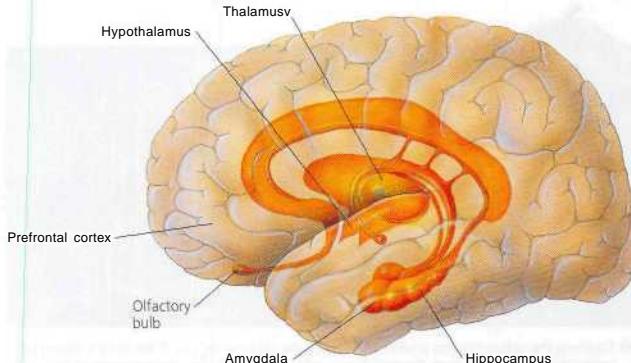

Emotions are the result of a complex interplay of many regions of the brain. Prominent among these regions is the limbic system, a ring of structures around the brainstem (Figure 48.30). The limbic system includes three parts of the cerebral cortex—the amygdala, hippocampus, and olfactory bulb—along with some inner portions of the cortex's lobes and sections of the thalamus and hypothalamus. These structures interact with sensory areas of the neocortex and other higher brain centers, mediating primary emotions that manifest themselves in behaviors such as laughing and crying. It also attaches emotional "feelings" to basic, survival-related functions controlled by the brainstem, including aggression, feeding, and sexuality. Moreover, the limbic system is central to some of the behaviors—such as extended nurturing of infants and emotional bonding to other individuals—that distinguish mammals from most reptiles and amphibians.

Structures of the limbic system form early in development and provide a foundation for the higher cognitive functions that appear later, during the development of neocortical areas. We are born with brain circuits prepared to recognize the crude elements of faces, to support bonding to a caregiver, to have visual and vocal interactions with that caregiver, and to express fear, distress, and anger. Learning and memory processes then build a history of the particular sensing and motor actions that are successful in obtaining warmth and food. We also begin very early to distinguish right from wrong—for example, by perceiving happy or angry facial or vocal expressions from a caregiver. The amygdala, a structure in the temporal lobe (see Figure 48.30), is central in recognizing the emotional content of facial expressions and laying down emotional memories.

This emotional memory system seems to appear earlier in development than the system that supports explicit recall of events, which requires the hippocampus. Adults who learn to avoid an aversive situation, such as an image that is always followed by a mild electric shock, remember the image and experience autonomic arousal—as measured by an increased heart rate or sweating—if the image is presented again. Some adults with damage to the hippocampus report that they do

A Figure 48.29 Mapping language areas in the cerebral cortex. These PET images show regions with different activity levels in one person's brain during four activities, all related to speech.

▲ Figure 48.30 The limbic system.

not recognize the image, but the autonomic arousal still occurs because the emotional memory mediated by the amygdala is still intact. Conversely, other patients with damage confined to the amygdala do not exhibit autonomic arousal, but they recall the image because explicit memory mediated by the hippocampus is intact.

As children develop, primary emotions such as pleasure and fear are associated with different situations in a process that requires portions of the neocortex, especially the forwardmost part of the frontal lobes, called the prefrontal cortex. The remarkable medical case of Phineas Gage reveals just how important this emotional learning can be. In 1848, Gage was working on a railroad construction site when a dynamite explosion drove a meter-long iron rod through his head. The rod entered his skull just below his left eye and exited through the top of his head. Astonishingly, Gage recovered, but his personality was drastically changed. Once an efficient, capable foreman, he had become impatient, profane, and capricious. In the late 1990s, neuroscientists studied Gage's skull and determined that the rod had destroyed portions of his frontal lobe known to mediate emotions. Today, patients who have been diagnosed with tumors or lesions in these regions sometimes suffer the same combination of symptoms. Their intellect and memory seem intact, but their motivation, foresight, goal formation, and decision making are flawed. Their emotions and feelings also are diminished.

Frontal lobotomy, a surgical procedure in which the connection between the prefrontal cortex and the limbic system is disrupted, was once widely performed to treat severe emotional disorders. However, the resulting docility in the patient was usually accompanied by a loss of the ability to concentrate, plan, and work toward goals. Therefore, drug therapy has replaced frontal lobotomy for treating such severely ill individuals.

Memory and Learning

Though we may not be aware of it, we are constantly checking what is happening right now against what just happened a few moments ago. We hold information, anticipation, or goals for a time in **short-term memory** locations in the frontal lobes and then release them if they become irrelevant. Should we wish to retain knowledge of a face or a phone number, the mechanisms of **long-term memory** are activated in a process that requires the hippocampus. If we later need to recall a name or number, we can fetch it from long-term memory and return it to short-term memory. The transfer of information from short-term to long-term memory is enhanced by rehearsal ("practice makes perfect"), positive or negative emotional states mediated by the amygdala, and the association of new data with data previously learned and stored in long-term memory. For example, it's easier to learn a new card game if you already have "card sense" from playing other games.

Many sensory and motor association areas of the cerebral cortex outside Broca's area and Wernicke's area are involved in storing and retrieving words and images. Studies of patients with brain lesions and imaging studies on unimpaired subjects suggest, for example, that recognition of people is associated with the anterior part of the left temporal lobe, recognition of animals with the lower middle part of this lobe, and recognition of tools with the lower posterior part.

The memorization of phone numbers, facts, and places—which can be very rapid and may require only one exposure to the relevant item—may rely mainly on rapid changes in the strength of existing neural connections. In contrast, the slow learning and remembering of skills and procedures, such as those required to improve one's tennis game, appear to involve cellular mechanisms very similar to ones responsible for brain growth and development. In such cases, neurons actually make new connections.

Motor skills, such as walking, tying your shoes, riding a bicycle, or writing, are usually learned by repetition. You can perform such skills without consciously recalling the individual steps required to do these tasks correctly. Once a skill memory is learned, it is difficult to unlearn. For example, a person who has played tennis for years with a self-taught, awkward backhand has a much tougher time learning the correct form than a beginner just learning the game. Habits, whether good or bad, are hard to break. Our gait, gestures, and accent are individual, and we are very aware of these traits in other people when we interact with them.

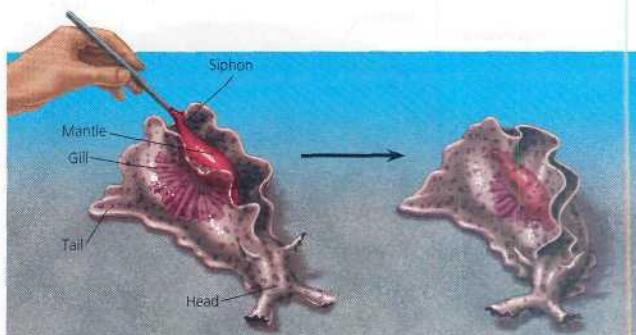

Cellular Mechanisms of Learning

Nobel laureate Eric Kandel and his colleagues at Columbia University have studied the cellular basis of learning using an animal with a small, experimentally accessible nervous system, the sea hare (*Aplysia californica*). The researchers were able to explain the mechanism of simple forms of learning in this mollusc in terms of changes in the strength of synaptic transmission between specific sensory and motor neurons. **Figure 48.31** describes one of their experiments.

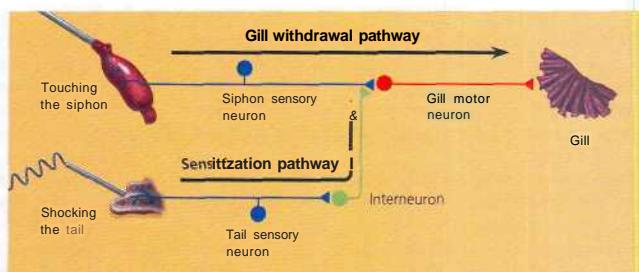

In the vertebrate brain, a form of learning called long-term potentiation (LTP) involves an increase in the strength of synaptic transmission that occurs when presynaptic neurons produce a brief, high-frequency series of action potentials. Because LTP can last for days or weeks, it may be a fundamental process by which memories are stored or learning takes place. The cellular mechanism of LTP has been studied most thoroughly at synapses in the hippocampus, where presynaptic neurons release the excitatory neurotransmitter glutamate (**Figure 48.32**). The postsynaptic neurons possess two types of glutamate receptors: AMPA receptors and NMDA receptors. AMPA receptors are part of ligand-gated ion channels; when glutamate binds to them, Na^+ and K^+ diffuse through the channels, and the postsynaptic membrane depolarizes. NMDA receptors are part of channels that are both ligand gated and voltage gated: The channels open only if glutamate is bound *and* the membrane is depolarized. As detailed in Figure 48.32, the binding of glutamate to these two types of receptors can lead to LTP through changes in both the presynaptic and the postsynaptic neurons.

Consciousness

The study of human consciousness was long considered outside the province of hard science, more appropriate as a subject for philosophy or religion. One reason for this view is that consciousness is both broad—encompassing our awareness of ourselves and of our own experiences—and subjective.

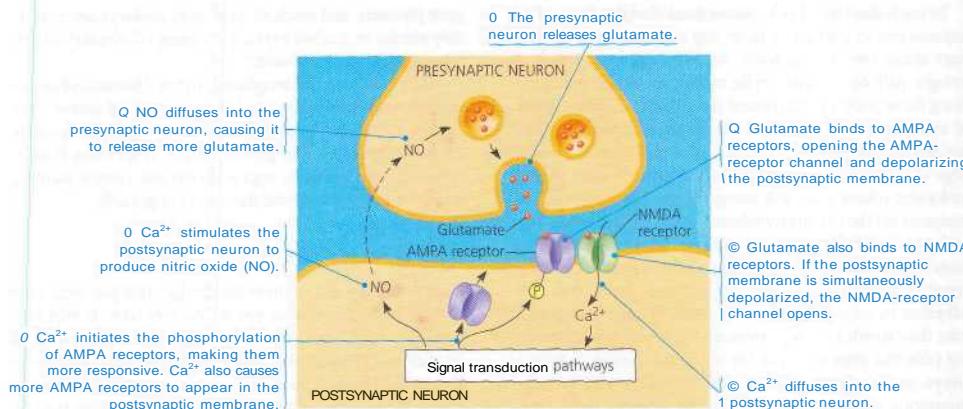

(a) Touching the siphon triggers a reflex that causes the gill to withdraw. If the tail is shocked just before the siphon is touched, the withdrawal reflex is stronger. This strengthening of the reflex is a simple form of learning called sensitization.

(b) Sensitization involves interneurons that make synapses on the synaptic terminals of the siphon sensory neurons. When the tail is shocked, the interneurons release serotonin, which activates a signal transduction pathway that closes K^+ channels in the synaptic terminals of the siphon sensory neurons. As a result, action potentials in the siphon sensory neurons produce a prolonged depolarization of the terminals. That allows more Ca^{2+} to diffuse into the terminals, which causes the terminals to release more of their excitatory neurotransmitter onto the gill motor neurons. In response, the motor neurons generate action potentials at a higher frequency, producing a more forceful gill withdrawal.

• **Figure 48.31** Sensitization in the sea hare (*Aplysia californica*).

Over the past few decades, however, neuroscientists have begun studying consciousness using brain-imaging techniques such as fMRI (see Figure 48.1). It is now possible to compare activity in the human brain during different states of consciousness—for example, before and after a person is aware of seeing an object. These imaging techniques can also be used to compare the conscious and unconscious processing of sensory information. Such studies do not pinpoint a "consciousness center" in the brain; rather, they offer an increasingly detailed picture of how neural activity correlates with conscious experiences. There is a growing consensus among neuroscientists that consciousness is an emergent property of the brain (see Chapter 1), one that recruits activities in

▲ Figure 48.32 Mechanism of long-term potentiation in the vertebrate brain.

many areas of the cerebral cortex. Several models postulate the existence of a sort of "scanning mechanism" that repetitively sweeps across the brain, integrating widespread activity into a unified, conscious moment.

Still, a well-supported theory of consciousness may have to wait until brain-imaging technology becomes more sophisticated. Analyzing dynamic patterns of activity that span the entire brain may reveal that these patterns bear no more direct relationship to individual nerve cells than do hurricanes to their constituent water molecules.

Concept 48.7

CNS injuries and diseases are the focus of much research

Unlike the PNS, the mammalian CNS cannot fully repair itself when damaged or assaulted by disease. Surviving neurons in the brain can make new connections and thus sometimes compensate for damage, as in the remarkable recoveries of some stroke victims. Generally speaking, however, brain and spinal cord injuries, strokes, and diseases that destroy CNS neurons, such as Alzheimer's disease and Parkinson's disease, have devastating effects. Current research on nerve cell development and the discovery of neural stem cells enhance our fundamental knowledge of the nervous system and may one day make it possible for physicians to repair or replace damaged neurons.

Nerve Cell Development

Among the key questions in neurobiology are how certain cells in a developing animal differentiate into neurons and how neurons migrate to their proper locations, grow axons to specific places, and make synapses with the correct postsynaptic cells (target cells). The labs of Corey Goodman (University of California, Berkeley) and Marc Tessier-Lavigne (University of California, San Francisco) have been studying how neurons "find their way" during development of the CNS. Their work combines elements of cell-to-cell communication (see Chapter 11), control of gene expression (see Chapter 19), and the genetic basis of development (see Chapter 21).

I Concept Check 48.6

- Based on Figure 48.28, what can you infer about the relative number of sensory neurons that innervate the hand and the neck? Explain.
- If a man with a severed corpus callosum were asked to view a photograph of a familiar face, first in his left field of vision and then in his right field, why would it be difficult for him to put a name to the face in either field?
- Two brain areas important in speech are Broca's area and Wernicke's area. How is the function of each area related to the area's location in the cerebral cortex?
- Explain how the binding of glutamate to NMDA receptors in the hippocampus exhibits properties of both direct and indirect synaptic transmission.

For suggested answers, see Appendix A.

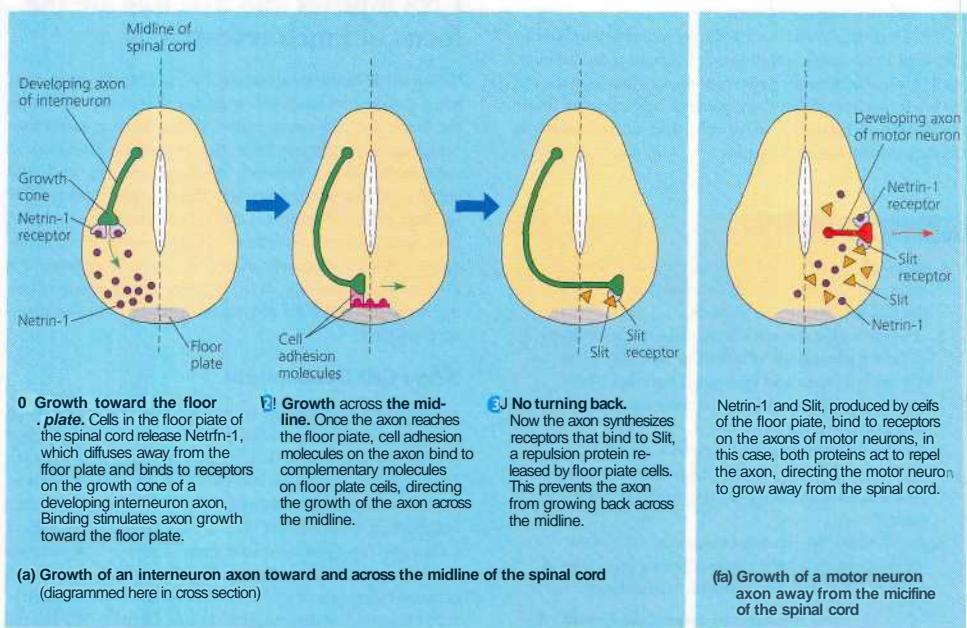

To reach their target cells, axons must elongate from a few micrometers to a meter or more (for example, from the human spinal cord to the foot). An axon does not follow a straight path to its target cells; rather, molecular signposts along the way direct and redirect the growing axon in a series of mid-course corrections that result in a meandering, but not random, elongation. The responsive region at the leading edge of the growing axon is called the **growth cone**. Signal molecules released by cells along the growth route bind to receptors on the plasma membrane of the growth cone, triggering a signal transduction pathway (Figure 48.33). The axon may respond by either growing toward the source of the signal molecules (attraction) or away from it (repulsion). Cell adhesion molecules on the axon's growth cone also play a role; they attach to complementary molecules on surrounding cells that provide tracks for the growing axon to follow. Nerve growth factor released by astrocytes and growth-promoting proteins produced by the neurons themselves contribute to the process by stimulating axonal elongation. The growing axon expresses different genes at different times during its development, and it is influenced by surrounding cells that it moves away from. This complex process has been conserved during millions of years of evolution, for the genes,

gene products, and mechanism of axon guidance are remarkably similar in studied nematode worms (*C. elegans*), insects (*prosophila*), and vertebrates.

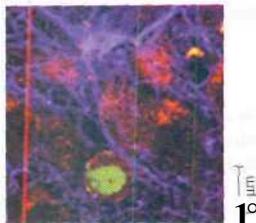

Work continues on deciphering the mechanisms of axonal growth, with the ultimate goal of repairing CNS damage. Using the right combination of attractants, repellants, growth-associated proteins, and growth factors, researchers hope to coax damaged axons to regrow, follow the correct pathway, and form connections with the correct target cells.

Neural Stem Cells

Until 1998, it was "common knowledge" that you were born with all the brain neurons you would ever have. In that year, however, Fred Gage from the Salk Institute for Biological Studies in California and Peter Ericksson from Sahlgrenska University Hospital in Sweden made a startling announcement: The human brain *does* produce new neurons in adulthood. Ericksson was working in Gage's lab, where researchers injected mice with the marker bromodeoxyuridine (BrdU) to label the DNA of dividing cells. After Ericksson returned to Sweden, he learned that a group of terminally ill cancer patients were receiving BrdU as part of a study to monitor tumor

A Figure 48.33 Molecular signals direct the growth of developing axons.

< Figure 48.34 A newly born neuron in the hippocampus of a human adult. All the red cells in this LM are neurons. The cell that is both red and green is a neuron that has incorporated BrdU, indicating that it resulted from a recent cell division.

growth. The patients agreed to donate their brains for research upon their death. In a postmortem study, Ericksson found newly divided neurons in the hippocampus of all the patients (**Figure 48.34**).

It is not clear what function these new cells play in the human brain. However, mice that live in stimulating environments and run on exercise wheels have more new neurons in their hippocampus and perform better on learning tasks than genetically identical caged mice that receive little stimulation.

Mature neurons, with their extensive processes and intricate connections with other cells, clearly are not able to undergo cell division. Therefore, the new brain neurons must have come from stem cells. Recall from Chapter 21 that stem cells are relatively unspecialized cells that continually divide. While some of their progeny remain undifferentiated, others may differentiate into specialized cells under the right conditions.

One of the difficulties of conducting research on stem cells is finding a source of human stem cells. Embryonic stem cells can be obtained from embryos produced through in vitro fertilization (see Chapter 46), but because harvesting these cells requires destroying the embryo, various ethical and political issues surround their use. Certain adult tissues, such as bone marrow (see Figure 42.16), also have stem cells, but those cells may be less developmentally versatile than embryonic stem cells.

In 2001, Gage and his colleagues announced that they had cultured neural progenitor cells from the brains of recently deceased individuals and surgical tissue samples. The term *livегemiov* refers to the fact that these stem cells are committed to becoming either neurons or glia. In culture, the cells divided 30 to 70 times and differentiated into neurons and astrocytes. One of the goals of further research is to find a way to induce the body's own neural progenitor cells to differentiate into specific types of neurons or glia when and where they are needed. Another goal is to transplant cultured neural progenitor cells into the damaged CNS.

Diseases and Disorders of the Nervous System

Mental illnesses, including schizophrenia and depression, and neurological disorders such as Alzheimer's disease and Parkinson's disease take an enormous toll on society, in both the

patient's potential loss of a productive life and the high cost of long-term medical care. They also severely disrupt the lives of patients' families. Finding proper treatments and cures is a research priority.

For many years, the only treatment for patients with mental illness was to sequester them in institutions, where most of them spent the rest of their lives. Today, with the advent of drugs that can treat (though not yet cure) many of these conditions, the average stay in a mental hospital is about two or three weeks. Attitudes toward the mentally ill are slowly changing as people become more aware that mental illnesses are caused by chemical or anatomical changes in the brain.

Schizophrenia

About 1% of the world's population suffers from **schizophrenia**, a severe mental disturbance characterized by psychotic episodes in which patients lose the ability to distinguish reality. The symptoms of schizophrenia typically include hallucinations (most often "voices" telling the patient that they are worthless and evil) and delusions (generally paranoid), as well as blunted emotions, distractibility, lack of initiative, and poverty of speech. Despite the commonly held belief, schizophrenics do not necessarily exhibit a split personality. There seem to be several different forms of schizophrenia, and it is unclear whether they represent different disorders or variations of the same underlying disease.

The cause of schizophrenia is unknown, although the disease has a strong genetic component. Studies of identical twins show that if one twin has schizophrenia, there is a 50% chance that the other twin has it, too. Since identical twins have identical genes, the fact that this likelihood is not 100% implies that schizophrenia must have an equally strong environmental component, which is unidentified. Now that the human genome has been sequenced, there is a vigorous effort underway to find the mutant genes that predispose a person to the disease. This effort includes DNA sequencing of individuals in families with a high incidence of schizophrenia. Multiple genes must be involved because the inheritance does not follow the Mendelian pattern expected for a single-gene mutation.

Treatments for schizophrenia have focused mostly on brain pathways that use dopamine as a neurotransmitter. Two lines of evidence support this protocol. First, amphetamine ("speed"), which stimulates dopamine release, can produce symptoms indistinguishable from those of schizophrenia. Second, many of the drugs that alleviate the symptoms block dopamine receptors, especially a subform called the D₂ receptor. However, additional neurotransmitters may also be involved because other drugs successful in treating schizophrenia, called atypical antipsychotics, block the D₂ receptor only very weakly but have stronger effects on serotonin and/or norepinephrine receptors. Furthermore, there are indications that glutamate receptors may play a role in schizophrenia: The street drug

"angel dust," or PCP, blocks the NMDA type of glutamate receptor (but not dopamine receptors) and induces strong schizophrenia-like symptoms.

Despite their ability to alleviate the major symptoms, many of the existing drugs have such negative side effects that patients frequently stop taking them. For example, the drugs often produce motor deficits that resemble those of Parkinson's disease. In about 25% of cases, chronic drug therapy produces a new and frequently irreversible condition called tardive dyskinesia, in which the patient has uncontrolled facial writhing movements. The atypical antipsychotics mostly avoid such side effects, but some of these drugs produce a blood disorder in certain individuals. Identification of the genetic mutations responsible for schizophrenia may yield new insights about the causes of the disease, which may in turn lead to new therapies.

Depression

Two broad forms of depressive illness are known: bipolar disorder and major depression. Bipolar disorder, or manic-depressive disorder, involves swings of mood from high to low and affects about 1% of the world's population. In contrast, people with major depression have a low mood most of the time; they constitute roughly 5% of the population.

In bipolar disorder, the manic phase is characterized by high self-esteem, increased energy, a flow of ideas, and overtalkativeness, as well as behaviors that often bring disaster, such as increased risk taking, promiscuity, and reckless spending. In its milder forms, this phase is sometimes associated with great creativity, and some well-known artists, musicians, and literary figures (including Keats, Tolstoy, Hemingway, and Schumann, to name a few) have had periods of intense output during manic phases. The depressive phase comes with lowered ability to feel pleasure, loss of interest, sleep disturbances, and feelings of worthlessness. Some people with bipolar disorder even attempt to commit suicide during the depressive phase. Nevertheless, some patients prefer to endure the pain of the depressive phase rather than take medication and risk losing the enhanced creative output of their manic phase.

Both bipolar disorder and major depression have a genetic component, as identical twins have about a 50% chance of sharing this mental illness. As with schizophrenia, this percentage means that there is also a strong environmental component, and there are indications that stress, especially severe stress in childhood, may be an important factor.

Several treatments for depression are available, some of which were identified serendipitously from the mood changes produced as side effects of drugs or procedures aimed at other conditions, including high blood pressure and tuberculosis. Many drugs effective against depression, including Prozac, increase the activity of biogenic amines in the brain. The mechanisms of various other treatments, such as electroconvulsive

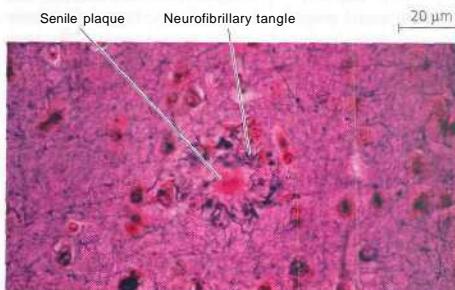

therapy, lithium administration, and talk therapy, are not well understood.

Alzheimer's Disease

Alzheimer's disease (AD) is a mental deterioration, or dementia, characterized by confusion, memory loss, and a variety of other symptoms. Its incidence is age related, rising from about 10% at age 65 to about 35% at age 85. Thus, by helping humans live longer, modern medicine is increasing the proportion of AD patients in the population. The disease is progressive, with patients gradually becoming less able to function and eventually needing to be dressed, bathed, and fed by others. There are also personality changes, almost always for the worse. Patients often lose their ability to recognize people, including their immediate family, and may act toward them with suspicion and hostility.

At present, a firm diagnosis of AD is difficult to make while the patient is alive because AD is one of several forms of dementia. However, AD results in a characteristic pathology of the brain: Neurons die in huge areas of the brain, often leading to massive shrinkage of brain tissue. This shrinkage can be seen with brain imaging but is not enough to positively identify AD. What is diagnostic is the postmortem finding of two features—neurofibrillary tangles and senile plaques—in remaining brain tissue (Figure 48.35). Neurofibrillary tangles are bundles of degenerated neuronal and glial processes. Senile plaques are aggregates of [3]-amyloid, an insoluble peptide that is cleaved from a membrane protein normally present in neurons. The role of the uncleaved protein is not known. Membrane enzymes, called secretases, catalyze the cleavage, causing [3]-amyloid to accumulate outside the neurons and to aggregate in the form of plaques. The plaques appear to trigger the death of surrounding neurons.

There has been an enormous effort devoted to developing a treatment for AD. In 2004, a team of researchers at Northwestern University used genetic engineering to eliminate one

A Figure 48.35 Microscopic signs of Alzheimer's disease. A hallmark of AD is the presence in brain tissue of neurofibrillary tangles surrounding senile plaques made of [3]-amyloid (LM).

In the secretases in a strain of mice prone to AD. The genetically engineered mice accumulated much less p-amyloid and did not experience the age-related memory deficits typical of mice in that strain. A successful treatment for AD in humans may hinge on the early detection of senile plaques, which commonly form before overt symptoms of the disease appear. One step in this direction may be a chemical nicknamed Pittsburgh Compound-B (PIB), which was synthesized by scientists at the University of Pittsburgh in 2004. The scientists linked PIB to a short-lived radioactive isotope and used a PET scanner to track the distribution of PIB in the brains of AD patients. They found that PIB accumulated selectively in brain regions that contain large amounts of (3-amyloid deposits. PIB may be useful in testing the effectiveness of drugs aimed at reducing the rate of production of fibrillar amyloid or of dispersing already-formed plaques. Several such drugs are currently in clinical trials.

Parkinson's Disease

Approximately 1 million people in the United States suffer from Parkinson's disease, a motor disorder characterized by difficulty in initiating movements, slowness of movement, and rigidity. Patients often have a masked facial expression, muscle tremors, poor balance, a flexed posture, and a shuffling gait. Like Alzheimer's disease, Parkinson's disease is a progressive brain illness whose risk increases with advancing age. The incidence of Parkinson's disease is about 1% at age 65 and about 5% at age 85.

The symptoms of Parkinson's disease result from the death of neurons in a midbrain nucleus called the substantia nigra. These neurons normally release dopamine from their synaptic terminals in the basal nuclei. The degeneration of dopamine neurons is associated with the accumulation of protein aggregates containing alpha-synuclein, a protein typically found in presynaptic nerve terminals.

Most cases of Parkinson's disease lack a clearly identifiable cause. However, the consensus among scientists who study the disease is that it results from a combination of environmental and genetic factors. For example, some families with an increased incidence of Parkinson's disease have a mutated form of the gene for alpha-synuclein. One hypothesis is that changes in the structure of alpha-synuclein cause dopamine neurons in the substantia nigra to become susceptible to oxidative cell damage.

At present there is no cure for Parkinson's disease, although various approaches are used to manage the symptoms, including brain surgery, deep-brain stimulation, and drugs such as L-dopa, a dopamine precursor that can cross the blood-brain barrier. One potential cure is to implant dopamine-secreting neurons, either in the substantia nigra or in the basal ganglia. Embryonic stem cells can be stimulated or genetically engineered to develop into dopamine-secreting neurons, and transplantation of these cells into rats with an experimentally induced condition that mimics Parkinson's disease has led to a recovery of motor control. Whether this kind of regenerative medicine will also work in humans is one of many important questions on the frontier of modern brain research.

Concept Check 48.7

- Based on Figure 48.33, what would be the likely effect of a mutation preventing spinal cord interneurons from having Netrin-1 receptors? What might result from interneurons lacking Slit receptors?
- What evidence indicates that schizophrenia, bipolar disorder, and major depression have both genetic and environmental components?
- What are some similarities between Alzheimer's disease and Parkinson's disease?

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 48.1

Nervous systems consist of circuits of neurons and supporting cells

- Organization of Nervous Systems (pp. 1012-1013)**
Invertebrate nervous systems range in complexity from simple nerve nets to highly centralized nervous systems having compli-

cated brains and ventral nerve cords. In vertebrates, the central nervous system (CNS) consists of the brain and the spinal cord, which is located dorsally.

- Information Processing (p. 1013)** Nervous systems process information in three stages: sensory input, integration, and motor output to effector cells. The CNS integrates information, while the nerves of the peripheral nervous system (PNS) transmit sensory and motor signals between the CNS and the rest of the body. The three stages are illustrated in the knee-jerk reflex.
- Neuron Structure (pp. 1013-1014)** Most neurons have highly branched dendrites that receive signals from other neurons. They also typically have a single axon that transmits signals to other

cells at synapses. Neurons have a wide variety of shapes that reflect their input and output interactions.

Activity *Neuron Structure*

- **Supporting Cells (Glia)** (pp. 1014-1015) Glia perform a number of functions, including providing structural support for neurons, regulating the extracellular concentrations of certain substances, guiding the migration of developing neurons, and forming myelin, which electrically insulates axons.

Concept 48.2

Ion pumps and ion channels maintain the resting potential of a neuron

- Every cell has a voltage across its plasma membrane called a membrane potential. The inside of the cell is negative relative to the outside (pp. 1015-1016).
- **The Resting Potential** (pp. 1016-1017) The membrane potential depends on ionic gradients across the plasma membrane: the concentration of Na^+ is higher in the extracellular fluid than in the cytosol, while the reverse is true for K^+ . A neuron that is not transmitting signals contains many open K^{+} channels and fewer open Na^+ channels in its plasma membrane. The diffusion of K^+ and Na^+ through these channels leads to the separation of charges across the membrane, producing the resting potential.
- **Gated Ion Channels** (p. 1017) Gated ion channels open or close in response to membrane stretch, the binding of a specific ligand, or a change in the membrane potential.

Concept 48.3

Action potentials are the signals conducted by axons

- An increase in the magnitude of the membrane potential is called a hyperpolarization; a decrease in magnitude is called a depolarization. Changes in membrane potential that vary with the strength of a stimulus are known as graded potentials (pp. 1017-1018).
- **Production of Action Potentials** (pp. 1018-1020) An action potential is a brief, all-or-none depolarization of a neuron's plasma membrane. When a graded depolarization brings the membrane potential to the threshold, many voltage-gated Na^{+} channels open, triggering an influx of Na^{+} that rapidly brings the membrane potential to a positive value. The membrane potential is restored to its normal resting value by the inactivation of Na^+ channels and by the opening of many voltage-gated K^+ channels, which increases K^+ efflux. A refractory period follows the action potential, corresponding to the interval when the Na^+ channels are inactivated.

Activity Nerve Signals: Action Potentials

Investigation What Triggers Nerve Impulses?

- **Conduction of Action Potentials** (pp. 1020-1021) An action potential travels from the axon hillock to the synaptic terminals by regenerating itself along the axon. The speed of conduction of an action potential increases with the diameter of the axon and, in many vertebrate axons, with myelination. Action potentials in myelinated axons jump between the nodes of Ranvier, a process called saltatory conduction.

Concept 48.4

Neurons communicate with other cells at synapses

- In an electrical synapse, electrical current flows directly from one cell to another via a gap junction. In a chemical synapse, depolarization of the synaptic terminal causes synaptic vesicles

to fuse with the terminal membrane and to release neurotransmitter into the synaptic cleft (pp. 1021-1022).

- **Direct Synaptic Transmission** (pp. 1022-1023) The neurotransmitter binds to ligand-gated ion channels in the postsynaptic membrane, producing an excitatory or inhibitory postsynaptic potential (EPSP or IPSP). After release, the neurotransmitter diffuses out of the synaptic cleft, is taken up by surrounding cells, or is degraded by enzymes. A single neuron has many synapses on its dendrites and cell body. Whether it generates an action potential depends on the temporal and spatial summation of EPSPs and IPSPs at the axon hillock.

Activity Signal Transmission at a Chemical Synapse

- **Indirect Synaptic Transmission** (pp. 1023-1024) The binding of neurotransmitter to some receptors activates signal transduction pathways, which produce slowly developing but long-lasting effects in the postsynaptic cell.
- **Neurotransmitters** (pp. 1024-1025) The same neurotransmitter can produce different effects on different types of cells. Major known neurotransmitters include acetylcholine, biogenic amines (epinephrine, norepinephrine, dopamine, and serotonin), various amino acids and peptides, and the gases nitric oxide and carbon monoxide.

Concept 48.5

The vertebrate nervous system is regionally specialized

- **The Peripheral Nervous System** (pp. 1026-1028) The PNS consists of paired cranial and spinal nerves and associated ganglia. Functionally, the PNS is divided into the somatic nervous system, which carries signals to skeletal muscles, and the autonomic nervous system, which regulates the primarily automatic, visceral functions of smooth and cardiac muscles. The autonomic nervous system has three divisions: the sympathetic and parasympathetic divisions, which usually have antagonistic effects on target organs, and the enteric division, which controls the activity of the digestive tract, pancreas, and gallbladder.
- **Embryonic Development of the Brain** (pp. 1028-1029) The vertebrate brain develops from three embryonic regions: the forebrain, the midbrain, and the hindbrain. In humans, the most expansive growth occurs in the part of the forebrain that gives rise to the cerebrum.
- **The Brainstem** (pp. 1029-1030) The medulla oblongata, pons, and midbrain make up the brainstem, which controls homeostatic functions such as breathing rate, conducts sensory and motor signals between the spinal cord and higher brain centers, and regulates arousal and sleep.
- **The Cerebellum** (p. 1030) The cerebellum helps coordinate motor, perceptual, and cognitive functions. It also is involved in learning and remembering motor skills.
- **The Diencephalon** (pp. 1030-1031) The thalamus is the main center through which sensory and motor information passes to and from the cerebrum. The hypothalamus regulates homeostasis; basic survival behaviors such as Seeding, fighting, fleeing, and reproducing; and circadian rhythms.
- **The Cerebrum** (pp. 1031-1032) The cerebrum has two hemispheres, each of which consists of cerebral cortex overlying white matter and basal nuclei, which are important in planning and learning movements. In mammals, the cerebral cortex has a convoluted surface called the neocortex. A thick band of axons, the corpus callosum, provides communication between the right and left cerebral cortices.

Concept 48.6

The cerebral cortex controls voluntary movement and cognitive functions

- Each side of the cerebral cortex has four lobes—frontal, temporal, occipital, and parietal—which contain primary sensory areas and association areas (p. 1032).

► Information Processing in the Cerebral Cortex

(pp. 1032–1033) Specific types of sensory input enter the primary sensory areas. Adjacent association areas process particular features in the sensory input and integrate information from different sensory areas, in the somatosensory cortex and the motor cortex, neurons are distributed according to the part of the body that generates sensory input or receives motor commands.

► **Lateralization of Cortical Function** (pp. 1033–1034) The left hemisphere is normally specialized for high-speed serial information processing essential to language and logic operations. The right hemisphere is stronger at pattern recognition, nonverbal ideation, and emotional processing.

► **Language and Speech** (p. 1034) Portions of the frontal and temporal lobes, including Broca's area and Wernicke's area, are essential for generating and understanding language.

► **Emotions** (pp. 1034–1035) The limbic system, a ring of cortical and noncortical centers around the brainstem, mediates primary emotions and attaches emotional "feelings" to survival-related functions. The association of primary emotions with different situations during human development requires parts of the neocortex, especially the prefrontal cortex.

► **Memory and Learning** (pp. 1035–1036) The frontal lobes are a site of short-term memory and can interact with the hippocampus and amygdala to consolidate long-term memory. Experiments on invertebrates and vertebrates have revealed the cellular basis of some simple forms of learning, including sensitization and long-term potentiation.

► **Consciousness** (pp. 1036–1037) Modern brain-imaging techniques suggest that consciousness may be an emergent property of the brain based on activity in many areas of the cortex.

TESTING YOUR KNOWLEDGE

Evolution Connection

An action potential is an all-or-none event. This on/off signaling is an evolutionary adaptation of animals that must sense and act in a complex environment. It is possible to imagine a nervous system in which the action potentials were graded, with the amplitude depending on the size of the stimulus. What advantage might on/off signaling have over a graded (continuously variable) kind of signaling?

Scientific Inquiry

From what you know about action potentials and synapses, propose two or three hypotheses for how various anesthetics might prevent pain.

Investigation *What Triggers Nerve Impulses?*

Science, Technology, and Society

Alcohol's depressant effects on the nervous system cloud judgment and slow reflexes. Alcohol consumption is a factor in most fatal traffic accidents in the United States. What are some other impacts of alcohol abuse on society? What are some of the responses of people and society to alcohol abuse? Do you think that alcohol abuse is primarily an individual problem or a societal problem? Do you think that society's responses to alcohol abuse are appropriate and proportional to the seriousness of the problem? Defend your position.

Concept 48.7

CNS injuries and diseases are the focus of much research

► **Nerve Cell Development** (pp. 1037–1038) Signal molecules direct an axon's growth by binding to receptors on the plasma membrane of the growth cone. The genes and basic events involved in axon guidance are similar in invertebrates and vertebrates. Knowledge of these events may be applied one day to stimulate axonal regrowth following CNS damage.

► **Neural Stem Cells** (pp. 1038–1039) The adult human brain contains stem cells that can differentiate into mature neurons. The induction of stem cell differentiation and transplantation of cultured stem cells are potential methods for replacing neurons lost to trauma or disease.

► **Diseases and Disorders of the Nervous System**

(pp. 1039–1041) Schizophrenia is characterized by hallucinations, delusions, blunted emotions, and other symptoms. Depression includes bipolar disorder, characterized by manic (high-mood) and depressive (low-mood) phases, and major depression, in which patients have a persistent low mood. Alzheimer's disease is an age-related dementia in which neurofibrillary tangles and senile plaques form in the brain. Parkinson's disease is a motor disorder caused by the death of dopamine-secreting neurons in the substantia nigra.

49 Sensory and Motor Mechanisms

Key Concepts

- 43.1 Sensory receptors transduce stimulus energy and transmit signals to the central nervous system
- 49.2 The mechanoreceptors involved with hearing and equilibrium detect settling particles or moving fluid
- 4S3 The senses of taste and smell are closely related in most animals
- 49.4 Similar mechanisms underlie vision throughout the animal kingdom
- 4.9.5 Animal skeletons function in support, protection, and movement
- ^•9.6 Muscles move skeletal parts by contracting
- 49.7 Locomotion requires energy to overcome friction and gravity

Overview

Sensing and Acting

In the gathering dusk, a male moth's antennae detect the chemical attractant of a female moth somewhere upwind. The male takes to the air, following the scent trail toward the female. Suddenly, vibration sensors in the male moth's abdomen detect the ultrasonic chirps of a rapidly approaching bat. The bat's sonar enables it to locate moths and other flying insect prey. Reflexively, the moth's nervous system alters the motor output to its wing muscles, sending the insect into an evasive spiral toward the ground. Although it is probably too late for the moth in **Figure 49.1**, many moths can escape in such situations because they can detect the sonar of a bat as much as 30 m away. The bat must be within 3 m to sense the

moth, but since the bat flies faster, it may still have time to detect, home in on, and catch its prey.

The outcome of this interaction depends on the abilities of both predator and prey to sense important environmental stimuli and to produce appropriate coordinated movement. We can trace the origins of sensing and acting back to the appearance, in prokaryotes, of cellular structures that sense pressure or chemicals in the environment and then direct movement in an appropriate direction. These structures have been transformed during evolution into diverse mechanisms that sense various types of energy and generate many different levels of physical movement in response. The detection and processing of sensory information and the generation of motor output provide the physiological basis for all animal behavior.

It is customary to think of animal behavior as a linear sequence of sensing, brain analysis, and action—similar to a computer passively waiting for instructions before it acts. This is not the case. When animals are in motion, they are probing the environment through that motion, sensing changes, and using the information to generate the next action. This is a continuous cycle rather than a linear sequence, as the brain carries on background activity that is constantly updated as sensing and acting proceed.

In Chapter 48, we examined how nervous systems transmit and integrate sensory and motor information. Here we will explore, in several invertebrate and vertebrate groups, the processes of sensing and acting. We will start with sensory processes that convey information about the external and internal environment to the brain. We will then consider the structure and function of skeletons and muscles that carry out movements as instructed by the brain. Finally, we will investigate various mechanisms of animal movement.

Concept 49.1

Sensory receptors transduce stimulus energy and transmit signals to the central nervous system

Information is transmitted through the nervous system in the form of nerve impulses, or action potentials, which are all-or-none events (see Figure 48.12c). An action potential triggered by light striking the eye is the same as an action potential triggered by air vibrating in the ear. The ability to distinguish any type of stimulus, such as sight or sound, depends on the part of the brain that receives the action potentials. What matters is where action potentials go, not what triggers them.

Sensations are action potentials that reach the brain via sensory neurons. Once the brain is aware of sensations, it interprets them, giving the perception of stimuli. Perceptions—such as colors, smells, sounds, and tastes—are constructions formed in the brain and do not exist outside it. If a tree falls and no animal is present to hear it, is there a sound? The fall certainly produces pressure waves in the air, but if sound is defined as a perception, then there is none unless an animal senses the waves and its brain perceives them.

Sensations and perceptions begin with sensory reception, the detection of a stimulus by sensory cells, which are called sensory receptors. Most sensory receptors are specialized neurons or epithelial cells that exist singly or in groups with other cell types in sensory organs, such as the eyes and ears. Exteroceptors are sensory receptors that detect stimuli coming from outside the body, including heat, light, pressure, and chemicals. Interoceptors detect stimuli coming from within the body, such as blood pressure and body position.

Functions Performed by Sensory Receptors

All stimuli represent forms of energy. Sensation involves converting this energy into a change in the membrane potential of sensory receptors, which leads to a change in frequency of action potentials transmitted to the central nervous system (CNS). Sensory receptors perform four functions in this process: sensory transduction, amplification, transmission, and integration. These functions are shown in Figure 49.2 for two types of sensory receptors: a stretch receptor in a crayfish and a hair cell, which detects motion in the vertebrate ear and in lateral line systems of fishes and amphibians.

Sensory Transduction

The conversion of stimulus energy into a change in the membrane potential of a sensory receptor is called sensory transduction, and the change in membrane potential itself is

known as a receptor potential. Note in Figure 49.2a that receptor potentials are graded potentials; their magnitude varies with the strength of the stimulus.

All receptor potentials result from the opening or closing of ion channels in the sensory receptor's plasma membrane, which changes the ionic permeability of the membrane. In the examples in Figure 49.2, stretching or bending of the membrane is the stimulus that causes ion channels to open or close. In other sensory receptors, channels open or close when substances outside the cell bind to proteins on the membrane or when pigments in the sensory receptor absorb light. We will examine these mechanisms later in the chapter.

One amazing feature of many sensory receptors is extreme sensitivity: They can detect the smallest physical unit of stimulus possible. Most light receptors can detect a single quantum (photon) of light; chemical receptors can detect a single molecule; and hair cells of the inner ear can detect a motion of only a fraction of a nanometer. Receptor sensitivity also changes with conditions. For example, the sensitivity of glucose receptors in the human mouth can vary over several orders of magnitude of sugar concentration as both the general state of nutrition and amount of sugar in the diet change.

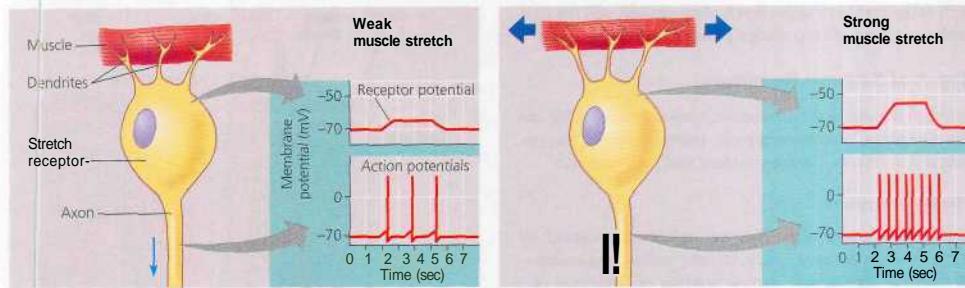

Amplification

The strengthening of stimulus energy by cells in sensory pathways is called amplification. For example, an action potential conducted from the eye to the brain has about 100,000 times as much energy as the few photons of light that triggered it. Some amplification occurs in sensory receptors, and signal transduction pathways involving second messengers often contribute to it. Amplification may also take place in accessory structures of a complex sense organ, as when sound waves are enhanced by a factor of more than 20 before reaching receptors of the inner ear.

Transmission

After energy in a stimulus has been transduced into a receptor potential, action potentials are transmitted to the CNS. Some sensory receptors, such as the crayfish stretch receptor, are sensory neurons that can produce action potentials and have an axon that extends into the CNS (see Figure 49.2a). Others, such as hair cells, lack an axon and cannot generate action potentials themselves; these receptors release neurotransmitters at synapses with sensory neurons (see Figure 49.2b). In almost all pathways where receptors synapse with sensory neurons, the receptor releases an excitatory neurotransmitter, causing the sensory neuron to transmit action potentials to the CNS. (An exception is in the vertebrate visual system, discussed in Concept 49.4.)

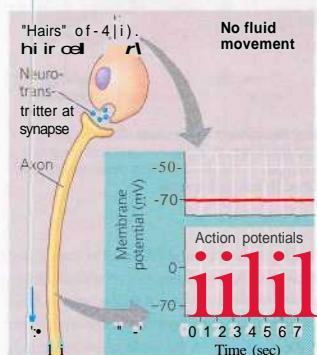

The magnitude of a receptor potential affects the frequency of action potentials that travel as sensations to the CNS. If a receptor is also a sensory neuron, a larger receptor potential

(a) **Crayfish stretch receptors** have dendrites embedded in abdominal muscles. When the abdomen bends, muscles and dendrites

stretch, producing a receptor potential in the stretch receptor. The receptor potential triggers action potentials in the axon of the stretch

receptor. A stronger stretch produces a larger receptor potential and higher frequency of action potentials.

(b) **Vertebrate hair cells** have specialized cilia or microvilli ("hairs") that bend when surrounding fluid moves. Each hair cell releases an excitatory neurotransmitter at a synapse

with a sensory neuron, which conducts action potentials to the CNS. Bending in one direction depolarizes the hair cell, causing it to release more neurotransmitter and increasing frequency

of action potentials in the sensory neuron. Bending in the other direction has the opposite effects. Thus, hair cells respond to the direction of motion as well as to its strength and speed.

▲ **Figure 49.2** Sensory reception: two mechanisms.

reaches the threshold sooner, resulting in more frequent action potentials (see Figure 49.2a). If a receptor synapses with a sensory neuron, a larger receptor potential causes more neurotransmitter to be released at the synapse, usually with the same result. Many sensory neurons spontaneously generate action potentials at a low rate. Therefore, a stimulus does not switch the production of action potentials on or off in these neurons; rather, it modulates action potential frequency (see Figure 49.2b). Such neurons alert the CNS not only to the presence or absence of a stimulus but also to changes in intensity or direction.

Integration

The processing, or integration, of sensory information begins as soon as the information is received. Receptor potentials

produced by stimuli delivered to different parts of a sensory receptor are integrated through summation, as are postsynaptic potentials in sensory neurons that synapse with multiple receptors. Another type of integration by receptors is **sensory adaptation**, a decrease in responsiveness during continued stimulation (not to be confused with the evolutionary sense of the term *adaptation*). Some receptors adapt to stimuli more quickly than others. Without sensory adaptation, you would feel every beat of your heart and every bit of clothing on your body. Receptors are selective in the information they send to the CNS, and adaptation reduces the likelihood that a maintained stimulus will result in a continuous sensation.

The integration of sensory information occurs at all levels within the nervous system, and the cellular actions just described are only the first steps. Complex sensory structures

such as the eyes have higher levels of integration, and the CNS further processes all incoming signals.

Types of Sensory Receptors

Based on the energy they transduce, sensory receptors fall into five categories: mechanoreceptors, chemoreceptors, electromagnetic receptors, thermoreceptors, and pain receptors.

Mechanoreceptors

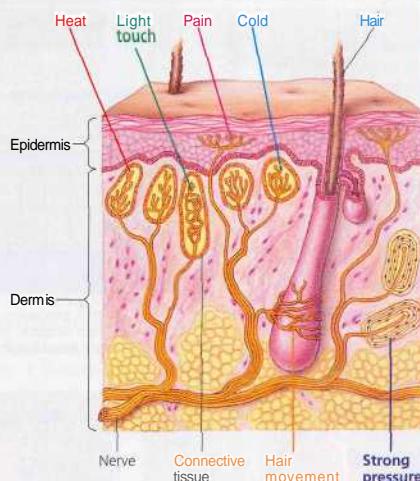

Mechanoreceptors sense physical deformation caused by stimuli such as pressure, touch, stretch, motion, and sound—all forms of mechanical energy. Bending or stretching of a mechanoreceptor's plasma membrane increases the membrane's permeability to sodium and potassium ions. When this happens, the membrane potential moves to a value between E_K and E_{Na^+} , resulting in depolarization (see Chapter 48).

The crayfish stretch receptor and the vertebrate hair cell in Figure 49.2 are mechanoreceptors. Another example is the vertebrate stretch receptor, which monitors the length of skeletal "muscles." The mechanoreceptors in this case are the dendrites of sensory neurons that spiral around the middle of small skeletal muscle fibers. Muscle spindles, each containing about 2 to 12 of these fibers surrounded by connective tissue, are distributed throughout the muscle, parallel to other muscle fibers. When the muscle is stretched, the spindle fibers are stretched, depolarizing sensory neurons and triggering action potentials that are transmitted to the spinal cord. Muscle spindles and the sensory neurons that innervate them are part of nerve circuits that underlie reflexes (see Figure 48.4).

The mammalian sense of touch also relies on mechanoreceptors that are the dendrites of sensory neurons. Often they are embedded in layers of connective tissue (Figure 49.3). The structure of the connective tissue and the location of the receptors dramatically affect the type of mechanical energy (light touch, vibration, or strong pressure) that best stimulates them. Receptors that detect light touch are close to the surface of the skin; they transduce very slight inputs of mechanical energy into receptor potentials. Receptors responding to strong pressure and vibrations are in deep skin layers. Other receptors sense movement of hairs (not to be confused with the hair cells in Figure 49.2); those at the base of the stout whiskers of mammals such as cats and many rodents are extremely sensitive and enable the animal to detect nearby objects in the dark.

Chemoreceptors

Chemoreceptors include both general receptors that transmit information about the total solute concentration of a solution and specific receptors that respond to individual kinds of molecules. Osmoreceptors in the mammalian brain, for example, are general receptors that detect changes in the total solute concentration of the blood and stimulate thirst when osmolarity increases (see Chapter 44). Water receptors in the feet of house-

A Figure 49.3 Sensory receptors in human skin. Receptors in the epidermis are naked dendrites, as are hair movement receptors wound around the base of hairs in the dermis. Most other receptors in the dermis are encapsulated by connective tissue.

flies respond to pure water or to a dilute solution of virtually any substance. Most animals also have receptors for specific molecules, including glucose, oxygen, carbon dioxide, and amino acids. Two of the most sensitive and specific chemoreceptors known are present in the antennae of the male silkworm moth (Figure 49.4). They detect the two chemical components of the female moth sex pheromone. In all these examples, the stimulus molecule binds to a specific site on the membrane of the receptor cell and initiates changes in membrane permeability.

Electromagnetic Receptors

Electromagnetic receptors detect various forms of electromagnetic energy, such as visible light, electricity, and magnetism. Photoreceptors, electromagnetic receptors that detect the radiation we know as visible light, are often organized into eyes. Some snakes have very sensitive infrared receptors that detect body heat of prey against a colder background (Figure 49.5a). Some fishes generate electric currents and use electroreceptors to locate objects, such as prey, that disturb those currents. The platypus, a monotreme mammal, has electroreceptors on its bill that probably detect electric fields generated by the muscles of crustaceans, frogs, small fish, and other prey. Many animals appear to use Earth's magnetic field lines to orient themselves as they migrate (Figure 49.5b). The iron-containing mineral magnetite is found in the skulls of many vertebrates (including salmon, pigeons, sea turtles, and humans), in the abdomen of

i. Figure 49.4 Chemoreceptors in an insect. The antennae of the male silkworm moth *Bombyx mori* are covered with sensory hairs, visible in the SEM enlargement. The hairs have chemoreceptors that are highly sensitive to the sex pheromone released by the female.

bees, in the teeth of some molluscs, and in certain protists and prokaryotes that orient to Earth's magnetic field. Once used by sailors as a compass, magnetite may be part of an orienting mechanism in many animals.

Thermoreceptors

Thermoreceptors, which respond to heat or cold, help regulate body temperature by signaling both surface and body core temperature. Debate continues about the identity of thermoreceptors in mammalian skin. Possible candidates are two receptors consisting of encapsulated, branched dendrites (see [Figure 49.3]). Many researchers, however, think that these 'structures are modified pressure receptors and that thermoreceptors consist of naked dendrites of certain sensor' neurons. There is general agreement that thermoreceptors in the skin and in the anterior hypothalamus send information to the body's thermostat, located in the posterior **hypothalamus**.

Pain Receptors

In humans, **pain receptors**, also called **nociceptors** (from the Latin *nocere*, to hurt) are a class of naked dendrites in the epidermis (see Figure 49.3). Most animals probably experience pain, although we cannot say what perceptions other animals associate with stimulation of pain receptors. Pain is an important sensation because the stimulus usually leads to a defensive reaction, such as withdrawal from danger. Rare individuals who are born without any pain sensation may die from

(a) This rattlesnake and other pit vipers have a pair of infrared receptors, one between each eye and nostril. The organs are sensitive enough to detect the infrared radiation emitted by a warm mouse a meter away. The snake moves its head from side to side until the radiation is detected equally by the two receptors, indicating that the mouse is straight ahead.

(b) Some migrating animals, such as these beluga whales, apparently sense Earth's magnetic field and use the information, along with other cues, for orientation.

A Figure 49.5 Specialized electromagnetic receptors.

conditions such as a ruptured appendix because they cannot feel the associated pain and are unaware of the danger.

Different groups of pain receptors respond to excess heat, pressure, or specific classes of chemicals released from damaged or inflamed tissues. Some chemicals that trigger pain include histamine and acids. Prostaglandins increase pain by sensitizing receptors—that is, lowering their threshold (see Chapter 45); aspirin and ibuprofen reduce pain by inhibiting prostaglandin synthesis. While density of nociceptors is highest in the skin, some are associated with other organs.

Concept Check 49.1

1. Why do drugs that interfere with synaptic transmission block some but not all sensations?
2. If you were to apply an anesthetic to your skin, which senses would be affected first? Which would be affected last or not at all? Explain.

For suggested answers, see Appendix A.

Concept 49.2

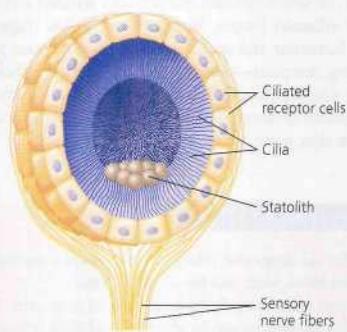

The mechanoreceptors involved with hearing and equilibrium detect settling particles or moving fluid

Hearing and the perception of body equilibrium, or balance, are related in most animals. Both involve mechanoreceptors that produce receptor potentials when some part of the membrane is bent by settling particles or moving fluid.

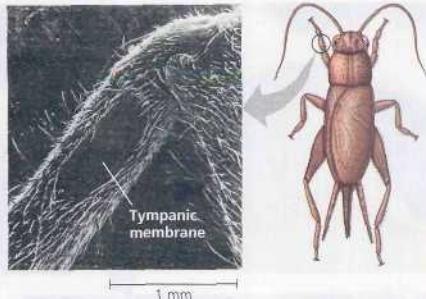

Sensing Gravity and Sound in Invertebrates

Most invertebrates have sensor¹ organs called statocysts that contain mechanoreceptors and function in their sense of equilibrium (**Figure 49.6**). A common type of statocyst consists of a layer of ciliated receptor cells surrounding a chamber that contains one or more statoliths, which are grains of sand or other dense granules. Gravity causes the statoliths to settle to the low point in the chamber, stimulating receptors in that location. Statocysts are located in different parts of invertebrates' bodies. For example, many jellies have statocysts at the fringe of their "bell," giving the animals an indication of body position. Lobsters and crayfish have statocysts near the base of their antennules. In experiments, crayfish have been "tricked" into swimming upside down when their statoliths were replaced with metal shavings that were pulled to the upper end of the statocysts with magnets.

Many invertebrates demonstrate a general sensitivity to sound, although structures specialized for hearing seem to be less widespread than gravity sensors. Hearing structures have been studied most extensively in terrestrial insects.

A Figure 49.6 The statocyst of an invertebrate. The settling of statoliths to the low point in the chamber bends cilia on receptor cells in that location, providing the brain with information about the orientation of the body with respect to gravity.

A Figure 49.7 An insect ear. The tympanic membrane, visible in this SEM of a cricket's front leg, vibrates in response to sound waves. The vibrations stimulate mechanoreceptors attached to the inside of the tympanic membrane.

Many (perhaps most) insects have body hairs that vibrate in response to sound waves. Hairs of different stiffnesses and lengths vibrate at different frequencies. The hairs are commonly tuned to frequencies of sounds produced by other organisms. For example, a male mosquito locates a mate by means of fine hairs on his antennae. The hairs vibrate in a specific way in response to the hum produced by the beating wings of flying females. A tuning fork that vibrates at the same frequency as a female mosquito's wings will also attract males. Some caterpillars (larval moths and butterflies) have vibrating body hairs that can detect the buzzing wings of predatory wasps, warning the caterpillars of the danger.

Many insects also have localized "ears," in which a tympanic membrane (eardrum) is stretched over an internal air chamber (**Figure 49.7**). Sound waves vibrate the tympanic membrane, stimulating receptor cells attached to the inside of the membrane and resulting in nerve impulses that are transmitted to the brain. Some moths can hear the high-pitched sounds that bats produce for sonar, and perceiving these sounds triggers the moths' escape maneuver, as mentioned at the beginning of this chapter. This also explains why it is so difficult to step on a cockroach; the insect senses your descending foot and moves very quickly to avoid it.

Hearing and Equilibrium in Mammals

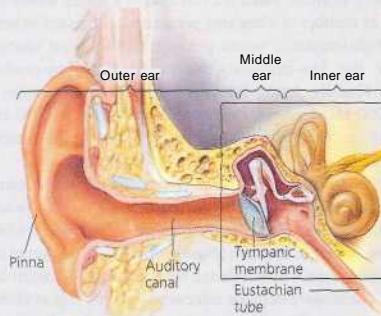

In mammals, as in most other terrestrial vertebrates, the sensory organs for hearing and equilibrium are closely associated in the ear. **Figure 49.8** explores the structure of these organs in the human ear.

Hearing

How does the ear convert the energy of pressure waves traveling through air into nerve impulses that the brain perceives as sound? Vibrating objects, such as a plucked guitar string or the

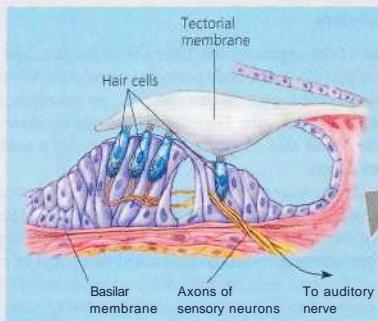

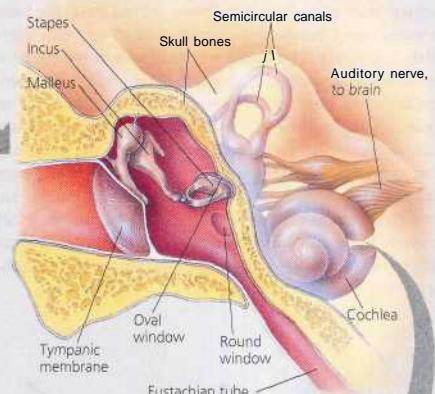

Exploring The Structure of the Human Ear

1 Overview of ear structure. The mammalian ear can be divided into three regions: the outer ear, middle ear, and inner ear. The **outer ear** consists of the external pinna and the auditory canal, which collect sound waves and channel them to the **tympanic membrane** (eardrum) separating the outer ear from the middle ear.

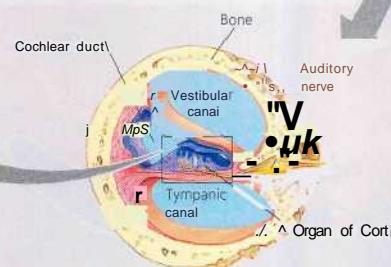

2 The middle ear and inner ear. In the **middle ear**, three small bones—the **malleus** (hammer), **incus** (anvil), and **stapes** (stirrup)—transmit vibrations to the **oval window**, which is a membrane beneath the stapes. The middle ear also opens into the **Eustachian tube**, which connects with the pharynx and equalizes pressure between the middle ear and the atmosphere, enabling you to "pop" your ears when you change altitude, for example.

The **inner ear** consists of a labyrinth of fluid-filled chambers within the temporal bone of the skull. These chambers include the **semicircular canals**, which function in equilibrium, and the coiled **cochlea** (Latin, "snail"), which is involved in hearing.

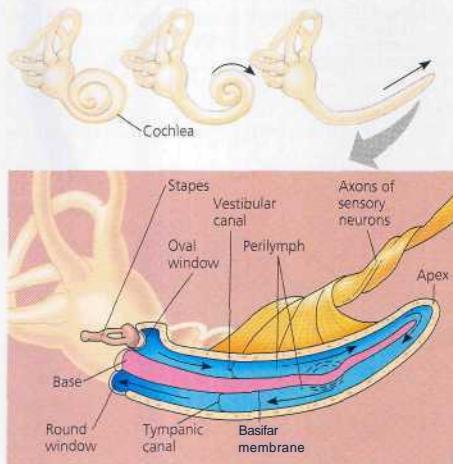

3 The organ of Corti. The floor of the cochlear duct, the **basil membrane**, bears the **organ of Corti**, which contains the mechanoreceptors of the ear, hair cells with hairs projecting into the cochlear duct. Many of the hairs are attached to the **tectorial membrane**, which hangs over the organ of Corti like a shelf. Sound waves make the basilar membrane vibrate, which results in bending of the hairs and depolarization of the hair cells.

4 The cochlea. The cochlea has two large canals—an upper **vestibular canal** and a lower **tympatic canal**—separated by a smaller **cochlear duct**. The vestibular and tympanic canals contain a fluid called **perilymph**, and the cochlear duct is filled with a fluid called **endolymph**.

vocal cords of a speaking person, create percussion waves in the surrounding air. These waves cause the tympanic membrane to vibrate with the same frequency as the sound. The three bones of the middle ear transmit the vibrations to the oval window, a membrane on the cochlea's surface. When one of those bones, the stapes, vibrates against the oval window, it creates pressure waves in the fluid of the cochlea. The waves travel through the vestibular canal, pass around the apex (tip) of the cochlea, and continue through the tympanic canal, dissipating as they strike the round window (**Figure 49.9**).

Pressure waves in the vestibular canal push down on the cochlear duct and basilar membrane. In response, the basilar membrane vibrates up and down, and its hair cells alternately brush against and are withdrawn from the tectorial membrane. That causes the hairs to bend first in one direction and then the other with each vibration. As shown in Figure 49.2b, bending in one direction depolarizes the hair cells, increasing neurotransmitter release and the frequency of action potentials in the sensory neurons with which they synapse. These neurons carry sensations to the brain through the auditory nerve. Bending of the hairs in the other direction hyperpolarizes the hair cells, reducing neurotransmitter release and the frequency of sensations in the auditory nerve.

A Figure 49.9 Transduction in the cochlea. For simplicity, the cochlea is shown uncoiled here and in Figure 49.10, even though it does not physically uncoil. Vibrations of the stapes against the oval window produce pressure waves in the perilymph of the cochlea. The waves (black arrows) travel to the apex of the cochlea through the vestibular canal and back toward the base through the tympanic canal. The energy in the waves causes the basilar membrane to vibrate, stimulating hair cells.

If sound is represented by changes in the frequency of sensations in the auditory nerve, how is the quality of sound conveyed? Two important sound variables are volume and pitch. Volume (loudness) is determined by the amplitude, or height of the sound wave. A large-amplitude sound wave causes a more vigorous vibration of the basilar membrane, a greater bending of the hairs on hair cells, and more action potentials in the sensory neurons. Pitch is a function of a sound wave's frequency, or number of vibrations per second, expressed in hertz (Hz). High-frequency waves produce high-pitched sounds, whereas the low-frequency waves produce low-pitched sounds. Healthy young humans can hear in the range of 20–20,000 Hz; dogs can hear sounds as high as 40,000 Hz; and bats can emit and hear clicking sounds at frequencies above 100,000 Hz, using this ability to locate objects.

The cochlea can distinguish pitch because the basilar membrane is not uniform along its length: It is relatively narrow and stiff at the base of the cochlea near the oval window and wider and more flexible at the apex (**Figure 49.10**). Each region of the basilar membrane is most affected by a particular vibration frequency. The sensory neurons associated with the region vibrating most vigorously at any instant send the highest frequency of action potentials along the auditory nerve. But the actual perception of pitch occurs in the brain. Axons in the auditory nerve project into specific auditory areas of the cerebral cortex according to the region of the basilar membrane in which the signal originated. When a particular site in our cortex is stimulated, we perceive the sound of a particular pitch.

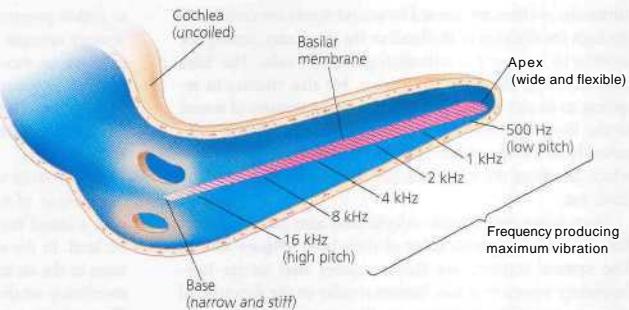

Equilibrium

Several of the organs in the inner ear of humans and most other mammals detect body position and balance. Behind the oval window is a vestibule that contains two chambers, called the **utricle** and **saccule**. The utricle opens into the three semicircular canals that complete the apparatus for equilibrium (**Figure 49.11**).

Sensations related to body position are generated much like the sensations of sound in humans and most other mammals. Hair cells in the utricle and the saccule respond to changes in head position with respect to gravity and movement in one direction. The hair cells are arranged in clusters, and all of the hairs project into a gelatinous material containing many small calcium carbonate particles called otoliths ("ear stones"). Because this material is heavier than the endolymph within the utricle and the saccule, gravity is always pulling downward on the hairs of the receptor cells, sending a constant series of action potentials along the sensor⁷ neurons of the vestibular branch of the auditory nerve. This mechanism is similar to how statocysts function in invertebrates, and indeed the utricle and saccule are considered to be specialized types of statocysts.

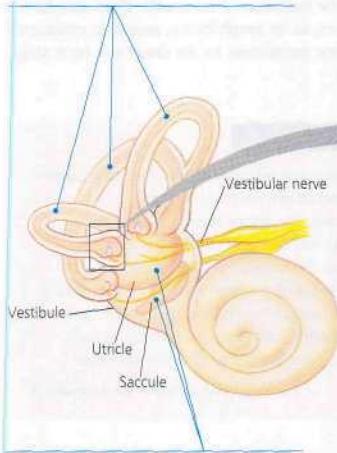

Different body angles cause different hair cells and their sensory neurons to be stimulated. When the position of the

Figure 49.10 How the cochlea distinguishes pitch. Variation in the width and stiffness of the basilar membrane (pink) along its length "tunes" specific regions of the basilar membrane to specific frequencies. As a result, different frequencies of pressure waves in the cochlea cause different places along the basilar membrane to vibrate, stimulating particular hair cells and sensory neurons. The selective stimulation of hair cells is perceived in the brain as sound of a certain pitch.

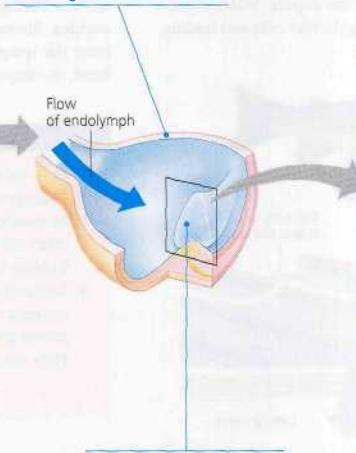

• **Figure 49.11 Organs of equilibrium in the inner ear.**

The semicircular canals, arranged in three spatial planes, detect angular movements of the head.

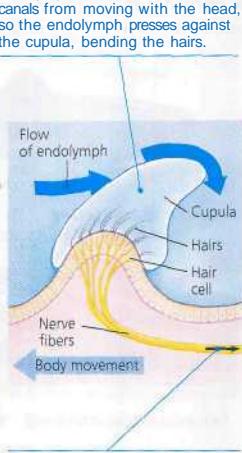

The utricle and saccule tell the brain which way is up and inform it of the body's position or linear acceleration.

Each canal has at its base a swelling called an ampulla, containing a cluster of hair cells.

The hairs of the hair cells project into a gelatinous cap called the cupula.

When the head changes its rate of rotation, inertia prevents endolymph in the semicircular canals from moving with the head, so the endolymph presses against the cupula, bending the hairs.

Bending of the hairs increases the frequency of action potentials in sensory neurons in direct proportion to the amount of rotational acceleration.

head changes with respect to gravity (as when the head bends forward), the force on a hair cell changes, and the cell increases or decreases its release of neurotransmitter. The brain interprets the resulting changes in impulse production by the sensory neurons as a change in the position of the head. By a similar mechanism, the semicircular canals, arranged in the three spatial planes, detect changes in the rate of rotation or angular movements of the head (see Figure 49.11). When you spin around, the equilibrium in the semicircular canals is disrupted, which is why you become dizzy.

Hearing and Equilibrium in Other Vertebrates

Like other vertebrates, fishes and aquatic amphibians also have inner ears located near the brain. There is no cochlea, but there are a saccule, an utricle, and semicircular canals, structures homologous to the equilibrium sensors of human ears. Within these chambers in the inner ear of a fish, the movement of otoliths stimulates sensory hairs. Unlike the mammalian hearing apparatus, the ear of a fish has no eardrum and does not open to the outside of the body. The

vibrations of the water caused by sound waves are conducted through the skeleton of the head to the inner ears, setting the otoliths in motion and stimulating the hair cells. The fish's air-filled swim bladder (see Chapter 34) also vibrates in response to sound and may contribute to the transfer of sound to the inner ear. Some fishes, including catfishes and minnows, have a series of bones, called the Weberian apparatus, which conducts the vibrations from the swim bladder to the inner ear.

Most fishes and aquatic amphibians also have a lateral line system along both sides of their body (Figure 49.12). The system contains mechanoreceptors that detect low-frequency waves by a mechanism similar to the function of the inner ear. Water from the animals surroundings enters the lateral line system through numerous pores and flows along a tube past the mechanoreceptors. The receptor units, called neuromasts, resemble the ampullae in our semicircular canals. Each neuromast has a cluster of hair cells whose hairs are embedded in a gelatinous cap, the cupula. Water movement bends the cupula, depolarizing the hair cells and leading

to action potentials that are transmitted along the axons of sensory neurons to the brain. This information helps the fish perceive its movement through water or the direction and velocity of water currents flowing over its body. The lateral line system also detects water movements or vibrations that are generated by other moving objects, including prey and predators.

In terrestrial vertebrates, the inner ear has evolved as the main organ of hearing and equilibrium. Some amphibians have a lateral line system as tadpoles, but not as adults living on land. In the ear of a terrestrial frog or toad, sound vibrations in the air are conducted to the inner ear by a tympanic membrane on the body surface and a single middle ear bone. There also is evidence that the lungs of a frog vibrate in response to sound and transmit their vibrations to the eardrum via the auditory tube. A small side pocket of the saccule functions as the main hearing organ of the frog, and it is this outgrowth of the saccule that gave rise to the more elaborate cochlea during the evolution of mammals. Birds also have a cochlea. However, as in amphibians, sound is conducted from the tympanic membrane to the inner ear by a single bone, the stapes.

Concept Check 49.2

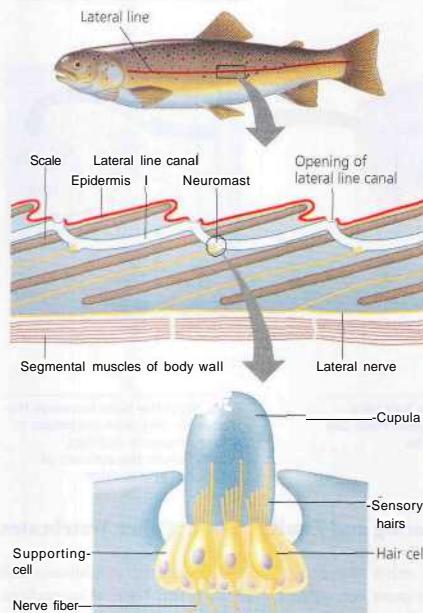

- How are statocysts adaptive for animals that burrow underground or live deep in the ocean?
- In otosclerosis, the stapes becomes fused to the other middle ear bones or to the oval window. Explain how this condition affects hearing.
- Suppose a series of pressure waves in your cochlea causes a vibration of the basilar membrane that moves gradually from the apex toward the base. How would your brain interpret this stimulus?

For suggested answers, see Appendix A.

Concept 49.3

The senses of taste and smell are closely related in most animals

Many animals use their chemical senses to find mates (as when male silk moths respond to pheromones emitted by females), to recognize territory that has been marked by some chemical substance (as when dogs and cats sniff boundaries that have been staked out by their spraying neighbors), and to help navigate during migration (as when salmon use the unique scent of their streams of origin to return for breeding). Chemical "conversation" is especially important for animals, such as ants and bees, that live in large social groups. In all

k Figure 49.12 The lateral line system in a fish. Water flowing through the system bends hair cells. The hair cells transduce the energy into receptor potentials, triggering action potentials that are conveyed to the brain. The lateral line system enables a fish to monitor water currents, pressure waves produced by moving objects, and low-frequency sounds conducted through the water.

animals, chemical senses are important in feeding behavior. For example, a hydra begins to make ingestive movements when it detects the compound glutathione, which is released from prey captured by the hydra's tentacles.

The perceptions of **gustation** (taste) and **olfaction** (smell) are both dependent on chemoreceptors that detect specific chemicals in the environment. In the case of terrestrial animals, taste is the detection of chemicals that are present in a solution, and smell is the detection of chemicals that are carried through the air. There is no distinction between taste and smell in aquatic animals.

The taste receptors of insects are located within sensory hairs called sensilla, which are located on the feet and in mouthparts. These animals use their sense of taste to select food. A tasting hair contains several chemoreceptors, each especially responsive to a particular class of chemical stimuli, such as sugar or salt (Figure 49.13). Insects are also capable of smelling airborne chemicals using olfactory hairs, usually located on the antennae (see Figure 49.4).

Taste in Humans

The receptor cells for taste in humans are modified epithelial cells organized into **taste buds**, which are scattered in several areas of the tongue and mouth, as shown in Figure 49.14 on the next page. Most taste buds on the tongue are associated with nipple-shaped projections called papillae. In addition to the four familiar taste perceptions—sweet, sour, salty, and bitter—a fifth, called umami (Japanese for "delicious"), is elicited by the amino acid glutamate and perhaps others. Glutamate is the key component of the flavor enhancer monosodium glutamate (MSG) and is abundant in foods such as meat and aged cheese. Each type of taste receptor can be stimulated by a broad range of chemicals but is most responsive to a particular type of substance. Complex flavors are perceived as the brain integrates the differential input from many taste receptors.

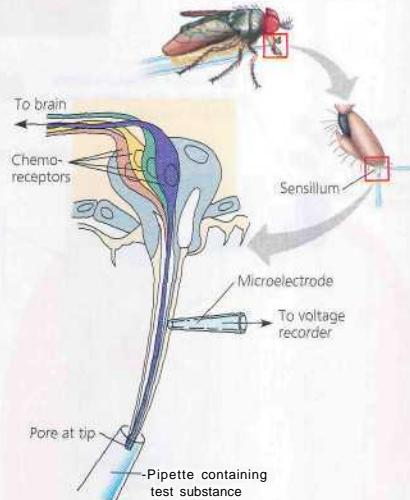

Transduction in taste receptors occurs by several mechanisms. Chemoreceptors that detect saltiness—mainly the presence of sodium ions (Na^+)—and sourness—hydrogen ions (H^+) generated by acids—have channels in their plasma membrane through which these ions can diffuse. The influx of Na^+ or H^+ depolarizes the cell. The mechanism for umami chemoreceptors may involve the binding of glutamate to Na^+ channels; when glutamate is bound, the channels open, Na^+ diffuses into the cell, and the cell depolarizes. In some chemoreceptors that detect bitter substances, such as quinine, the substance binds to potassium ion (K^+) channels and closes them; the resulting decrease in the membrane's permeability to K^+ depolarizes the cell. Finally, sweetness is detected by chemoreceptors that have receptor proteins for sugars; binding of a sugar molecule to a receptor protein triggers a signal transduction pathway that results in depolarization (see Figure 49.14). In all taste receptors, the depolarization causes

Figure 49.13

inquiry How do insects detect different tastes?

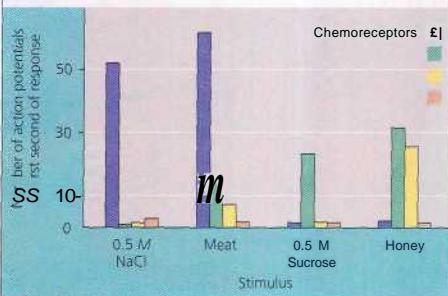

EXPERIMENT

insects taste using gustatory sensilla (hairs) on their feet and mouthparts. Each sensillum contains four chemoreceptors with dendrites that extend to a pore at the tip of the sensillum. To study the sensitivity of each chemoreceptor, researchers immobilized a blowfly (*Phormia regina*) by attaching it to a rod with wax. They then inserted the tip of a microelectrode into one sensillum to record action potentials in the chemoreceptors, while they used a pipette to touch the pore with various test substances.

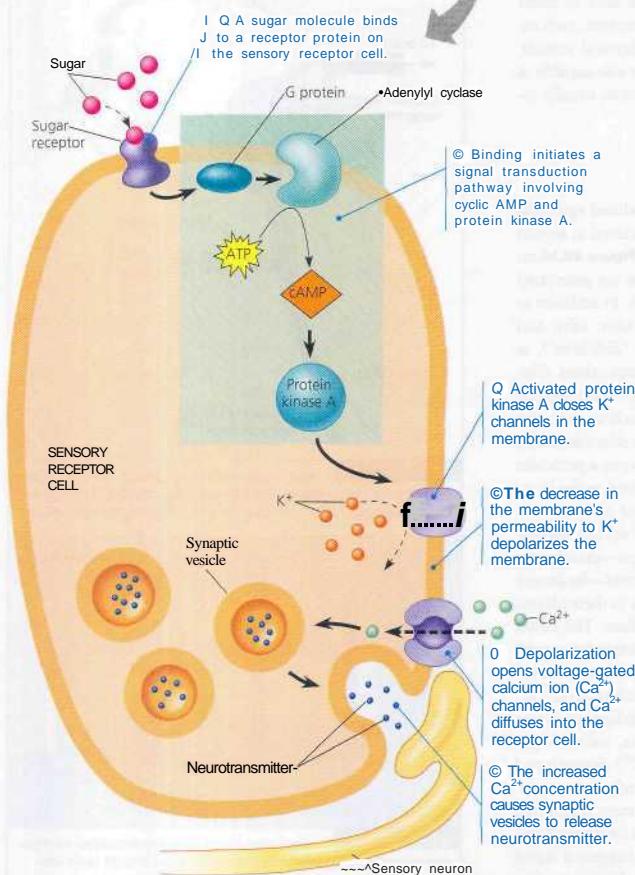

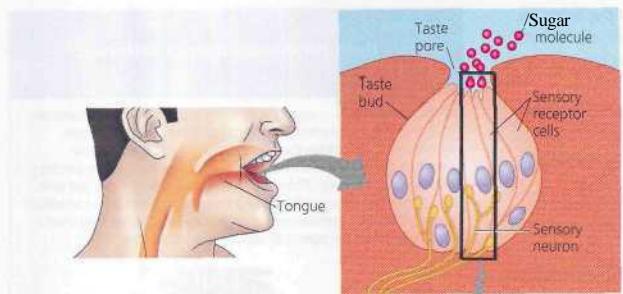

RESULTS

Each chemoreceptor is especially sensitive to a particular class of substance, but this specificity is relative; each cell can respond to some extent to a broad range of different chemical stimuli.

CONCLUSION

Any natural food probably stimulates multiple chemoreceptors. By integrating sensations, the insect's brain can apparently distinguish a very large number of tastes.

A Figure 49.14 Sensory transduction by a sweetness receptor.

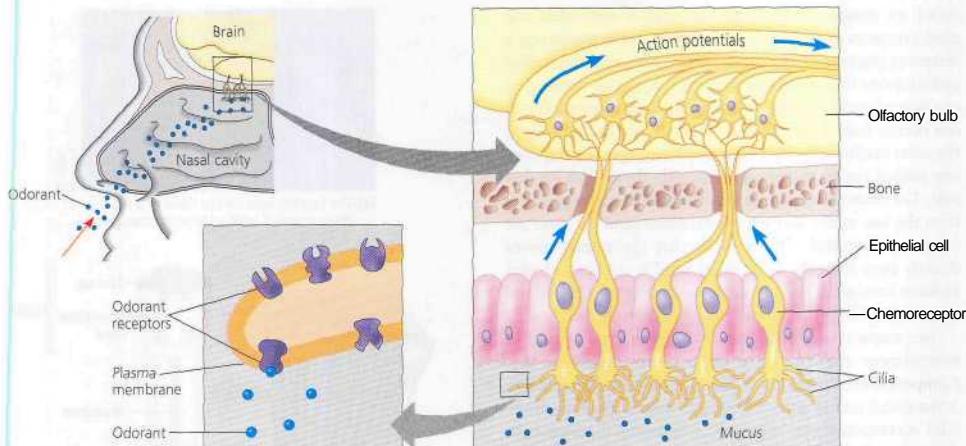

the cell to release neurotransmitter onto I sensory neuron, which transmits action potentials to the brain.

Smell in Humans

Olfactory receptor cells are neurons that line the upper portion of the nasal cavity and send impulses along their axons directly to the olfactory bulb of the brain (Figure 49.15). The receptive ends of the cells contain cilia that extend into the layer of mucus coating the nasal cavity. When an odorous substance, or odorant, diffuses into this region, it binds to specific proteins called odorant receptors (ORs) on the plasma membrane of the olfactory cilia. The binding triggers a signal transduction pathway involving a G protein, the enzyme adenyl cyclase, and the second messenger cyclic AMP. The second messenger opens channels in the plasma membrane that are permeable to both Na⁺ and Ca²⁺ ions. The influx of these ions depolarizes the membrane, causing the receptor cell to generate action potentials.

Humans can distinguish thousands of different odors, each caused by a structurally distinct odorant. This level of sensory discrimination requires many different ORs. There are more than 1,000 OR genes—about 3% of all human genes. Each olfactory receptor cell expresses only one or at most a few OR genes. Cells with different odorant selectivities are interspersed in the nasal cavity, but their axons sort themselves out in the olfactory bulb. Cells that express the same OR gene transmit action potentials to the same small region of the olfactory bulb. In 2004, Richard Axel, of Columbia University, and Linda Buck, of the Fred Hutchinson Cancer Research Center in Seattle, shared a Nobel Prize for their studies of the gene family and receptors that function in olfaction.

Although the receptors and brain pathways for taste and smell are independent, the two senses do interact. Indeed, much of what we call taste is really smell. If the olfactory system is blocked, as by a head cold, the perception of taste is sharply reduced.

1 Figure 49.15 Smell in humans. Odorant molecules bind to specific receptor proteins in the plasma membrane of chemoreceptors, triggering action potentials.

Concept Check 49.3

- How is the location of gustatory sensilla on a fly an adaptation to the fly's feeding behavior?
- Compare sensory transduction in gustatory chemoreceptors for sweetness and olfactory chemoreceptors.

For suggested answers, see Appendix A.

Concept 49.4

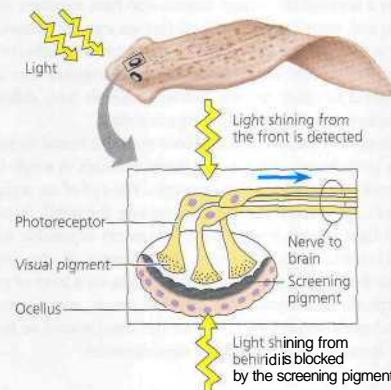

Similar mechanisms underlie vision throughout the animal kingdom

Many types of light detectors have evolved in the animal kingdom, from simple clusters of cells that detect only the direction and intensity of light to complex organs that form images. Despite their diversity all photoreceptors contain similar pigment molecules that absorb light, and most, if not all, photoreceptors in the animal kingdom may be homologous. Animals as diverse as flatworms, annelids, arthropods, and vertebrates share genes associated with the embryonic development of photoreceptors. Thus, the genetic underpinnings of all photoreceptors may have evolved in the earliest bilateral animals. The specific types of eyes that form in an animal depend on developmental patterns regulated by genetic mechanisms that evolved later, and

effects of those mechanisms appear to be superimposed on the common ancestral mechanism.

Vision in Invertebrates

Most invertebrates have some kind of light-detecting organ. One of the simplest is the ocellus (plural, **ocelli**) of planarians, which provides information about light intensity and direction but does not form images (Figure 49.16). Sometimes

A Figure 49.16 Ocelli and orientation behavior of a planarian. The brain directs the body to turn until the sensations from the two ocelli are equal and minimal, causing the animal to move away from light.

called an eyespot or eye cup, an ocellus surrounds the photoreceptors and is formed by a layer of cells containing a screening pigment that blocks light. Light can enter an ocellus and stimulate the photoreceptors only through an opening on one side where there is no screening pigment. The opening of one ocellus faces left and slightly forward, and the opening of the other ocellus faces right-forward. Thus, light shining from one side of the planarian can enter only the ocellus on that side. The brain compares the rate of action potentials coming from the two ocelli, and the animal turns until the rates are equal and minimal. The result is that the animal moves directly away from the light source until it reaches a shaded location beneath a rock or some other object, a behavioral adaptation that helps hide the planarian from predators.

Two major types of image-forming eyes have evolved in invertebrates: the compound eye and the single-lens eye. **Compound eyes** are found in insects and crustaceans (phylum Arthropoda) and in some polychaete worms (phylum Annelida). A compound eye consists of up to several thousand light detectors called **ommatidia** (the "facets" of the eye), each with its own light-focusing lens (**Figure 49.17**). Each ommatidium detects light from a tiny portion of the visual field. Differences in the intensity of light entering the many ommatidia result in a mosaic image. The animal's brain may sharpen the image when it integrates the visual information. The compound eye is extremely capable of detecting movement, an important adaptation for flying insects and small animals constantly threatened with predation. For comparison, note that the human eye can distinguish light flashes up to about 50 flashes per second, whereas the compound eyes of some insects can detect the flickering of a light flashing 330 times per second. Such an insect viewing a movie could easily resolve each frame of the film as a separate still image. Insects also have excellent color vision, and some (including bees) can see into the ultraviolet range of the electromagnetic spectrum, which is invisible to us. In studying animal behavior, we cannot extrapolate our sensory world to other species; different animals have different sensitivities and different brain organizations.

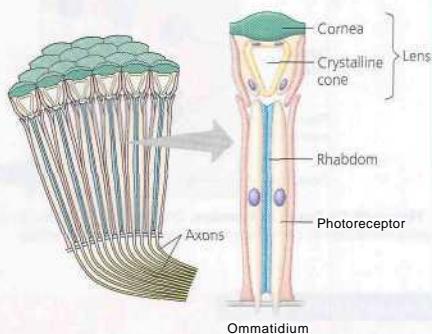

Among invertebrates, single-lens eyes are found in some jellies, polychaetes, spiders, and many molluscs. A single-lens eye works on a camera-like principle. The eye of an octopus or squid, for example, has a small opening, the pupil, through which light enters. Analogous to a camera's adjustable aperture (f-stop), the iris changes the diameter of the pupil; behind the pupil, a single lens focuses light on a layer of photoreceptors. Also similar to a camera's action, muscles in an invertebrate's single-lens eye move the lens forward or backward, focusing on objects at different distances.

The Vertebrate Visual System

Like the single-lens eyes of many invertebrates, the eyes of vertebrates are also camera-like, but they evolved independently in

(a) The faceted eyes on the head of a fly, photographed with a stereomicroscope.

(b) The cornea and crystalline cone of each ommatidium function as a lens that focuses light on the rhabdom, a stack of pigmented plates inside a circle of photoreceptors. The rhabdom traps light and guides it to photoreceptors. The image formed by a compound eye is a mosaic of dots produced by different intensities of light entering the many ommatidia from different angles.

A **Figure 49.17 Compound eyes.**

the vertebrate lineage and differ from the single-lens eyes of invertebrates in several details. Although the eye is the first stage in vision, remember that it is actually the brain that "sees." Thus, to understand vision, we must examine how the vertebrate eye generates sensations (action potentials) and then follow these signals to the visual centers of the brain, where images are perceived.

Structure of the Eye

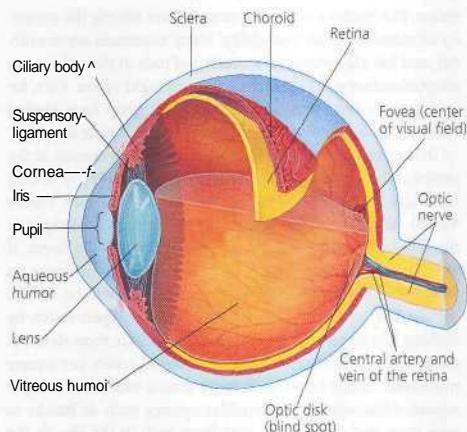

The globe of the vertebrate eye, or **eyeball**, consists of a tough, white outer layer of connective tissue called the **sclera** and a thin, pigmented inner layer that is called the **choroid** (**Figure 49.18**). A delicate layer of epithelial cells forms a mucous membrane, the **conjunctiva**, that covers the outer surface of the sclera and helps keep the eye moist. At the front of the eye, the sclera becomes the transparent **cornea**, which lets light into the eye and acts as a fixed lens. The conjunctiva does not cover the cornea. The anterior choroid forms the doughnut-shaped **iris**, which gives the eye its color. By

changing size, the iris regulates the amount of light entering the **pupil**, the hole in the center of the iris, just inside the choroid, the **retina** forms the innermost layer of the eyeball and contains the photoreceptors. Information from the photoreceptors leaves the eye at the optic disk, where the optic nerve attaches to the eye. Because there are no photoreceptors in the optic disk, this spot on the lower outside of the retina is a "blind spot". Light focused onto that part of the retina is not detected.

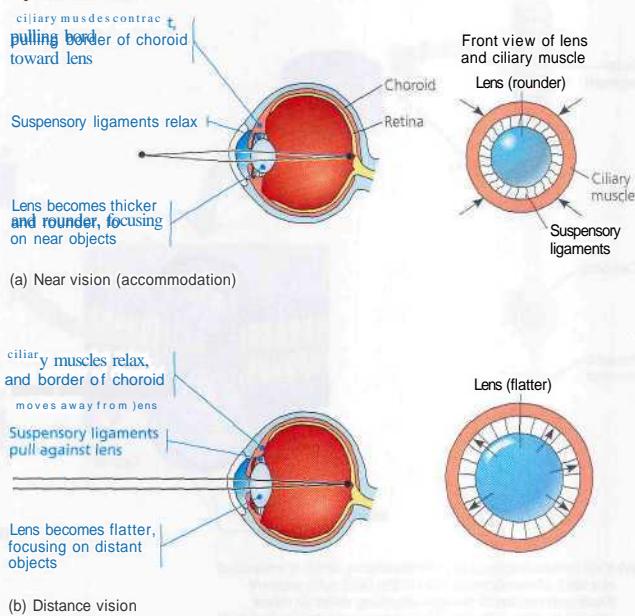

The lens and ciliary body divide the eye into two cavities, an anterior cavity between the lens and the cornea and a much larger posterior cavity behind the lens within the eyeball itself. The ciliary body constantly produces the clear, watery aqueous humor that fills the anterior cavity. Blockage of the ducts that drain the aqueous humor can produce glaucoma, a condition in which increased pressure compresses the retina, causing blindness. The posterior cavity, filled with the jellylike vitreous humor, constitutes most of the volume of the eye. The aqueous and vitreous humors function as liquid lenses that help focus light onto the retina. The lens itself is a transparent protein disk. Like squids and octopuses, many fishes focus by moving the lens forward or backward, as in a camera. Humans and other mammals, however, focus by changing the shape of the lens (**Figure 49.19**). When focusing on a close object, the lens becomes almost spherical, a change called accommodation. When viewing a distant object, the lens is flattened.

The human retina contains about 125 million rods and about 6 million **cones**, two types of photoreceptors that are named for their shapes. These cells account for about 70% of all the sensory receptors in the body, a fact that underscores the importance of the eyes and visual information in how humans perceive their environment.

Rods and cones have different functions in vision, and the relative numbers of these two photoreceptors in the retina are partly correlated with whether an animal is most active during the day or at night. Rods are more sensitive to light but do not distinguish colors; they enable us to see at night, but only in black and white. Because cones are less sensitive, they contribute very little to night vision, but they can distinguish colors in daylight. Color vision is found in all vertebrate classes, though not in all species. Most fishes, amphibians, and reptiles, including birds, have strong color

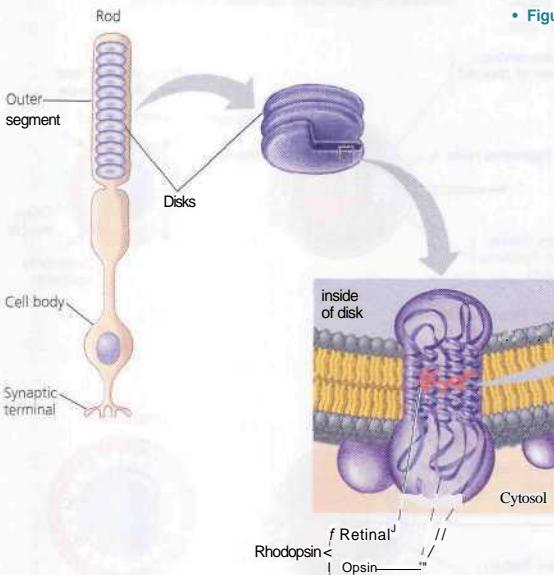

A Figure 49.18 Structure of the vertebrate eye. In this longitudinal section of the eye, the jellylike vitreous humor is illustrated only in the lower half of the eyeball. The conjunctiva, a mucous membrane that surrounds the sclera, is not shown.

4. Figure 49.19 Focusing in the mammalian eye. Ciliary muscles control the shape of the lens, which bends light and focuses it on the retina. The thicker the lens, the more sharply the light is bent.

vision, but humans and other primates are among the minority of mammals with this ability. Many mammals are nocturnal, and having a maximum number of rods in the retina is an adaptation that gives these animals keen night vision. Cats, for instance, are usually most active at night; they have limited color vision and probably see a pastel world during the day.

In the human eye, rods are found in greatest density at the peripheral regions of the retina and are completely absent from the **fovea**, the center of the visual field (see Figure 49.18). You cannot see a dim star at night by looking at it directly because the star's image is focused on the fovea; if you view the star at an angle, however, focusing the image on a region of the retina that contains rods, you will be able to see the star. In daylight, you achieve your sharpest vision by looking directly at an object because cones are most dense at the fovea, where there are about 150,000 cones per square millimeter. Some birds have more than a million cones per square millimeter, which enables species such as hawks to spot mice and other small prey from high in the sky. In the retina, as in all biological structures, variations represent evolutionary adaptations.

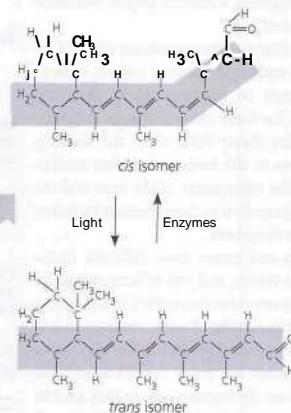

- (a) Rods contain the visual pigment rhodopsin, which is embedded in a stack of membranous disks in the rod's outer segment. Rhodopsin consists of the light-absorbing molecule retinal bonded to opsin, a protein. Opsin has seven α helices that span the disk membrane.

Sensory Transduction in the Eye

Each rod or cone in the vertebrate retina contains visual pigments that consist of a light-absorbing molecule called retinal (a derivative of vitamin A) bonded to a membrane protein called an **opsin**. Opsins vary in structure from one type of photoreceptor to another, and the light-absorbing ability of retinal is affected by the specific identity of its opsin partner. Rods have one type of opsin, which, combined with retinal, makes up the visual pigment **rhodopsin**. To understand the relationship between the structure of rods and light absorption, examine Figure 49.20.

As Figure 49.20 explains, rhodopsin changes shape when it absorbs light, a process referred to as "bleaching." Bright light keeps rhodopsin bleached, and the rods become unresponsive. When you move from a very bright environment into a dark one, such as when you enter a movie theater on a sunny afternoon, you are initially almost blind to the faint light. There is too little light to stimulate your cones, and it takes at least a few minutes for your bleached rods to become fully responsive again.

• Figure 49.20 Rod structure and light absorption.

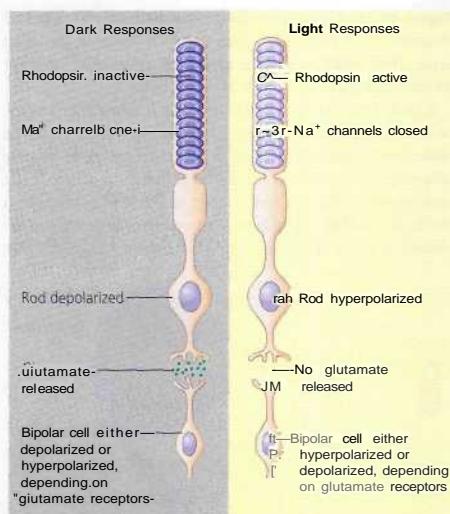

- (b) Retinal exists as two isomers. Absorption of light converts the *cis* isomer to the *trans* isomer, which causes opsin to change its conformation (shape). After a few minutes, retinal detaches from opsin. In the dark, enzymes convert retinal back to its *cis* form, which recombines with opsin to form rhodopsin.

Color vision involves even more complex signal processing than the rhodopsin mechanism in rods. There are three classes of cones in the retina—red, green, and blue—each with its own type of opsin associated with retinal in a visual pigment. The three visual pigments of cones are collectively called **photopsins**. The name of each cone class refers to the color that its type of photopsin absorbs best. These visual pigments have overlapping absorption spectra, and the brain's perception of intermediate hues depends on the differential stimulation of two or more classes of cones. For example, when both red and green cones are stimulated, we may see yellow or orange, depending on which class is more strongly stimulated. Color blindness, which is more common in males than in females because it is generally inherited as a sex-linked trait (see Figure 45.9), is the result of a deficiency or absence of one or more types of photopsin.

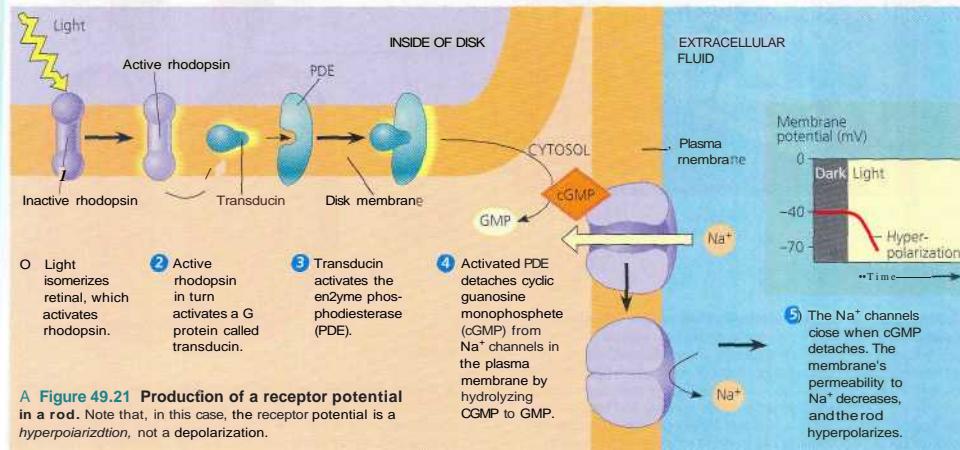

Processing Visual Information

The processing of visual information begins in the retina itself, where both rods and cones make synapses with neurons called **bipolar cells**. In the dark, rods and cones are depolarized, and they continually release the neurotransmitter glutamate (see Table 48.1) at these synapses. This steady glutamate release in the dark depolarizes some bipolar cells and hyperpolarizes others, depending on the type of postsynaptic receptor molecules they contain (Figure 49.21). In the light, rods and cones hyperpolarize, shutting off their release of glutamate. In response, the bipolar cells that are depolarized by glutamate hyperpolarize, and those that are hyperpolar-

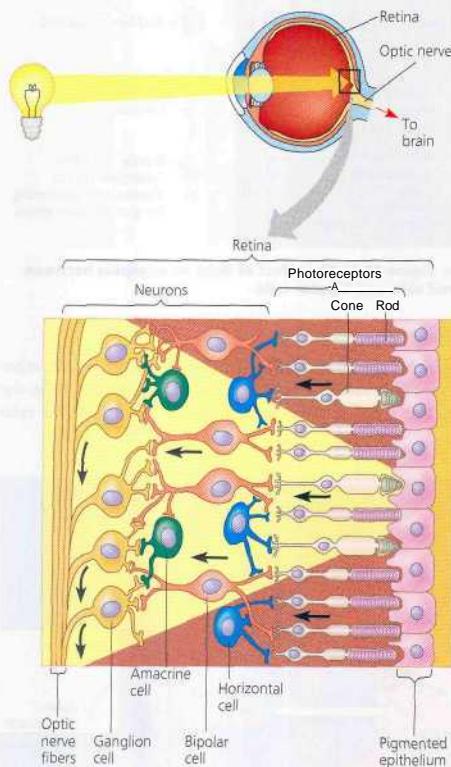

A Figure 49.22 The effect of light on synapses between rod cells and bipolar cells.

ized by glutamate depolarize (Figure 49.22). Three other types of neurons contribute to information processing in the retina: ganglion cells, horizontal cells, and amacrine cells

(Figure 49.23). Ganglion cells synapse with bipolar cells and transmit action potentials to the brain via axons in the optic nerve. Horizontal cells and amacrine cells help integrate the information before it is sent to the brain.

Signals from the rods and cones may follow either a vertical or a lateral pathway in the retina. In the vertical pathway, information passes directly from photoreceptors to bipolar cells to ganglion cells. In the lateral pathway, horizontal cells carry signals from one rod or cone to other photoreceptors and to several bipolar cells, and amacrine cells distribute information from one bipolar cell to several ganglion cells.

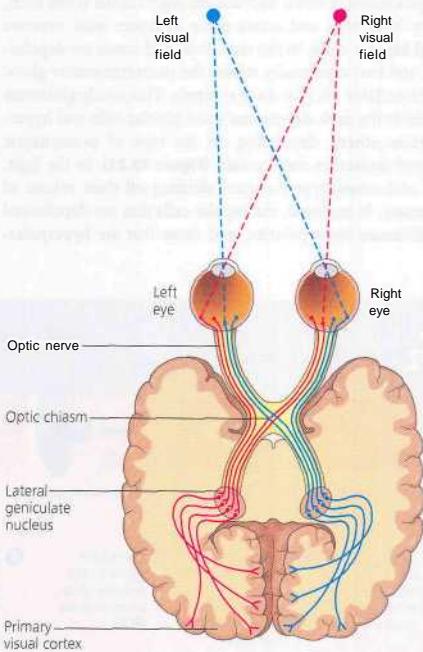

A Figure 49.23 Cellular organization of the vertebrate retina. Light must pass through several relatively transparent layers of cells before reaching the rods and cones. These photoreceptors communicate via bipolar cells with ganglion cells, which have axons that transmit visual sensations (action potentials) to the brain. Each bipolar cell receives information from several rods or cones, and each ganglion cell from several bipolar cells. Horizontal and amacrine cells integrate information across the retina. Black arrows indicate the pathway of visual information from the photoreceptors to the optic nerve.

When an illuminated rod or cone stimulates a horizontal cell, the horizontal cell inhibits more distant photoreceptors and bipolar cells that are not illuminated, making the light spot appear lighter and the dark surroundings even darker. This form of integration, called lateral inhibition, sharpens edges and enhances contrast in the image. Lateral inhibition is repeated by the interactions of the amacrine cells with the ganglion cells and occurs at all levels of visual processing in the brain.

All the rods or cones that feed information to one ganglion cell form the *receptive field* for that cell. A larger receptive field (in which more rods or cones supply a ganglion cell) results in a less sharp image than a smaller receptive field because the larger field provides less information about exactly where light struck the retina. The ganglion cells of the fovea have very small receptive fields, so visual acuity is high in the fovea.

Axons of ganglion cells form the optic nerves that transmit sensations from the eyes to the brain (**Figure 49.24**). The two

A Figure 49.24 Neural pathways for vision. Each optic nerve contains about a million axons that synapse with interneurons in the lateral geniculate nuclei. The nuclei relay sensations to the primary visual cortex, one of many brain centers that cooperate in constructing our visual perceptions.

optic nerves meet at the optic chiasm near the center of the base of the cerebral cortex. Axons in the optic nerves are routed at the optic chiasm such that sensations from the left visual field of both eyes are transmitted to the right side of the brain, and sensations from the right visual field are transmitted to the left side of the brain. Most ganglion cell axons lead to the lateral geniculate nuclei of the thalamus. Neurons in the lateral geniculate nuclei have axons that extend to the primary visual cortex in the occipital lobe of the cerebrum. Additional interneurons carry the information to higher-order visual processing and integrating centers elsewhere in the cortex.

Point-by-point information in the visual field is projected along neurons onto the visual cortex. How does the cortex convert a complex set of action potentials representing two-dimensional images focused on our retinas into three-dimensional perceptions of our surroundings? Researchers estimate that at least 30% of the cerebral cortex—hundreds of millions of interneurons in perhaps dozens of integrating centers—take part in formulating what we actually “see.” Determining how these centers integrate such components of our vision as color, motion, depth, shape, and detail is the goal of an exciting, fast-moving research effort.

Concept Check 49.4

1. Contrast the light-detecting organs of planarians and flies. How is each organ adaptive for the lifestyle of the animal?
2. In a condition called presbyopia, the eye's lenses lose their elasticity and maintain a constant, flat shape. Explain how this condition would affect a person's vision.
3. Concentrating on the vertical pathway through the retina, explain how illuminating a photoreceptor can lead to an increased frequency of action potentials in ganglion cells.

For suggested answers, see Appendix A.

Concept 49.5

Animal skeletons function in support, protection, and movement

Throughout our discussions of sensory mechanisms, we have seen several examples of how sensory inputs to the nervous system result in specific behaviors: the escape maneuver of a moth that hears a bat's sonar, the upside-down swimming of a

crayfish with manipulated statocysts, the feeding movements of a hydra when it tastes glutathione, and the movement of planarians away from light. Animal behavior flows in a seamless cycle involving continuous brain operations that generate actions, note the consequences of those actions via input from sensory receptors, and use that input to determine the next action. Underlying the diverse forms of behavior in animals are common fundamental mechanisms. Swimming, crawling, running, hopping, and flying all result from muscles working against some type of skeleton.

Types of Skeletons

The three main functions of a skeleton are support, protection, and movement. Most land animals would sag from their own weight if they had no skeleton to support them. Even an animal living in water would be a formless mass with no framework to maintain its shape. In many animals, a hard skeleton provides protection for soft tissues. For example, the vertebrate skull protects the brain, and the ribs of terrestrial vertebrates form a cage around the heart, lungs, and other internal organs. Skeletons also aid in movement by giving muscles something firm to work against. There are three main types of skeletons: hydrostatic skeletons, exoskeletons, and endoskeletons.

Hydrostatic Skeletons

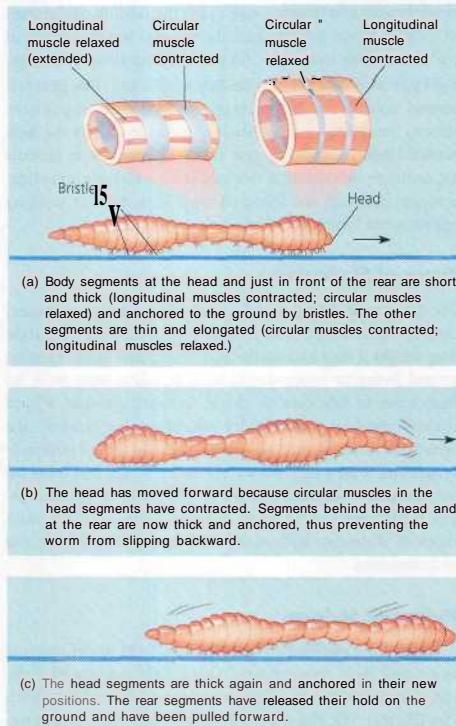

A hydrostatic skeleton consists of fluid held under pressure in a closed body compartment. This is the main type of skeleton in most cnidarians, flatworms, nematodes, and annelids (see Chapter 33). These animals control their form and movement by using muscles to change the shape of fluid-filled compartments.

Among the cnidarians, for example, a hydra can elongate by closing its mouth and using contractile cells in the body wall to constrict the central gastrovascular cavity. Because water cannot be compressed very much, decreasing the diameter of the cavity forces the cavity to increase in length.

In planarians and other flatworms, the interstitial fluid is kept under pressure and functions as the main hydrostatic skeleton. Planarian movement results mainly from muscles in the body wall exerting localized forces against the hydrostatic skeleton.

Nematodes (roundworms) hold fluid in their body cavity, which is a pseudocoelom (see Figure 32.8b). The fluid is under a high pressure, and contractions of longitudinal muscles result in thrashing movements.

In earthworms and other annelids, the coelomic fluid functions as a hydrostatic skeleton. The coelomic cavity is divided by septa between the segments in many annelids, allowing the animal to change the shape of each segment individually, using both circular and longitudinal muscles. Such annelids use

A Figure 49.25 Peristaltic locomotion in an earthworm.

Contraction of the longitudinal muscles thickens and shortens the worm; contraction of the circular muscles constricts and elongates it.

their hydrostatic skeleton for peristalsis, a type of movement on land produced by rhythmic waves of muscle contractions passing from front to back (**Figure 49.25**).

Hydrostatic skeletons are well suited for life in aquatic environments. They may also cushion internal organs from shocks and provide support for crawling and burrowing in terrestrial animals. However, a hydrostatic skeleton cannot support terrestrial activities in which an animal's body is held off the ground, such as walking or running.

Exoskeletons

An exoskeleton is a hard encasement deposited on the surface of an animal. For example, most molluscs are enclosed in a calcareous (calcium carbonate) shell secreted by the mantle, a sheetlike extension of the body wall (see Figure 33.16). As the animal grows, it enlarges the shell by

adding to its outer edge. Clams and other bivalves close their hinged shell using muscles attached to the inside of this exoskeleton.

The jointed exoskeleton of arthropods is a cuticle, a non-living coat secreted by the epidermis. Muscles are attached to knobs and plates of the cuticle that extend into the interior of the body. About 30–50% of the cuticle consists of chitin, a polysaccharide similar to cellulose. Fibrils of chitin are embedded in a protein matrix, forming a composite material that combines strength and flexibility. Where protection is most important, the cuticle is hardened with organic compounds that cross-link the proteins of the exoskeleton. Some crustaceans, such as lobsters, harden portions of their exoskeleton even more by adding calcium salts. In contrast, there is little cross-linking of proteins or inorganic salt deposition in places where the cuticle must be thin and flexible, such as leg joints. An arthropod must shed its exoskeleton (molt) and produce a larger one with each growth spurt (see Figure 5.10).

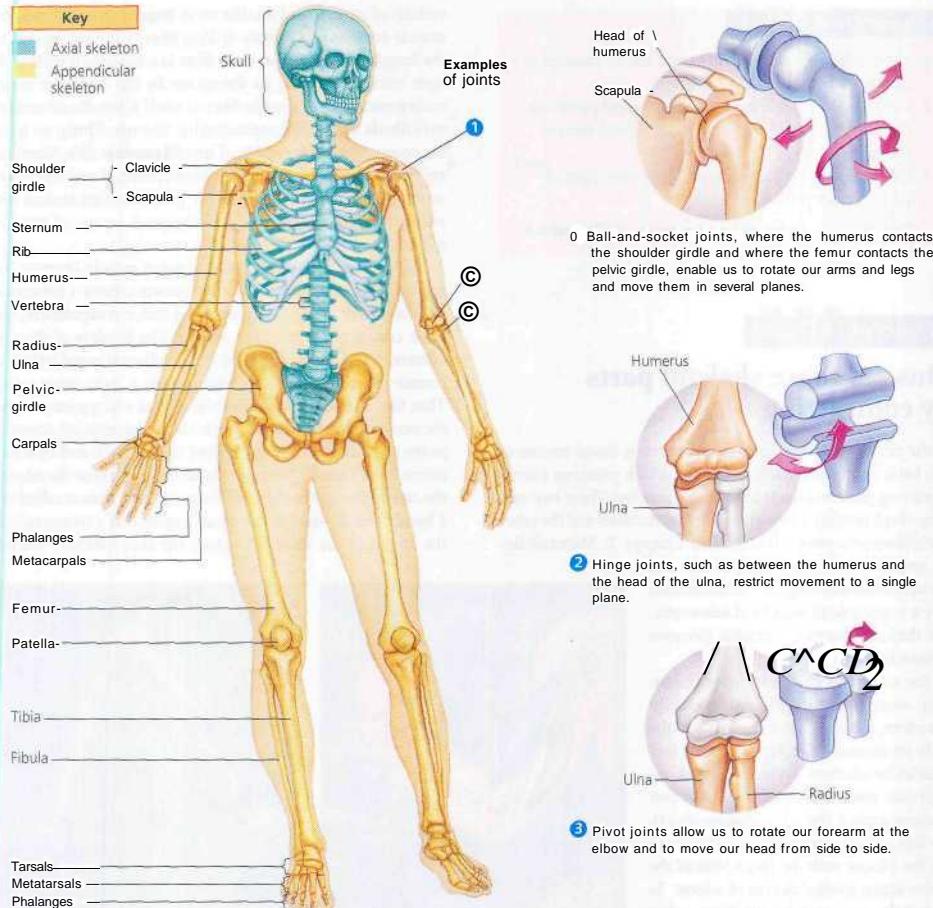

Endoskeletons

An endoskeleton consists of hard supporting elements such as bones, buried within the soft tissues of an animal. Sponges are reinforced by hard spicules of inorganic material or by softer fibers made of protein (see Figure 33.4). Echinoderms have an endoskeleton of hard plates called ossicles beneath the skin. The ossicles are composed of magnesium carbonate and calcium carbonate crystals and are usually bound together by protein fibers. Whereas the ossicles of sea urchins are tightly bound, the ossicles of sea stars are more loosely linked, allowing a sea star to change the shape of its arms.

Chordates have an endoskeleton consisting of cartilage, bone, or some combination of these materials (see Figure 40.5). The mammalian skeleton is built from more than 200 bones, some fused together and others connected at joints by ligaments that allow freedom of movement (**Figure 49.26**). Anatomists divide the vertebrate skeleton into two main parts: the axial skeleton, consisting of the skull, vertebral column (backbone), and rib cage; and the appendicular skeleton, made up of limb bones and the pectoral and pelvic girdles that anchor the appendages to the axial skeleton. In each appendage, several types of joints provide flexibility for body movements.

Physical Support on Land

An engineer designing a bridge or tall building must take into account the effects of changes in size, or scale. An increase in size from a small-scale model to the real thing has a significant impact on building design. For example, the strength of a building support depends on its cross-sectional area, which increases with the square of its diameter. In

① Ball-and-socket joints, where the humerus contacts the shoulder girdle and where the femur contacts the pelvic girdle, enable us to rotate our arms and legs and move them in several planes.

② Hinge joints, such as between the humerus and the head of the ulna, restrict movement to a single plane.

③ Pivot joints allow us to rotate our forearm at the elbow and to move our head from side to side.

K Figure 49.26 Bones and joints of the human skeleton.

sharp contrast, the strain on that support depends on the building's weight, which increases with the cube of its height or other linear dimension. In common with the structure of a bridge or building, an animal's body structure must support its size. Consequently, a large animal has very different body proportions than a small animal. If a mouse were scaled up to an elephant's size, its slender legs would buckle under its weight.

In simply applying the building analogy we might predict the size of an animal's leg bones to be directly proportional to the strain imposed by its body weight. However, our pre-

diction would be inaccurate; animal bodies are complex and nonrigid, and the building analogy only partly explains the relationship between body structure and support. An animal's leg size relative to its body size is only part of the story. It turns out that body posture—the position of the legs relative to the main body—is a more important structural feature in supporting body weight, at least in mammals and birds. Muscles and tendons (connective tissue that joins muscle to bone), which hold the legs of large mammals relatively straight and positioned under the body, bear most of the load.

Concept Check 49.5

- Explain how an earthworm would use its muscles to mend its body to its full length.
- Contrast the properties of a lobsters exoskeleton on the gripping surfaces of its claws (pincers) and on the hinge joints of the claws.
- Contrast the motions allowed by the two types of joints found in the elbow.

For suggested answers, see Appendix A.

Concept 49.6

Muscles move skeletal parts by contracting

At the cellular level, all animal movement is based on one of two basic contractile systems, both of which consume energy in moving protein strands against one another. These two systems of cell motility—one invoking microtubules and the other microfilaments—were discussed in Chapter 7. Microtubules are responsible for the beating of cilia and the undulations of flagella. Microfilaments play a major role in amoeboid movement, and they are also the contractile elements of muscle cells.

The action of a muscle is always to contract; muscles can extend only passively. Therefore, the ability to move parts of the body in opposite directions requires that muscles be attached to the skeleton in antagonistic pairs, each member of the pair working against the other (Figure 49.27). We flex an arm, for instance, by contracting the biceps, with the hinge joint of the elbow acting as the fulcrum of a lever. To extend the arm, we relax the biceps while the triceps on the opposite side contracts.

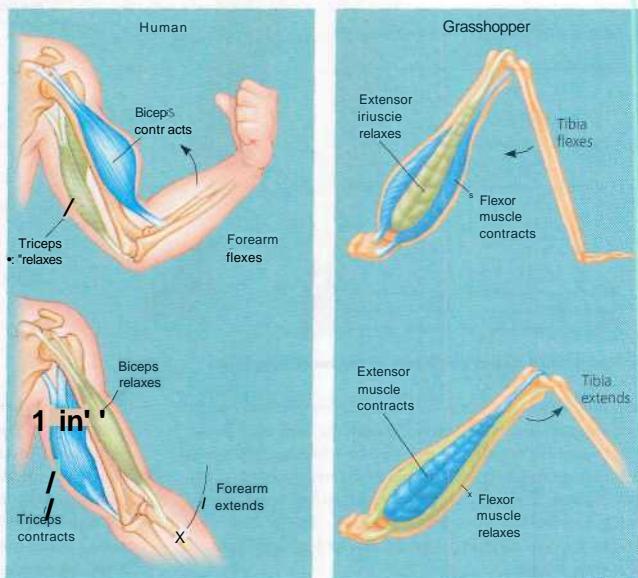

To understand how a muscle contracts, we must analyze its structure. We will begin by examining the structure and mechanism of contraction of vertebrate skeletal muscle and then turn our attention to other types of muscle.

Vertebrate Skeletal Muscle

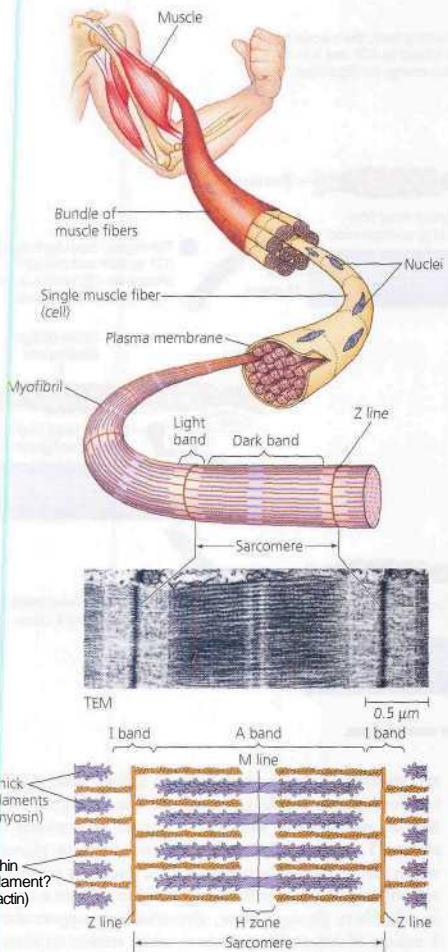

Vertebrate skeletal muscle, which is attached to the bones and is responsible for their movement, is characterized by a hi-

erarchy of smaller and smaller units (Figure 49.28). A skeletal muscle consists of a bundle of long fibers running parallel to the length of the muscle. Each fiber is a single cell with multiple nuclei, reflecting its formation by the fusion of many embryonic cells. A muscle fiber is itself a bundle of smaller myofibrils arranged longitudinally. The myofibrils, in turn, are composed of two kinds of myofilaments: thin filaments and thick filaments. Thin filaments consist of two strands of actin and one strand of regulatory protein coiled around one another. Thick filaments are staggered arrays of myosin molecules.

Skeletal muscle is also called striated muscle because the regular arrangement of the myofilaments creates a pattern of light and dark bands. Each repeating unit is a sarcomere, the basic contractile unit of the muscle. The borders of the sarcomere, the Z lines, are lined up in adjacent myofibrils and contribute to the striations visible with a light microscope. Thin filaments are attached to the Z lines and project toward the center of the sarcomere, while thick filaments are centered in the sarcomere. In a muscle fiber at rest, thick and thin filaments do not overlap completely, and the area near the edge of the sarcomere where there are only thin filaments is called the I band. The A band is the broad region that corresponds to the length of the thick filaments. The thin filaments do not

A **Figure 49.27** The interaction of muscles and skeletons in movement. Back-and-forth movement of a body part is generally accomplished by antagonistic muscles. This arrangement works with either an endoskeleton or an exoskeleton.

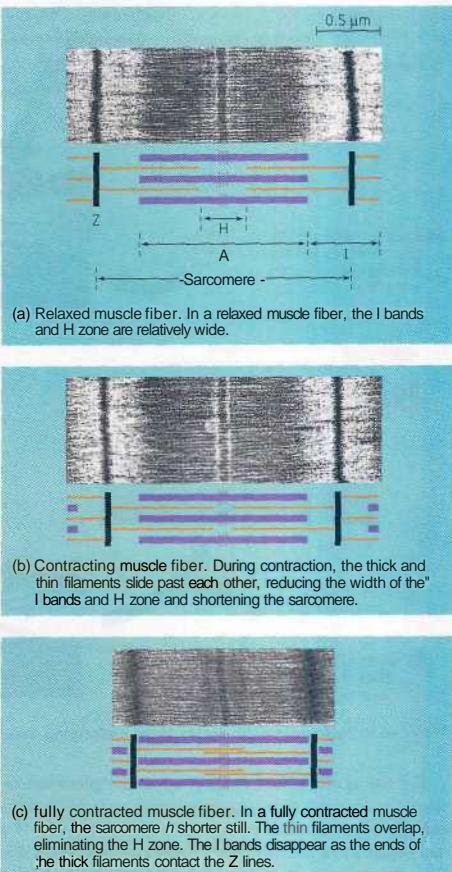

▲ Figure 49.28 The structure of skeletal muscle.

extend completely across the sarcomere, so the H zone in the center of the A band contains only thick filaments. This arrangement of thick and thin filaments is the key to how the sarcomere, and hence the whole muscle, contracts.

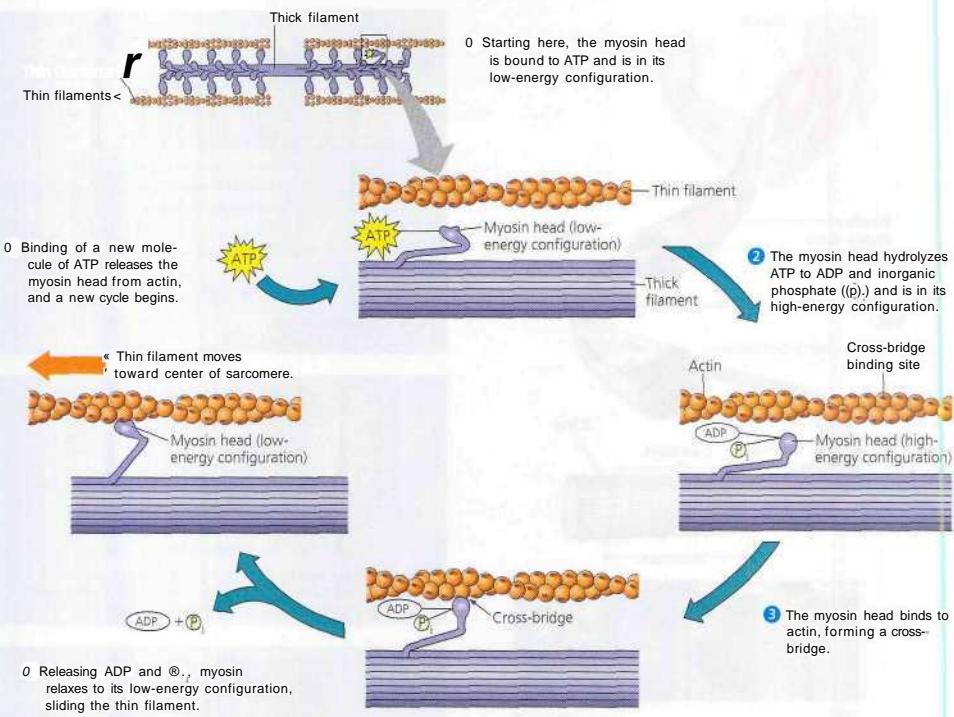

The Sliding-Filament Model of Muscle Contraction

We can explain much of what happens during contraction of a whole muscle by focusing on a single muscle fiber

A **Figure 49.29 The sliding-filament model of muscle contraction.** These transmission electron micrographs show that the lengths of the thick (myosin) filaments (purple) and thin (actin) filaments (orange) remain the same as a muscle fiber contracts.

(Figure 49.29). According to the sliding-filament model of muscle contraction, neither the thin filaments nor the thick filaments change in length when the sarcomere shortens; rather, the filaments slide past each other longitudinally, producing more overlap between the thin and thick filaments. As a result, both the region occupied only by thin filaments (the I band) and the region occupied only by thick filaments (the H zone) will shrink.

A Figure 49.30 Myosin-actin interactions underlying muscle fiber contraction.

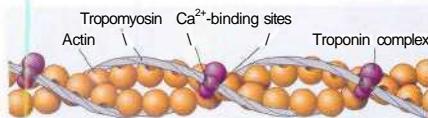

The sliding of the filaments is based on the interaction between the actin and myosin molecules that make up the thick and thin filaments. Each myosin molecule consists of a long "tail" region and a globular "head" region extending to the side. The tail adheres to the tails of other myosin molecules that form the thick filament. The head is the center of bioenergetic reactions that power muscle contractions. It can bind ATP and hydrolyze it into ADP and inorganic phosphate. As shown in **Figure 49.30**, hydrolysis of ATP triggers steps in which myosin binds to actin, forming a cross-bridge and pulling the thin filament toward the center of the sarcomere. The cross-bridge is broken when a new molecule of ATP binds to the myosin head. In a repeating cycle, the free head cleaves the new ATP and attaches to a new binding site on another actin molecule farther along the thin filament. Each of the approximately 350 heads of a thick filament forms and re-forms about five cross-bridges per second, driving filaments past each other.

A typical muscle fiber at rest contains only enough ATP for a few contractions. The energy needed for repetitive contractions is stored in two other compounds: creatine phosphate

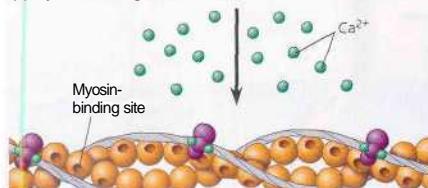

and glycogen. Creatine phosphate can quickly make ATP by transferring a phosphate group to ADP. The resting supply of creatine phosphate is sufficient to sustain contractions for about 15 seconds. Glycogen is broken down to glucose, which can be used to generate ATP via glycolysis or aerobic respiration (see Chapter 9). Using the glucose from a typical muscle fiber's glycogen store, glycolysis can support about 1 minute of sustained contraction, while aerobic respiration can power contractions for nearly an hour.

The Role of Calcium and Regulatory Proteins

A skeletal muscle fiber contracts only when stimulated by a motor neuron. When the muscle fiber is at rest, the myosin-binding sites on the thin filament are blocked by the regulatory protein tropomyosin (**Figure 49.31a**). For the muscle fiber to contract, those binding sites must be uncovered. This occurs when calcium ions (Ca^{2+}) bind to another set of regulator* proteins, the troponin complex, which controls the position of tropomyosin on the thin filament. Calcium binding rearranges

(a) Myosin-binding sites blocked.

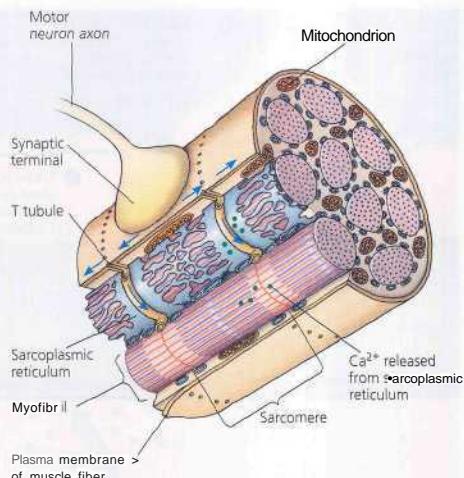

(b) Myosin-binding sites exposed.

A Figure 49.31 The role of regulatory proteins and calcium in muscle fiber contraction. Each thin filament consists of two strands of actin twisted into a helix.

the tropomyosin-troponin complex, exposing the myosin-binding sites on the thin filament (Figure 49.31b). When Ca^{2+} is present in the cytosol, the thin and thick filaments slide past each other, and the muscle fiber contracts. When the Ca^{2+} concentration falls, the binding sites are covered, and contraction stops.

The stimulus leading to the contraction of a skeletal muscle fiber is an action potential in a motor neuron that makes a synapse with the muscle fiber (Figure 49.32). The synaptic terminal of the motor neuron releases the neurotransmitter acetylcholine, depolarizing the muscle fiber and causing it to produce an action potential. That action potential spreads deep into the interior of the muscle fiber along infoldings of the plasma membrane called transverse (T) tubules. The T tubules make close contact with the sarcoplasmic reticulum (SR), a specialized endoplasmic reticulum. When the muscle fiber is at rest, the membrane of the SR pumps Ca^{2+} from the cytosol into the interior of the SR, which is thus an intracellular storehouse for Ca^{2+} . When the muscle fiber produces an action potential, however, the action potential opens Ca^{2+} channels in the SR, allowing Ca^{2+} to enter the cytosol. Calcium ions bind to the troponin complex, triggering contraction of the muscle fiber. Contraction stops when the SR pumps the Ca^{2+} back out of the cytosol, and tropomyosin again blocks the myosin-binding sites on the thin filaments. Figure 49.33, on the next page, reviews the steps in the contraction of a skeletal muscle fiber.

Several diseases cause paralysis by interfering with the excitation of skeletal muscle fibers by motor neurons. In amyotrophic lateral sclerosis (ALS), formerly called Lou Gehrig's disease, motor neurons in the spinal cord and brainstem degenerate, and the muscle fibers with which they synapse

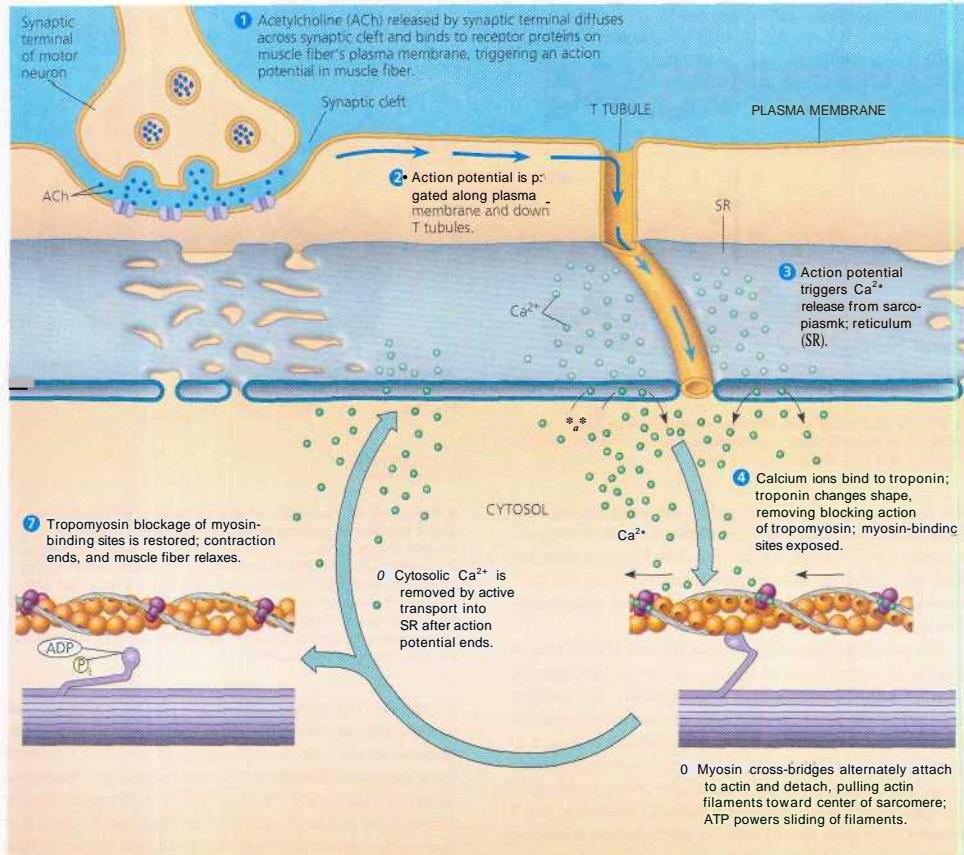

A Figure 49.32 The roles of the sarcoplasmic reticulum and T tubules in muscle fiber contraction. The synaptic terminal of a motor neuron releases acetylcholine, which depolarizes the plasma membrane of the muscle fiber. The depolarization causes action potentials (blue arrows) to sweep across the muscle fiber and deep into it along the transverse (T) tubules. The action potentials trigger the release of calcium (green dots) from the sarcoplasmic reticulum into the cytosol. Calcium initiates the sliding of filaments by allowing myosin to bind to actin.

atrophy. ALS is progressive and usually fatal within five years after symptoms appear; there is no cure or treatment at this time. Botulism results from the consumption of an exotoxin secreted by the bacterium *Clostridium botulinum* in improperly preserved foods (see Chapter 27). The toxin, which paralyzes muscles by blocking the release of acetylcholine from motor neurons, is also injected into certain facial muscles to eliminate frown lines in "Botox" treatments. Myasthenia gravis is an autoimmune disease in which a person produces antibodies to the acetylcholine receptors on skeletal muscle fibers. The number of these receptors decreases, and the synaptic transmission between motor neurons and the muscle fibers becomes less effective.

Neural Control of Muscle Tension

When an action potential in a motor neuron releases acetylcholine on a skeletal muscle fiber, the muscle fiber responds by producing a brief, all-or-none contraction, called a twitch. However, our everyday experience shows that the contraction of a whole muscle, such as the biceps, is graded; we can voluntarily alter the extent and strength of its contraction. Experimental studies confirm this observation. There are two basic mechanisms by which the nervous system produces graded contractions of whole muscles: (1) by varying the number of muscle

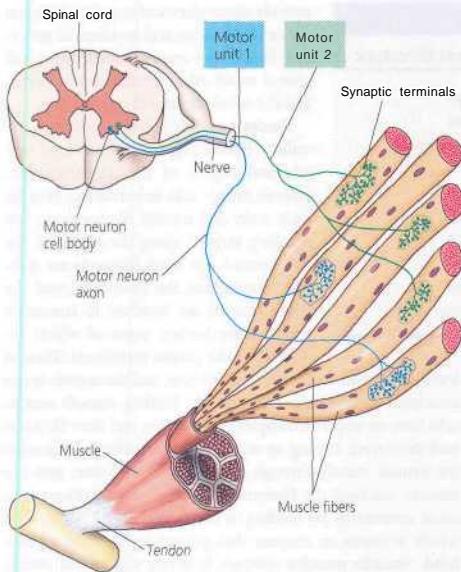

A Figure 49.33 Review of contraction in a skeletal muscle fiber.

fibers that contract and (2) by varying the rate at which muscle fibers are stimulated. Let's consider each mechanism in turn.

In a vertebrate skeletal muscle, each muscle fiber is innervated by only one motor neuron, but each branched motor neuron may synapse with many muscle fibers (Figure 49.34). There may be hundreds of motor neurons controlling a muscle, each with its own pool of muscle fibers scattered throughout the muscle. A **motor unit** consists of a single motor neuron and all the muscle fibers it controls. When a motor neuron produces an action potential, all the muscle fibers in its motor unit contract as a group. The strength of the resulting contraction therefore depends on how many muscle fibers the motor neuron controls. In most muscles, the number of muscle fibers in different motor units ranges from a few to

hundreds. The nervous system can thus regulate the strength of contraction in a whole muscle by determining how many motor units are activated at a given instant and by selecting large or small motor units to activate. The force (tension) developed by a muscle progressively increases as more and more of the motor neurons controlling the muscle are activated, a process called **recruitment** of motor neurons. Depending on the number of motor neurons your brain recruits and the size of their motor units, you can lift a fork or something much heavier, like your biology textbook.

Some muscles, especially those that hold the body up and maintain posture, are almost always partially contracted. Prolonged contraction can result in muscle fatigue caused by the depletion of ATP, dissipation of ion gradients required for

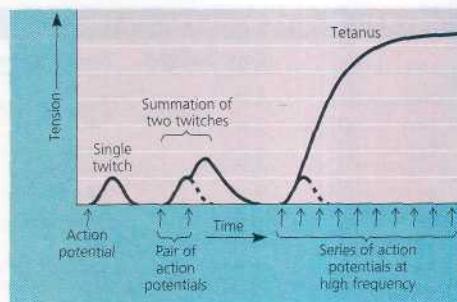

i. Figure 49.34 Motor units in a vertebrate skeletal muscle. Each muscle fiber (cell) has a single synapse with one motor neuron, but each motor neuron typically synapses with several or many muscle fibers. A motor neuron and all the muscle fibers it controls constitute a motor unit.

normal electrical signaling and accumulation of lactate (see Figure 9.17). Recent research suggests that although lactate may contribute to muscle fatigue, it may have a beneficial effect on muscle function. In a mechanism that reduces fatigue, the nervous system alternates activation among the motor units in a muscle, allowing different motor units to take turns maintaining the prolonged contraction.

The second mechanism by which the nervous system produces graded whole-muscle contractions is by varying the rate of muscle fiber stimulation. A single action potential will produce a twitch lasting about 100 milliseconds (msec) or less. If a second action potential arrives before the muscle fiber has completely relaxed, the two twitches will sum, resulting in greater tension (Figure 49.35). Further summation occurs as the rate of stimulation increases. When the rate is high enough that the muscle fiber cannot relax at all between stimuli, the twitches fuse into one smooth, sustained contraction called tetanus (not to be confused with the disease of the same name). Motor neurons usually deliver their action potentials in rapid-fire volleys, and the resulting summation of tension results in the smooth contraction typical of tetanus rather than the jerky actions of individual twitches.

The increase in tension during summation and tetanus occurs because muscle fibers are not directly attached to bones

A Figure 49.35 Summation of twitches. This graph compares the tension developed in a muscle fiber in response to a single action potential in a motor neuron, a pair of action potentials, and a series of action potentials. The dashed lines show the tension that would have developed if only the first action potential had occurred.

but instead are connected via tendons and connective tissues. When a muscle fiber contracts, it stretches these elastic structures, which then transmit tension to the bones. In a single twitch, the muscle fiber begins to relax before the elastic structures are fully stretched. During summation, however, the high-frequency action potentials maintain an elevated concentration of calcium in the muscle fiber's cytosol, prolonging cross-bridge cycling and causing greater stretching of the elastic structures. During tetanus, the elastic structures are fully stretched, and all of the tension generated by the muscle fiber is transmitted to the bones.

T[†]es of Muscle Fibers

All skeletal muscle fibers contract when stimulated by an action potential in a motor neuron, but the speed at which they contract differs among muscle fibers. This difference is mainly due to the rate at which their myosin heads hydrolyze ATP. Based on their speed of contraction, we can classify muscle fibers as either fast or slow. Fast fibers are used for brief, rapid, powerful contractions. In contrast, slow fibers, often found in muscles that maintain posture, can sustain long contractions. A slow fiber has less sarcoplasmic reticulum and slower calcium pumps than fast fiber, so calcium remains in the cytosol longer. This causes a twitch in a slow fiber to last about five times as long as one in a fast fiber.

Another criterion for classifying muscle fibers is the major metabolic pathway they use for producing ATP. Fibers that rely mostly on aerobic respiration are called oxidative fibers, while those that primarily use glycolysis are called glycolytic fibers. Oxidative fibers are specialized to make use of a steady supply of energy: They have many mitochondria, a rich blood supply, and a large amount of an oxygen-storing protein called myoglobin. Myoglobin, the brownish-red pigment in the dark meat of poultry and fish, binds oxygen more tightly than does

Table 49.1 Types of Skeletal Muscle Fibers

| | Slow Oxidative | Fast Oxidative | Fast Glycolytic |
|---------------------------------|---------------------|---------------------|-----------------|
| Contraction speed | Slow | Fast | Fast |
| Myosin ATPase activity | Slow | Fast | Fast |
| Major pathway for ATP synthesis | Aerobic respiration | Aerobic respiration | Glycolysis |
| Race of fatigue | Slow | Intermediate | Fast |
| Fiber diameter | Small | Intermediate | Large |
| Mitochondria | Many | Many | Few |
| Capillaries | Many | Many | Few |
| Myoglobin content | High | High | Low |
| Color | Red | Red to pink | White |

hemoglobin, so it can effectively extract oxygen from the blood. All glycolytic fibers are fast, but oxidative fibers can be either fast or slow. Therefore, considering both contraction speed and ATP synthesis, we can identify three main types of skeletal muscle fibers: slow oxidative, fast oxidative, and fast glycolytic. **Table 49.1** compares some of their characteristics.

Most human skeletal muscles contain all three fiber types, although the muscles of the eye and hand lack slow oxidative fibers. In muscles that have a mixture of fast and slow fibers, the relative proportions of each are genetically determined. However, if such a muscle is used repeatedly for activities requiring high endurance, some fast glycolytic fibers can develop into fast oxidative fibers. Since fast oxidative fibers fatigue more slowly than fast glycolytic fibers, the muscle as a whole will become more resistant to fatigue.

Other Types of Muscle

There are many types of muscles in the animal kingdom. As noted previously, however, they share the same fundamental mechanism of contraction; the sliding of actin and myosin filaments past each other. In addition to skeletal muscle, vertebrates have cardiac muscle and smooth muscle (see Figure 40.5).

Vertebrate **cardiac muscle** is found in only one place—the heart. Like skeletal muscle, cardiac muscle is striated. However, structural differences between skeletal and cardiac muscle fibers result in differences in their electrical and membrane properties. Whereas skeletal muscle fibers will not produce action potentials unless stimulated by a motor neuron, cardiac muscle cells have ion channels in their plasma membrane that cause rhythmic depolarizations, triggering action potentials without input from the nervous system. Action potentials of cardiac muscle cells last up to 20 times longer than those of skeletal muscle fibers and play a key role in controlling duration of contraction. Plasma membranes of adjacent cardiac muscle cells interlock at specialized regions called **intercalated disks**, where gap junctions (see Figure 6.30)

provide direct electrical coupling between the cells. Thus, an action potential generated by a cell in one part of the heart will spread to all other cardiac muscle cells, and the whole heart will contract.

Smooth muscle is found mainly in the walls of hollow organs, such as blood vessels and organs of the digestive tract. Smooth muscle cells lack striations because their actin and myosin filaments are not regularly arrayed along the length of the cell. Instead, the thick filaments are scattered throughout the cytoplasm, and the thin filaments are attached to structures called dense bodies, some of which are tethered to the plasma membrane. There is less myosin than in striated muscle fibers, and the myosin is not associated with specific actin strands. Further, smooth muscle cells have no troponin complex or T tubules, and their SR is not well developed. During an action potential, calcium ions enter the cytosol mainly through the plasma membrane, and the amount reaching the filaments is rather small. Calcium ions cause contraction by binding to calmodulin (see Chapter 11), which activates an enzyme that phosphorylates the myosin head. Smooth muscles contract relatively slowly but over a much greater range of length than striated muscle. Some smooth muscle cells contract only when stimulated by neurons of the autonomic nervous system. Others can generate action potentials without neural input and are electrically coupled to one another.

Invertebrates have muscle cells similar to vertebrate skeletal and smooth muscle cells. Arthropod skeletal muscles are nearly identical to vertebrate skeletal muscles. However, the flight muscles of insects are capable of independent, rhythmic contraction, so the wings of some insects can actually beat faster than action potentials can arrive from the central nervous system. Another interesting evolutionary adaptation has been discovered in the muscles that hold clam shells closed. The thick filaments in these muscles contain a protein called paramyosin that enables the muscles to remain contracted with a low rate of energy consumption for as long as a month.

Concept Check 49.6

- Summarize the microscopic evidence indicating that thick and thin filaments slide past each other when a skeletal muscle fiber contracts.
- How can the nervous system cause a skeletal muscle to produce the most forceful contraction it is capable of?
- Contrast the role of calcium ions in the contraction of a skeletal muscle fiber and a smooth muscle cell.

For suggested answers, see Appendix A.

Concept 49.7

Locomotion requires energy to overcome friction and gravity

Movement is a hallmark of animals. To catch food, an animal must either move through its environment or move the surrounding water or air past itself. Although all sponges are sessile, they use beating flagella to generate water currents that draw and trap small food particles, and sessile cnidarians wave tentacles that capture prey (see Chapter 33). Most animals, however, are mobile and spend a considerable portion of their time and energy actively searching for food, as well as escaping from danger and looking for mates. Our focus here is locomotion, or active travel from place to place.

The modes of animal locomotion are diverse. Most animal phyla include species that swim. On land and in the sediments on the floor of the sea and lakes, animals crawl, walk, run, or hop. Active flight (in contrast to gliding downward from a tree or elevated ground) has evolved in only a few animal groups: insects, reptiles (including birds), and, among the mammals, bats. A group of large flying reptiles died out millions of years ago, leaving birds and bats as the only flying vertebrates.

In all its modes, locomotion requires that an animal expend energy to overcome two forces that tend to keep it stationary: friction and gravity. Exerting force requires energy-consuming cellular work.

Swimming

Because most animals are reasonably buoyant in water, overcoming gravity is less of a problem for swimming animals than for species that move on land or through the air. On the other hand, water is a much denser and more viscous medium than air, and thus drag (friction) is a major problem for aquatic animals. A sleek, fusiform (torpedo-like) shape is a common adaptation of fast swimmers (see Figure 40.2).

Animals swim in diverse ways. For instance, many insects and four-legged vertebrates use their legs as oars to push against the water. Squids, scallops, and some cnidarians are jet-propelled, taking in water and squirting it out in bursts. Sharks and bony fishes swim by moving their body and tail from side to side, while whales and other aquatic mammals move by undulating their body and tail up and down.

Locomotion on Land

In general, the problems of locomotion on land are the opposite of those in water. On land, a walking, running, hopping, or crawling animal must be able to support itself and move against gravity, but air poses relatively little resistance, at least at moderate speeds. When a land animal walks, runs, or hops, its leg muscles expend energy both to propel it and to keep it

from falling down. With each step, the animal's leg muscles must overcome inertia by accelerating a leg from a standing start. For moving on land, powerful muscles and strong skeletal support are more important than a streamlined shape.

Diverse adaptations for traveling on land have evolved in various vertebrates. For example, kangaroos have large, powerful muscles in their hind legs, suitable for locomotion by hopping (Figure 49.36). When a kangaroo lands, tendons in its hind legs momentarily store energy. The farther the animal hops, the more energy the tendons store. Analogous to the energy in a compressed spring on a pogo stick, the energy stored in the tendons is available for the next jump and reduces the total amount of energy the animal must expend to travel. The pogo stick analogy applies to many land animals; for instance, the legs of an insect, a dog, or a human retain some energy during walking or running, although considerably less than those of a kangaroo.

Maintaining balance is another prerequisite for walking, running, or hopping. A kangaroo's large tail helps balance its body during leaps and also forms a stable tripod with its hind legs when the animal sits or moves slowly. Illustrating the same principle, a walking cat, dog, or horse keeps three feet on the ground. Bipedal animals, such as humans and birds, keep part of at least one foot on the ground when walking. When an animal runs, all four feet (or both feet for bipeds) may be off the ground briefly, but at running speeds it is momentum more than foot contact that keeps the body upright.

Crawling poses a very different situation. Because much of its body is in contact with the ground, a crawling animal must exert considerable effort to overcome friction. You have read how earthworms crawl by peristalsis. Many snakes crawl by undulating their entire body from side to side. Assisted by

A Figure 49.36 Energy-efficient locomotion on land.

Members of the kangaroo family travel from place to place mainly by leaping on their large hind legs. Kinetic energy momentarily stored in tendons after each leap provides a boost for the next leap. In fact, a large kangaroo hopping at 30 km/hr uses no more energy per minute than it does at 6 km/hr. The large tail helps balance the kangaroo when it leaps as well as when it sits.

large, movable scales on the underside, a snake's body pushes against the ground, driving the animal forward. Boa constrictors and pythons creep straight forward, driven by muscles that lift belly scales off the ground, tilt the scales forward, and then push them backward against the ground.

Flying

Gravity poses a major problem for flight because wings must develop enough lift to overcome gravity's downward force. The key to flight is wing shape. All types of wings, including those of airplanes, are airfoils—structures whose shape alters air currents in a way that helps them stay aloft.

Flying animals are relatively light, with body masses ranging from less than a gram for some insects to about 20 kg for the largest flying birds. Many flying animals have structural adaptations that reduce body mass. Birds, for example, have hollow, air-filled bones and lack teeth (see Chapter 34). A fusiform shape helps reduce drag in air as it does in water.

Comparing Costs of Locomotion

The study of locomotion returns us to the theme of animal bioenergetics, discussed in Chapter 40. The energy cost of locomotion depends on the mode of locomotion and the environment (Figure 49.37). Running animals generally will expend more energy per meter traveled than equivalently sized animals specialized for swimming, partly because running or walking requires energy to overcome gravity. Swimming is the most energy-efficient mode of locomotion (assuming that an animal is specialized for swimming). And if we were to compare the energy consumption per minute rather than per meter, we would find that flying animals use more energy than swimming or running animals with the same body mass.

The downward slope of each line on the graph in Figure 49.37 also shows that a larger animal travels more efficiently than a smaller animal specialized for the same mode of transport. For example, a 450-kg horse expends less energy *per kilogram of body mass* than a 4-kg cat running the same distance. Of course, the total amount of energy expended in locomotion is greater for the larger animal.

An animal's use of energy to move determines how much energy in the food it consumes is available for other activities, such as growth and reproduction. Therefore, structural and behavioral adaptations that maximize the efficiency of locomotion increase an animal's evolutionary fitness.

Although we have discussed sensory receptors and muscles separately in this chapter, they are part of a single integrated system linking together brain, body and the external world. An animal's behavior is the product of this system. Unit Eight discusses behavior within the broader context of ecology, the study of interactions between organisms and their environment.

Figure 49.37

Inquiry? What are the energy costs of locomotion?

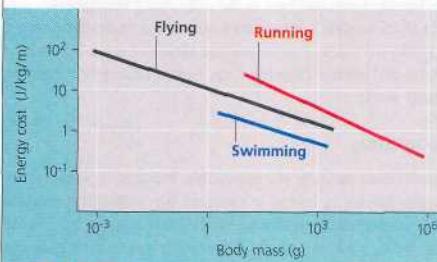

EXPERIMENT

Physiologists typically determine an animal's rate of energy use during locomotion by measuring its oxygen consumption or carbon dioxide production while it swims in a water flume, runs on a treadmill, or flies in a wind tunnel. For example, the trained parakeet shown below is wearing a plastic face mask connected to a tube that collects the air the bird exhales as it flies.

RESULTS

This graph compares the energy cost, in joules per kilogram of body mass per meter traveled, for animals specialized for running, flying, and swimming ($1 \text{ J} = 0.24 \text{ cal}$). Notice that both axes are plotted on logarithmic scales.

CONCLUSION

For animals of a given body mass, swimming is the most energy-efficient and running the least energy-efficient mode of locomotion. In any mode, a small animal expends more energy per kilogram of body mass than a large animal.

Concept Check 49.7

1. Contrast swimming and flying in terms of the main problems they pose and the adaptations that allow animals to overcome those problems.
2. Based on Figure 49.37, which animal uses more energy per kilogram of body mass to move 1 m—a 1-g flyer or a 1-kg runner?

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 49.1

Sensory receptors transduce stimulus energy and transmit signals to the central nervous system

- **Functions Performed by Sensory Receptors** (pp. 1046–1048) Sensory receptors are usually specialized neurons or epithelial cells that detect environmental stimuli. Exteroceptors detect external stimuli; interoceptors detect internal stimuli. Sensory transduction is the conversion of stimulus energy into a change in membrane potential called a receptor potential. Signal transduction pathways in receptor cells often amplify the signal, which causes the receptor cell either to produce action potentials or to release neurotransmitter at a synapse with a sensory neuron.

Concept 49.2

Mechanoreceptors respond to stimuli such as pressure, touch, stretch, motion, and sound. Chemoreceptors detect either total solute concentrations or specific molecules. Electromagnetic receptors detect different forms of electromagnetic radiation. Various types of thermoreceptors signal surface and core temperatures of the body. Pain is detected by a group of diverse receptors that respond to excess heat, pressure, or specific classes of chemicals.

Concept 49.2

The mechanoreceptors involved with hearing and equilibrium detect settling particles or moving fluid

- **Sensing Gravity and Sound in Invertebrates** (p. 1050) Most invertebrates sense their orientation with respect to gravity by means of statocysts. Many arthropods sense sounds with body hairs that vibrate and with localized "ears," consisting of a tympanic membrane and receptor cells.
- **Hearing and Equilibrium in Mammals** (pp. 1050–1053) The tympanic membrane (eardrum) transmits sound waves to three small bones of the middle ear, which transmit the waves through the oval window to the fluid in the coiled cochlea of the inner ear. Pressure waves in the fluid vibrate the basilar membrane, depolarizing hair cells in the organ of Corti and triggering action potentials that travel via the auditory nerve to the brain. Each region of the basilar membrane vibrates most vigorously at a particular frequency and leads to excitation of a specific auditory area of the cerebral cortex. The utricle, saccule, and three semicircular canals in the inner ear function in balance and equilibrium.

Concept 49.3

(pp. 1053–1054) The detection of water movement in fishes and aquatic amphibians is accomplished by a lateral line system containing clustered hair cells.

Concept 49.3

The senses of taste and smell are closely related in most animals

- **Taste in Humans** (pp. 1055–1056) Taste and smell both depend on the stimulation of chemoreceptors by small, dissolved molecules that bind to proteins on the plasma membrane. In humans, taste receptors are organized into taste buds on the

tongue and in the mouth. Five taste perceptions—sweet, sour, salty, bitter, and umami (elicited by glutamate)—involve several different transduction mechanisms.

- **Smell in Humans** (pp. 1056–1057) Olfactory receptor cells line the upper part of the nasal cavity and send their axons to the olfactory bulb of the brain. More than 1,000 genes code for membrane proteins that bind to specific classes of odorants, and each receptor cell expresses only one or at most a few of those genes.

Concept 49.4

Similar mechanisms underlie vision throughout the animal kingdom

- **Vision in Invertebrates** (pp. 1057–1058) The light detectors of invertebrates include the simple, light-sensitive eyespot of planarians; the image-forming compound eyes of insects, crustaceans, and some polychaetes; and the single-lens eyes of some jellies, polychaetes, spiders, and many molluscs.
- **The Vertebrate Visual System** (pp. 1058–1063) The main parts of the vertebrate eye are the sclera, which includes the cornea, conjunctiva; the choroid, which includes the iris; the retina, which contains the photoreceptors; and the lens, which focuses light on the retina. Photoreceptors (rods and cones) contain a pigment, retinal, bonded to a protein (opsin). Absorption of light by retinal triggers a signal transduction pathway that hyperpolarizes the photoreceptors, causing them to release less neurotransmitter. Synapses transmit information from photoreceptors to bipolar cells and then to ganglion cells, whose axons in the optic nerve convey action potentials to the brain. Other neurons in the retina integrate information before it is sent to the brain. Most axons in the optic nerves go to the lateral geniculate nuclei of the thalamus, which relays information to the primary visual cortex. Several integrating centers in the cerebral cortex are active in creating visual perceptions.

Activity Structure and Function of the Eye

Concept 49.5

Animal skeletons function in support, protection, and movement

- **Types of Skeletons** (pp. 1063–1064) A hydrostatic skeleton, found in most cnidarians, flatworms, nematodes, and annelids, consists of fluid under pressure in a closed body compartment. Exoskeletons, found in most molluscs and arthropods, are hard coverings deposited on the surface of an animal. Endoskeletons, found in sponges, echinoderms, and chordates, are hard supporting elements embedded within an animal's body.

Activity Human Skeleton

- **Physical Support on Land** (pp. 1064–1066) In addition to the skeleton, muscles and tendons help support large land vertebrates.

Concept 49.6

Muscles move skeletal parts by contracting

- **Vertebrate Skeletal Muscle** (pp. 1066–1072) Skeletal muscles, often present in antagonistic pairs, provide movement by contracting and pulling against the skeleton. Vertebrate skeletal muscle consists of a bundle of muscle cells (fibers), each of which contains myofibrils composed of thin filaments of actin and thick filaments of myosin. Myosin heads, energized by the hydrolysis of ATP, bind to the thin filaments, forming cross-bridges. Bending of the myosin heads exerts force on the thin filaments. When ATP binds to the myosin heads, they release,

ready to start a new cycle. Repeated cycles cause the thick and thin filaments to slide past each other, shortening the sarcomere and contracting the muscle fiber.

A motor neuron initiates contraction by releasing acetylcholine, which depolarizes the muscle fiber. Action potentials travel to the interior of the muscle fiber along the T tubules, stimulating the release of Ca^{2+} from the sarcoplasmic reticulum. The calcium ions reposition the tropomyosin-tropronin complex on the thin filaments, exposing the myosin-binding sites on actin and allowing the cross-bridge cycle to proceed. A motor unit consists of a motor neuron and the muscle fibers it innervates. Recruitment of multiple motor units results in stronger contractions. A twitch results from a single action potential in a motor neuron. More rapidly delivered action potentials produce a graded contraction by summation. Tetanus is a state of smooth and sustained contraction produced when motor neurons deliver a volley of action potentials. Skeletal muscle fibers are classified as slow oxidative, fast oxidative, or fast glycolytic based on their contraction speed and major pathway for producing ATP.

Activity *Skeletal Muscle Structure*

Activity *Muscle Contraction*

Investigation *How Do Electrical Stimuli Affect Muscle Contraction?*

- **Other Types of Muscle** (p. 1072) Cardiac muscle, found only in the heart, consists of striated cells that are electrically connected by intercalated disks and can generate action potentials without neural input. In smooth muscle, contractions are slow and may be initiated by the muscles themselves or by stimulation from neurons in the autonomic nervous system.

Concept 49.7

Locomotion requires energy to overcome friction and gravity

- **Swimming** (p. 1073) Overcoming friction is a major problem for swimmers. Gravity is less of a problem for swimming animals than for those that move on land or fly.
- **Locomotion on Land** (pp. 1073-1074) Walking, running, hopping, or crawling on land requires an animal to support itself and to move against gravity.
- **Flying** (p. 1074) Flight requires that wings develop enough lift to overcome the downward force of gravity.
- **Comparing Costs of Locomotion** (p. 1074) Animals that are specialized for swimming expend less energy per meter traveled than equivalently sized animals specialized for flying or running.

TESTING YOUR KNOWLEDGE

Evolution Connection

In general, locomotion on land requires more energy than locomotion in water. By integrating what you have learned throughout these chapters on animal functions, discuss some of the evolutionary adaptations of mammals that support the high energy requirements for moving on land.

Scientific Inquiry

Although skeletal muscles generally fatigue fairly rapidly, clam shell muscles have a protein called paramyosin that allows them to sustain contraction for up to a month. From your knowledge of the cellular mechanism of contraction, propose a hypothesis to explain how paramyosin might work. How would you test your hypothesis experimentally?

Investigation *How Do Electrical Stimuli Affect Muscle Contraction?*

Science, Technology, and Society

You may know an older person who has broken a bone (often a hip) partly because of osteoporosis, a loss of bone density that affects many women after menopause. As a means of avoiding osteoporosis, researchers recommend exercise and maximum calcium intake when a person is between 10 and 30 years old. Is it realistic to expect young people to view themselves as future senior citizens? How would you suggest that they be encouraged to develop good health habits that might not pay off for 40 or 50 years?

Global

and place, and now more than ever, we are faced with difficult decisions about what to do with our planet. We must make choices that will affect the future of our environment, and those choices must be made now.

of global soils at direct benefit. In such the soil no carbon sinks are possible until a sufficient level of atmospheric CO₂ is reached.

Further, and more seriously, climate change increases the risk of extreme events such as floods, droughts, and storms. These events can have a significant impact on agriculture, infrastructure, and human health. For example, flooding can lead to soil erosion, which can reduce soil quality and productivity. Droughts can also reduce soil moisture levels, leading to crop failure and water scarcity. Storms can cause landslides, damage infrastructure, and displace people. All of these factors can contribute to food insecurity and poverty, which in turn can lead to social instability and conflict. Therefore, it is crucial that we take action to mitigate the effects of climate change on our soils and our food security.

Agroforestry is one tool that can help address these challenges.

Agroforestry is a sustainable land management system that integrates trees with crops and animals. It can help reduce soil erosion, increase soil organic matter, and improve soil health. By adding trees to agricultural systems, agroforestry can provide shade, reduce soil temperature, and increase soil moisture retention. This can help reduce soil evaporation and increase soil infiltration, which can help reduce soil erosion and improve soil health.

Agroforestry can also help reduce greenhouse gas emissions by sequestering carbon dioxide from the atmosphere. This is because trees absorb CO₂ through photosynthesis and store it in their biomass.

However, there are challenges to implementing agroforestry on a large scale. One challenge is finding the right tree species for a particular location. Different trees have different requirements for soil, water, and light, and some may not survive in certain environments. Another challenge is finding the right way to integrate trees into existing agricultural systems. This requires careful planning and management to ensure that trees do not compete with crops for resources, and that they do not interfere with other agricultural activities.

Despite these challenges, agroforestry has the potential to play a key role in addressing climate change and ensuring food security for generations to come.

One way to overcome these challenges is to work with local communities and farmers to develop agroforestry systems that are tailored to their specific needs and conditions. This can involve providing training and support to farmers, as well as developing policies and incentives to encourage the adoption of agroforestry. It is also important to research and develop new technologies and methods for integrating trees into agricultural systems, such as no-till cultivation and intercropping.

In conclusion, soil and food security are interconnected, and both must be addressed together.

Agroforestry is a promising solution for addressing the challenges of climate change and ensuring food security. By integrating trees with crops and animals, agroforestry can help reduce soil erosion, increase soil organic matter, and improve soil health. This can help reduce soil evaporation and increase soil infiltration, which can help reduce soil erosion and improve soil health. Agroforestry can also help reduce greenhouse gas emissions by sequestering carbon dioxide from the atmosphere. However, there are challenges to implementing agroforestry on a large scale. One challenge is finding the right tree species for a particular location. Different trees have different requirements for soil, water, and light, and some may not survive in certain environments. Another challenge is finding the right way to integrate trees into existing agricultural systems. This requires careful planning and management to ensure that trees do not compete with crops for resources, and that they do not interfere with other agricultural activities.

Global Climate Change

global climate change is a complex issue that requires a multi-faceted approach. While there is scientific consensus that climate change is real and primarily driven by human activity, the causes and impacts of climate change are not fully understood. This lack of understanding makes it difficult to develop effective policies and actions to address climate change. In addition, the impacts of climate change are likely to be felt most acutely by vulnerable populations and ecosystems, such as low-income communities and indigenous peoples. Therefore, it is essential to prioritize equity and justice in climate policy development and implementation.

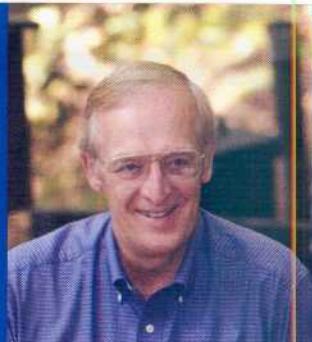

One way to address climate change is to reduce greenhouse gas emissions. This can be done through a variety of measures, such as transitioning to renewable energy sources, improving energy efficiency, and reducing deforestation. It is also important to develop adaptation strategies to help vulnerable populations and ecosystems cope with the impacts of climate change. This may involve investing in infrastructure, such as sea walls and flood defenses, or developing new agricultural techniques to withstand changing weather patterns. It is essential to involve all stakeholders in the process of climate policy development, including governments, businesses, and civil society organizations, to ensure that policies are effective, equitable, and just.

Another way to address climate change is to promote sustainable development. This involves shifting away from a growth-based economy towards a more sustainable model that prioritizes environmental protection, social justice, and economic resilience. This may involve investing in green jobs, promoting sustainable agriculture, and protecting natural resources. It is essential to involve all stakeholders in the process of climate policy development, including governments, businesses, and civil society organizations, to ensure that policies are effective, equitable, and just.

In conclusion, climate change is a complex issue that requires a multi-faceted approach. While there is scientific consensus that climate change is real and primarily driven by human activity, the causes and impacts of climate change are not fully understood. This lack of understanding makes it difficult to develop effective policies and actions to address climate change. In addition, the impacts of climate change are likely to be felt most acutely by vulnerable populations and ecosystems, such as low-income communities and indigenous peoples. Therefore, it is essential to prioritize equity and justice in climate policy development and implementation.

Ecology

AN INTERVIEW WITH Gene E. Likens

If scientists wore medals on their chests like military generals, ecologist Gene Likens would be one of biology's most decorated heroes. His recent awards include the 2001 National Medal of Science and the 2003 Blue Planet Prize, which honors "outstanding scientific research that helps solve environmental problems." Dr. Likens shared the latter award with his longtime collaborator, Herbert Bormann, with whom Likens pioneered the field of "long-term ecological research" at the Hubbard Brook Experimental Forest in the White Mountains of New Hampshire. As President and Director of the Institute of Ecosystem Studies in upstate New York, Dr. Likens manages a large team of scientists and educators, but he returns to Hubbard Brook each summer to continue his inquiry about how forest and aquatic ecosystems work. We conducted this interview at one of Hubbard Brook's historic research sites.

How did the Hubbard Brook Experimental Forest become the focus of your ecosystem research?
When I joined the Dartmouth Faculty in 1961, I met Herb Bormann, who had this idea for a small-watershed approach for studying forest ecosystems. The Hubbard Brook Experimental Forest was ideal for such studies and was close by. And so it was one of those chance situations where it all just fell together. Much of my scientific career has been the result of such serendipity—that is, keeping your eyes, your ears, and your mind open, and when there's an opportunity, jump in and try to make something productive from it.

Why is Hubbard Brook so attractive as a field station for ecosystem research?
Our challenge from the beginning was to confront the complexity of this ecosystem and make

sense of it. So, we started with the small-watershed approach. The idea was very simple: We used a medical analogy. We figured we could measure the chemistry of stream water, much like a physician would measure the chemistry of blood, to analyze the health of the watershed, the patient. We wanted to measure all the inputs to the system, such as in precipitation, and all the outputs such as in the stream water draining the system, and from that, try to understand the health of this patient. In each watershed, we find a place where the bedrock is close to the surface, and then build a gauging station, also called a weir. All the water coming down the hill is forced to pass through the weir, so we can measure the amount and chemical composition of the stream water very accurately year round.

This is your forty-second straight summer of such studies here at Hubbard Brook. It must be tough to get funding to support research over such a long term.
Our proposals for research grants mostly emphasize short-term questions that require long-term data. For example, long-term data from Hubbard Brook were critical in establishing that acid rain exists, and also provide the basis for shorter-term measurements of whether the problem of acid rain is getting worse or better. Long-term ecological research, has become a hallmark of Hubbard Brook studies.

What was the public impact of evidence for acid rain in the Hubbard Brook Forest?

Although Swedish scientists studied acid rain earlier, our research was the first documentation of acid rain in North America. When we published our first paper on acid rain in 1972, the press really picked up on it. The evidence that there was something wrong with rain was a powerful issue that the public could relate to. The long-term data from Hubbard Brook made it very

difficult to argue that there was no such thing, as acid rain, and I think it's fair to say that the quality of those long-term data contributed to the 1990 amendments to the Clean Air Act that addressed the link between acid rain and combustion of fossil fuels.

Hubbard Brook is also famous for experiments on the effects of deforestation. How do you do such large-scale experiments, arid what were some key results?

An example of these experimental manipulations is when we cut down all the trees in one of the watersheds and left them where they fell. We then used herbicides to prevent regrowth for three years. We compared the inputs and outputs for this experimental watershed with a reference watershed that was not altered. We expected more water to run off the experimental watershed, and that turned out to be the case. What we didn't expect was that the chemistry of the runoff would change so dramatically. For example, nitrate levels in the water shot up to a level that exceeded public health standards for drinking. Cutting the trees totally disrupted the recycling of nitrogen in the soil, and the nitrate that accumulated moved downstream. The nitrogen loss slowed after the second year, but some soil nutrients, such as calcium, still haven't come back to the levels and patterns that existed before the trees were cut in 1965.

How do these tree-cutting experiments relate to issues of forest management?

The research is fundamentally important to our basic understanding of how an ecosystem like this works, but the popular press picked up the story in terms of the clear-cutting controversy. Based on our long-term data, we proposed in a 1978 *Science* article that you can do clear-cutting in these kinds of forests if you follow specific guidelines. Clear cutting shouldn't be

done on really steep slopes or in very large blocks, and certainly the stream channel should be protected. But most importantly, a site should not be clear cut very often. If a forest is harvested too frequently then the system will become depleted of critical nutrients. It's just like a garden; if you continue to take away and never put anything back, you're going to deplete the soil. The Forest Service has now adopted a 100-year rotation policy (a particular section of forest can be logged only once every 100 years), and we're very proud of that. That forest management protocol is based on science.

Which current research projects at Hubbard Brook do you think are most likely to capture the attention of both the ecology community and the general public?

Richard Holmes at Dartmouth College and his colleagues are conducting really elegant long-term studies of bird populations. I think one of their newsworthy findings is that the total number of birds of all species present in the forest is currently about a third of what it was in 1969. Some species have actually increased in abundance, while others have almost disappeared from here. The researchers are now focusing on how predation, food availability, and other factors may be affecting the bird populations. Another project that I think is quite newsworthy involves a beautiful little lake at the bottom of this valley called Mirror Lake. One of the things I started at the very beginning of my work here, about 1965, was to record the period of ice cover on the lake. The ice cover is related to the total heat budget

for the lake, so it's an indication of temperature and climate change. Well, as you might expect, the period of ice cover is highly variable over the short term because the weather *varies* from year to year. But our long-term data show that there is a highly statistically significant decline in the period of ice cover—about 19 fewer days of ice cover on the lake now than in the 1960s. This is a clear indication of global warming.

Along with your work at Hubbard Brook, you are President and Director of the Institute of Ecosystem Studies (IES). What motivated you 20 years ago to trade a prestigious endowed chair at Cornell for the challenge of leading a not-for-profit research and education institute?

I was asked that question many times by my colleagues, and some thought I was crazy. The job description for the IES position basically said that I could do anything I wanted as long as I did it well. And I liked that a lot. I was the founding director of IES, and I'm extremely proud of how the Institute has built such an outstanding international reputation. We have a superb scientific staff, often working together on projects ranging from a study of invasive zebra mussels in the Hudson River to research on the ecology of infectious diseases, including Lyme disease.

What do you find so attractive about the multidisciplinary, team-oriented research you direct at IES?
Many brains can often make faster and better advances than a single brain. The only way you can

do big projects in science today is with teams, particularly in fields that emphasize bio-complexity. But such collaborative science requires trust in your colleagues. I think we should offer more training to graduate students to prepare them for working with research teams.

Speaking of training, IES complements its scientific mission with education programs. Are there any opportunities there for undergrads?

We have an NSF Research Experiences for Undergraduates (REU) program. Each summer, about 10 to 12 REU students are selected. In addition to participating in research, the REUs receive instruction on writing scientific papers, finding jobs, and scientific ethics. Two of the students this year are doing research here at Hubbard Brook, and the rest of the group will come for a visit next week.

What was it about your own education, formal or otherwise, that made you so interested in nature?

I grew up on a small farm in Indiana, and my early childhood was spent barefoot, out in the forests and particularly around lakes. When I went to college, I was planning to become an elementary school teacher and a baseball coach. But I had a professor who just kept insisting that I go to graduate school. So to get him off my back, I applied to graduate schools and went to the University of Wisconsin, where I studied lake systems. It was another wonderful serendipitous event for me.

How have your 42 years of experience here at Hubbard Brook affected your view of nature?

Hubbard Brook has provided me with just wonderful questions to explore. I've gone from being a naive farm kid to using very sophisticated techniques to answer questions about this complex system and trying to help people understand why it's important to protect this kind of complexity in natural ecosystems. You must respect nature because it provides the basic life support system: clean air, clean water, clean soil, and nourishing food. And if you give these ecosystems a chance, they're resilient and will continue to provide the life support we need. Learning that here at Hubbard Brook changed my life. And can you believe someone pays me to work in such a beautiful place?

Much of my scientific career has been the result of such serendipity—that is, keeping your eyes, your ears, and your mind open, and when there's an opportunity, jump in and try to take something productive from it.

An Introduction to Ecology and the Biosphere

& Figure 50.1 The richness of the biosphere evident in one area of a Panamanian forest.

Key Concepts

- 50.1 Ecology is the study of interactions between organisms and the environment
- 50.2 Interactions between organisms and the environment limit the distribution of species
- 50.3 Abiotic and biotic factors influence the structure and dynamics of aquatic biomes
- 50.4 Climate largely determines the distribution and structure of terrestrial biomes

Overview

The Scope of Ecology

Organisms are open systems that interact continuously with their environment—a theme that has already surfaced many times in this book. The scientific study of the interactions between organisms and the environment is called **ecology** (from the Greek *oikos*, home, and *logos*, to study). These interactions determine both the distribution of organisms and their abundance, leading to three questions that ecologists often ask about organisms: Where do they live? Why do they live where they do? And how many are there? Ecologists also study how interactions between organisms and the environment affect phenomena such as the number of species living in a particular area, the cycling of nutrients in a forest or lake, and the growth of populations.

Because of its great scope, ecology is an enormously complex and exciting area of biology, as well as one of critical importance. Ecology reveals the richness of the biosphere—the entire portion of Earth inhabited by life—and can provide the basic understanding that will help us to conserve and sustain that richness, now threatened more than ever by human activity. The richness of the biosphere is particularly apparent in tropical forests, such as the Panamanian forest where the

Hercules scarab beetle (*Dynastes hercules*) pictured in **Figure 50.1** lives. Earth's tropical forests are home to millions of species, including an estimated 5–30 million still undescribed species of insects, spiders, and other arthropods. In fact, every part of the biosphere is inhabited by diverse life-forms, most of which, especially the microbial species, are unknown to science. This chapter introduces the science of ecology and describes some of the factors, both living and nonliving, that affect the distribution of organisms. It also surveys the major types of aquatic and terrestrial habitats where organisms live and where ecologists go to study them.

Concept 50.1

Ecology is the study of interactions between organisms and the environment

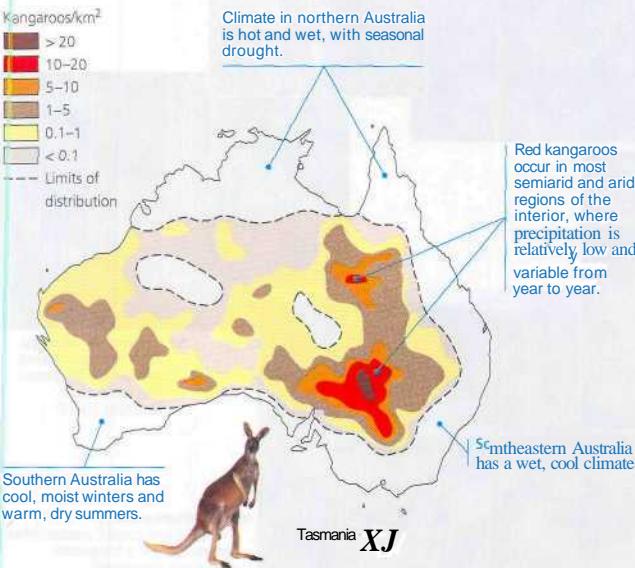

Humans have always had an interest in the distribution and abundance of other organisms. As hunters and gatherers, prehistoric people had to learn where game and edible plants could be found in abundance. With the development of agriculture and the domestication of animals, people learned more about how the environment affects the growth, survival, and reproduction of plants and animals. Later, naturalists from Aristotle to Darwin and beyond observed and described organisms in their natural habitats and systematically recorded their observations. Because extraordinary insight can still be gained through this descriptive approach to discovery science (see Chapter 1), natural history remains a fundamental part of the science of ecology.

In addition to its long history as a descriptive science, ecology is also a rigorous experimental science. Despite the

difficulties of conducting experiments in natural environments, ecologists often test their hypotheses through field experiments. The long-term research by Gene Likens and his colleagues in the Hubbard Brook Experimental Forest is one example (see the interview on pages 1078–1079). Other examples of field experiments include studies in which researchers measure the impact of herbivory (plant-eating) on plant species diversity by comparing open control plots to experimental “exclosures” designed to keep out certain herbivore species. Perhaps because of ecology’s focus on complex systems that challenge the capacity of scientists to produce consistent results, ecologists have been innovators in the areas of experimental design and the application of statistical inference. You will encounter many examples of ecological experiments throughout this unit.

Ecology and Evolutionary Biology

Ecology and evolutionary biology are closely related sciences. Darwin’s extensive observations of the distribution of organisms and their adaptation to specific environments led him to propose that environmental factors interacting with variation within populations could cause **evolutionary** change (see Chapter 22). Today, we have ample evidence that events that occur in the framework of ecological time (minutes, months, and years) translate into effects over the longer scale of evolutionary

A Figure 50.2 Distribution and abundance of the red kangaroo in Australia, based on aerial surveys.

time (decades, centuries, millennia, and longer). For instance, hawks feeding on field mice have an immediate impact on the prey population by killing certain individuals, thereby reducing population size (an ecological effect) and altering the gene pool (an evolutionary effect). One long-term evolutionary effect of this predator-prey interaction may be selection for mice with fur coloration that camouflages the animals.

Organisms and the Environment

The environment of any organism includes **abiotic**, or nonliving, components—chemical and physical factors such as temperature, light, water, and nutrients—and **biotic**, or living, components—all the organisms, or the **biota**, that are part of the individual’s environment. Other organisms may compete with an individual for food and other resources, prey upon it, parasitize it, provide its food, or change its physical and chemical environment.

Questions about the relative influence of various environmental components, both abiotic and biotic, are frequently at the heart of ecological studies. For example, **Figure 50.2** shows the geographic range of the red kangaroo in Australia and illustrates the basis for two common ecological questions: What environmental factors limit the geographic range, or **distribution**, of a species such as the red kangaroo? And what factors determine its **abundance**? Some of the climatic factors that ecologists might consider in the case of the red kangaroo are indicated in **Figure 50.2**. Notice that red kangaroos do not live in regions around the periphery of Australia, where the climate varies from moist to wet. Notice also that red kangaroos are most abundant in a few areas, shaded dark brown to orange, where the climate is drier and more variable from year to year. Near the edges of their range, where the climate is wetter than in the interior and where the mean annual temperature is higher, red kangaroos are scarce.

These patterns suggest that an abiotic factor, the amount and variability of precipitation, influences the distribution of red kangaroos in Australia. However, are the controls on red kangaroo distribution only abiotic? Perhaps climate influences red kangaroo populations indirectly through **biotic** factors, such as pathogens, parasites, competitors, predators, and food availability. For instance, do wetter regions harbor pathogens and parasites deadly to red kangaroos? Ecologists generally need to consider multiple factors and alternative hypotheses when attempting to explain patterns of distribution and abundance.

Subfields of Ecology

Ecology can be divided into areas of study ranging from the ecology of individual organisms to the dynamics of ecosystems and landscapes (Figure 50.3). While each of these sub-fields has some unique terminology and scientific concerns, modern ecological studies increasingly cross the boundaries between traditionally separate areas.

Organismal ecology, which may be subdivided into the disciplines of physiological ecology, evolutionary ecology, and behavioral ecology, concerns how an organism's structure, physiology, and (for animals) behavior meet the challenges posed by the environment.

A **population** is a group of individuals of the same species living in a particular geographic area. **Population ecology** concentrates mainly on factors that affect how many individuals of a particular species live in an area.

A **community** consists of all the organisms of all the species that inhabit a particular area; it is an assemblage of populations of many different species. Thus, **community ecology** deals

with the whole array of interacting species in a community. This area of research focuses on how interactions such as predation, competition, and disease, as well as abiotic factors such as disturbance, affect community structure and organization.

An ecosystem consists of all the abiotic factors in addition to the entire community of species that exist in a certain area. An ecosystem—a lake, for example—may contain many different communities. In ecosystem **ecology**, the emphasis is on energy flow and chemical cycling among the various biotic and abiotic components.

Landscape **ecology** deals with arrays of ecosystems—just two examples are a corridor of trees lining a river flowing through a sparsely vegetated plain, or patches of coral reef surrounded by turtle grass—and how they are arranged in a geographic region. Every landscape or seascapes consists of a mosaic of different types of "patches," an environmental characteristic ecologists refer to as **patchiness**. Landscape ecological research focuses on the factors controlling exchanges of energy, materials, and organisms among the ecosystem patches making up a landscape or seascapes.

(a) **Organismal ecology.**

How do humpback whales select their calving areas?

(b) **Population ecology.**

What environmental factors affect the reproductive rate of deer mice?

(c) **Community ecology.**

What factors influence the diversity of species that make up a particular forest?

(d) **Ecosystem ecology.**

What factors control photosynthetic productivity in a temperate grassland ecosystem?

A Figure 50.3 Examples of questions in different subfields of ecology.

The **biosphere** is the global ecosystem—the sum of all the planet's ecosystems. This broadest area of ecology includes the entire portion of Earth inhabited by life: the atmosphere to an altitude of several kilometers, the land down to and including water-bearing rocks at least 3 kilometers below-ground, lakes and streams, caves, and the oceans to a depth of several kilometers. An example of research at the biosphere level is the analysis of how changes in atmospheric CO₂ concentration may affect Earth's climate and, in turn, all life.

Ecology and Environmental Issues

Because the term ecology is so often misused in popular writing to refer to environmental concerns, it is important to clarify the difference between ecology and environmentalism (advocating for the protection or preservation of the natural environment). To address environmental problems, we need to understand the often complicated and delicate relationships between organisms and the environment. The science of ecology provides that understanding. If we know that phosphate promotes the growth of algae in lakes, for instance, we may decide to limit the use of phosphate-rich fertilizers in surrounding areas to protect lakes from becoming clogged with algae.

Much of society's current awareness of environmental issues had its beginnings in 1962 with Rachel Carson's *Silent Spring* (Figure 50.4). In that now-classic book, Carson warned that the widespread use of pesticides such as DDT was causing population declines in many nontarget organisms. Today, acid precipitation, localized famine aggravated by land misuse and population growth, the poisoning of soil and streams with toxic wastes, and the growing list of species extinct or endangered because of habitat destruction are just a few of the problems that threaten the home we share with millions of other forms of life.

Many influential ecologists, including Gene Likens, recognize a responsibility to educate legislators and the general public about decisions that affect the environment. An important part of this responsibility is communicating the scientific complexity of environmental issues. Politicians and lawyers often want definitive answers to such environmental questions as how much old-growth forest is needed to "save

• Figure 50.4 Rachel Carson. In *Silent Spring*, a book seminal to the modern environmental movement, Carson had a broad message: "The 'control of nature' is a phrase conceived in arrogance, born of the Neanderthal age of biology and philosophy, when it was supposed that nature exists for the convenience of man."

the spotted owls." While ecological studies can certainly provide essential information for making policy decisions on habitat preservation, responses to such questions often include further questions: How many owls must be saved? With what certainty must they be saved? How long can they survive in this amount of forest? Ecologists can help answer these questions so that the public and policymakers can make informed decisions about environmental issues.

Although our ecological information is always incomplete, we cannot abstain from making decisions about environmental issues until all the answers are known. But given what we do know about the interconnectedness of the biosphere, it is probably wise to follow the **precautionary principle**, which can be expressed simply as "An ounce of prevention is worth a pound of cure." Aldo Leopold, the famous wildlife conservationist, expressed the precautionary principle well when he wrote, "To keep every cog and wheel is the first precaution to intelligent tinkering."

Concept 50.1

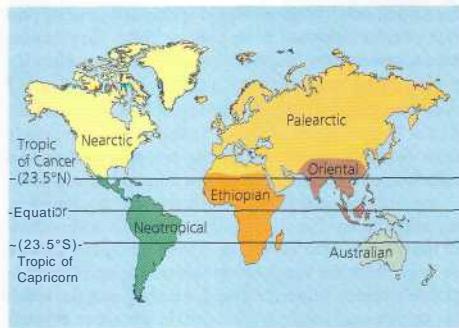

1. Contrast the terms *ecology* and *environmentalism*. How does ecology relate to environmentalism?
2. How can an event that occurs on the ecological time scale affect events that occur on an evolutionary time scale?
3. Within which area of ecology is each of the following directly working: (a) an ecologist studying the distribution and abundance of red kangaroos in Australia; (b) an ecologist studying changes in which plant species are most abundant in a forest following a wildfire?

For suggested answers, see Appendix A.

Concept 50.2

Interactions between organisms and the environment limit the distribution of species

In Chapter 22, we discussed *biogeography*, the study of the past and present distribution of individual species, in the context of evolutionary theory. Ecologists have long recognized global and regional patterns in the distribution of organisms within the biosphere. Kangaroos occur in Australia but not in North America, whereas pronghorn antelope occur in the western United States but not in Europe or Africa. More than a century ago, Darwin, Wallace, and other naturalists began to identify broad patterns of distribution by naming biogeographic

A Figure 50.5 Biogeographic realms. Continental drift and barriers such as deserts and mountain ranges all contribute to the distinctive flora and fauna found in Earth's major biogeographic realms. The realms are not sharply delineated but grade together in zones where species from adjacent realms coexist.

realms (Figure 50.5). We now associate these biogeographic realms with patterns of continental drift that followed the breakup of the supercontinent Pangaea (see Chapter 26).

Biogeography provides a good starting point for understanding what limits the geographic distribution of a species. To see how ecologists might arrive at such an understanding, let's work our way through the series of questions in the flowchart in Figure 50.6.

Dispersal and Distribution

The movement of individuals away from centers of high population density or from their area of origin, called dispersal, contributes to the global distribution of organisms. For example, why are there no kangaroos in North America? A biogeographer might propose this simple hypothesis: They could not

get there because a barrier to their dispersal existed; the area has been inaccessible to kangaroos since they first appeared. However, while land-bound kangaroos have not reached North America under their own power, some other organisms that are adapted for long-distance dispersal, such as some birds, have. The dispersal of organisms is critical to understanding both geographic isolation in evolution (see Chapter 24) and the broad patterns of current geographic distributions of species.

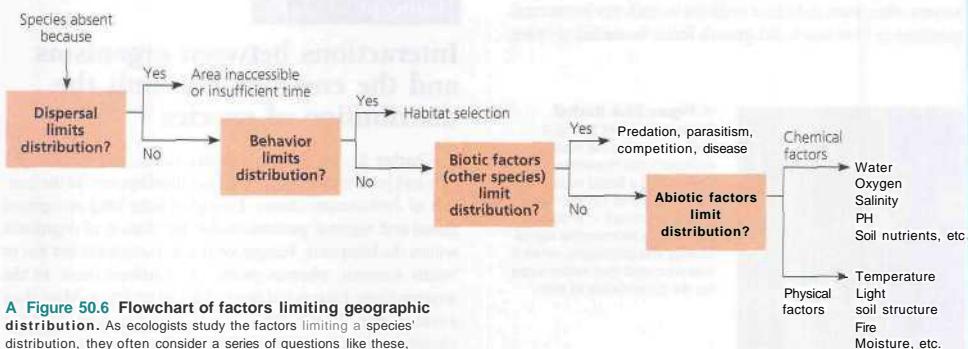

Natural Range Expansions

The role of dispersal is demonstrated when organisms expand their range by moving into areas where they did not exist previously. For instance, the cattle egret (see Figure 53.10), a species widely distributed in Africa, Eurasia, and Australia, was not found in the Americas 200 years ago. But in the late 1800s, some of these strong-flying birds managed to fly across the Atlantic Ocean and colonize northeastern South America. From there, cattle egrets gradually spread northward through Central America and into North America, reaching Florida in the 1950s. They have since spread widely and today have breeding populations as far west as the Pacific Coast and as far north as southern Canada. The great-tailed grackle, a large, conspicuous bird related to blackbirds and orioles, is another species that has expanded its range over time, moving northward from the coast of the Gulf of Mexico and the Rio Grande Valley (Figure 50.7).

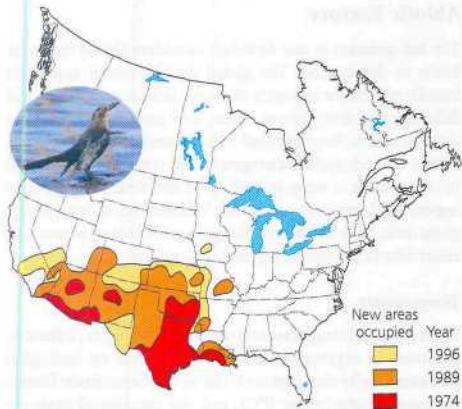

Natural range expansions clearly show the influence of dispersal on distribution, but opportunities to observe such dispersal are rare. As a consequence, ecologists have often turned to experimental methods to better understand the role of dispersal in limiting the distribution of species.

Species Transplants

One direct way to determine if dispersal is a key factor limiting distribution is to observe the results of intentional or accidental transplants of a species to areas where it was previously

A Figure 50.6 Flowchart of factors limiting geographic distribution. As ecologists study the factors limiting a species' distribution, they often consider a series of questions like these,

i Figure 50.7 Spread of breeding populations of the great-tailed grackle in the United States from 1974 to 1996. The grackle expanded its breeding range substantially in just 22 years.

absent. For a transplant to be considered successful, some of the organisms must not only survive in the new area but also reproduce there. Thus, a transplant's success may not be determined until at least one life cycle is complete. If a transplant is successful, then we can conclude that the *potential* range of the species is larger than its *actual* range; in other words, the species *could* live in certain areas where it currently does not.

Species introduced to new geographic locations often disrupt the communities and ecosystems to which they have been introduced and spread far beyond the area of intended introduction (see Chapter 55). Consequently, ecologists rarely conduct transplant experiments today. Instead, they document the outcome when a species has been transplanted for other purposes, such as to introduce game animals or sport fish, or when a species has been accidentally transplanted.

Behavior and Habitat Selection

As transplant experiments show, some organisms do not occupy all of their potential range, even though they may be physically able to disperse into the unoccupied areas. To follow our line of questioning from Figure 50.6, does behavior play a role in limiting distribution in such cases? When individuals seem to avoid certain habitats, even when the habitats are suitable, their distribution may be limited by habitat selection behavior. While habitat selection is typically applied to animals, plants may also select their habitats—for instance, by producing seeds that germinate only under a restricted set of environmental conditions—even though individual plants cannot move once they are rooted.

Although habitat selection is one of the least understood ecological processes, some instances have been closely studied, including habitat selection by several insect species. Female insects often oviposit (deposit eggs) only in response to a very narrow set of stimuli, which may restrict distribution of the insects to certain host plants. Larvae of the European corn borer, for example, can feed on a wide variety of plants but occur almost exclusively on corn because the ovipositing females are attracted by odors produced by the corn plant. And consider the ecology of anopheline mosquitoes. Important carriers of disease, these insects have been extensively studied as part of efforts to eradicate malaria in tropical areas. Each anopheline species is usually associated with a particular type of habitat. Surprisingly, large areas of apparently suitable tropical habitat are completely free of dangerous mosquitoes. Habitat selection for oviposition sites by female mosquitoes appears to restrict their distribution.

It might seem that a tropical mosquito is deficient because she does not lay eggs in apparently suitable rice field habitats. But this behavior may simply reflect the fact that rice fields are an evolutionarily recent habitat, and the mosquito is not adapted to it. Adaptation is not instantaneous, nor does evolution produce organisms perfectly adapted to every environment (see Chapter 23).

Biotic Factors

If behavior does not limit the distribution of a species, our next question is whether biotic factors—that is, other species—are responsible. In many cases, a species cannot complete its full life cycle if transplanted to a new area. This inability to survive and reproduce may be due to negative interactions with other organisms in the form of predation, parasitism, disease, or competition. Or survival and reproduction may be limited by the absence of other species on which the transplanted species depends. For instance, the absence of particular pollinator species could prevent reproduction by a transplanted plant species, though such specific dependence is rare. More common examples of biotic limitation on geographic distribution involve predators (organisms that kill their prey) and herbivores (organisms that eat plants or algae). Simply put, organisms that eat can limit the distribution of organisms that get eaten.

Let's examine one specific case of an herbivore limiting the distribution of a food species. In certain marine ecosystems, there is often an inverse relationship between the abundance of sea urchins and the abundance of seaweeds (large marine algae, such as kelp). Where sea urchins that graze on seaweeds and other algae are common, large stands of seaweeds do not become established. Thus, the local distribution of seaweeds appears to be limited by sea urchins. This kind of interaction can be tested by "removal and addition" experiments. In studies near Sydney, Australia, W. J. Fletcher, of the University of

Sydney, tested the hypothesis that sea urchins are a biotic factor limiting seaweed distribution. Fletcher reasoned that if this hypothesis is correct, then more seaweeds should invade an area from which sea urchins have been removed. Conversely, if urchins are added to an area rich in seaweeds, the seaweeds should be diminished. One complication is that there are often several other herbivores in addition to sea urchins in the habitats where seaweeds may grow; thus, Fletcher needed to perform a series of manipulative field experiments to isolate the influence of sea urchins on seaweeds in his study area (Figure 50.8).

In addition to predation and herbivory, the presence or absence of food resources, parasites, diseases, and competing organisms can act as biotic limitations on species distribution. Unfortunately, some of the most dramatic cases of limitation occur when humans introduce (either accidentally or intentionally) exotic predators or diseases into new areas and wipe out native species. You will encounter examples of these impacts in Chapter 55, which discusses conservation ecology.

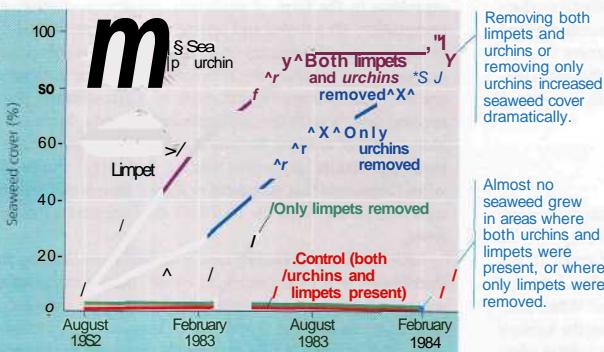

Figure 50.8
Does feeding by sea urchins and limpets affect seaweed distribution?

EXPERIMENT

W. J. Fletcher tested the effects of two algae-eating animals, sea urchins and limpets, on seaweed abundance near Sydney, Australia. In areas adjacent to a control site, either the urchins, the limpets, or both were removed.

RESULTS

Fletcher observed a large difference in seaweed growth between areas with and without sea urchins.

CONCLUSION

Removing both limpets and urchins resulted in the greatest increase of seaweed cover, indicating that both species have some influence on seaweed distribution. But since removing only urchins greatly increased seaweed growth while removing only limpets had little effect, Fletcher concluded that sea urchins have a much greater effect than limpets in limiting seaweed distribution.

Abiotic Factors

The last question in our flowchart considers abiotic factors as limits to distribution. The global distribution of organisms broadly reflects the influence of abiotic factors, such as regional differences in temperature, water, and sunlight. Throughout this discussion, keep in mind that the environment is characterized by both *spatial heterogeneity* and *temporal heterogeneity*. In other words, it varies in both space and time. Although two regions of Earth may experience different conditions at any given time, daily and annual fluctuations of abiotic factors may either blur or accentuate regional distinctions.

Temperature

Environmental temperature is an important factor in the distribution of organisms because of its effect on biological processes. Cells may rupture if the water they contain freezes (at temperatures below 0°C), and the proteins of most organisms denature at temperatures above 45°C. In addition, few organisms can maintain an appropriately active metabolism at very low or very high temperatures. Extraordinary adaptations enable some organisms, such as thermophilic prokaryotes (see Chapter 27), to live outside the temperature range habitable by other life.

An organism's internal temperature is affected by heat exchange with its environment, and most organisms cannot maintain tissue temperatures more than a few degrees above or below the ambient temperature (see Chapter 40). As endotherms, mammals and birds are the major exceptions, but even endothermic species function best within various, quite narrow environmental temperature ranges.

Water

The dramatic variation in water availability among habitats is another important factor in species distribution. Freshwater and marine organisms live submerged in aquatic environments, but most are restricted to either freshwater or saltwater habitats by their limited ability for osmoregulation. Terrestrial organisms face a nearly constant threat of desiccation, and their global distribution reflects their ability to obtain and conserve water. Desert organisms exhibit a variety of adaptations for water acquisition and conservation in a desiccating environment, as described in Chapter 44.

Sunlight

Sunlight provides the energy that drives nearly all ecosystems, although only plants and other photosynthetic organisms use this energy source directly. Light intensity is not the most important factor limiting plant growth in many terrestrial environments, although shading by a forest canopy makes competition for light in the understory intense. In aquatic environments, however, the intensity and quality of light limit the distribution of photosynthetic organisms. Every meter of water depth selectively absorbs about 45% of the red light and about 2% of the blue light passing through it. As a result, most photosynthesis in aquatic environments occurs relatively near the surface. The photosynthetic organisms themselves absorb some of the light that penetrates, further reducing light levels in the waters below.

Light is also important to the development and behavior of many organisms that are sensitive to photoperiod, the relative lengths of daytime and nighttime. Photoperiod is a more reliable indicator than temperature for cuing seasonal events, such as flowering by plants (see Chapter 39) or migration by animals.

Wind

Wind amplifies the effects of environmental temperature on organisms by increasing heat loss due to evaporation and convection (see Chapter 40). It also contributes to water loss in organisms by increasing the rate of evaporative cooling in animals and transpiration in plants. In addition, wind can have a substantial effect on the morphology of plants by inhibiting the growth of limbs on the windward side of trees, resulting in a "flagged" appearance (**Figure 50.9**).

Rocks and Soil

The physical structure, pH, and mineral composition of rocks and soil limit the distribution of plants and thus of the animals that feed upon them, contributing to the patchiness of terrestrial ecosystems. In streams and rivers, the composition of the substrate (bottom surface) can affect water chemistry, which in turn

• **Figure 50.9 "Flagging" of tree limbs due to wind.**

influences the resident organisms. In freshwater and marine environments, the structure of the substrate determines the organisms that can attach to or burrow in it.

Now that we have surveyed the abiotic factors that affect the distribution of organisms, let's focus on how those factors vary with climate as we consider the major role that climate plays in determining species distribution.

Climate

Four abiotic factors—temperature, water, sunlight, and wind—are the major components of **climate**, the prevailing weather conditions in a particular area. Climatic factors, particularly temperature and water, have a major influence on the distribution of organisms. We can describe climate patterns on two scales: **macroclimate**, patterns on the global, regional, and local level; and **microclimate**, very fine patterns, such as those encountered by the community of organisms underneath a fallen log. First, let's consider Earth's macroclimate.

Global Climate Patterns

Earth's global climate patterns are determined largely by the input of solar energy and the planet's movement in space. The sun's warming effect on the atmosphere, land, and water establishes the temperature variations, cycles of air movement, and evaporation of water that are responsible for dramatic latitudinal variations in climate. **Figure 50.10**, on the next two pages, summarizes Earth's climate patterns and how they are formed.

Regional, Local, and Seasonal Effects on Climate

Proximity to bodies of water and topographic features such as mountain ranges create regional climatic variations, and smaller features of the landscape contribute to local climatic variation. These regional and local variations in climate contribute to the patchiness of the biosphere. Seasonal variation is another influence on climate.

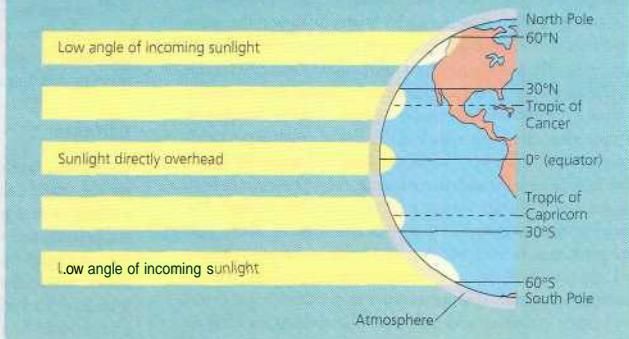

Bodies of Water. Ocean currents influence climate along the coasts of continents by heating or cooling overlying air masses, which may then pass across the land. Coastal regions are generally moister than inland areas at the same latitude. The cool, misty climate produced by the cold California current that flows southward along the western United States supports a temperate rain forest ecosystem dominated by large coniferous trees in the Pacific Northwest and large redwood groves farther south. Similarly, the warm Gulf Stream flowing northward from the Caribbean Sea and across the North Atlantic tempers the climate on the west coast of northern Europe. As a result, northwest Europe is warmer during winter than New England, which is actually farther south but is cooled by the Labrador Current flowing south from the coast of Greenland.

Figure 50.10

Exploring Global Climate Patterns

LATITUDINAL VARIATION IN SUNLIGHT INTENSITY

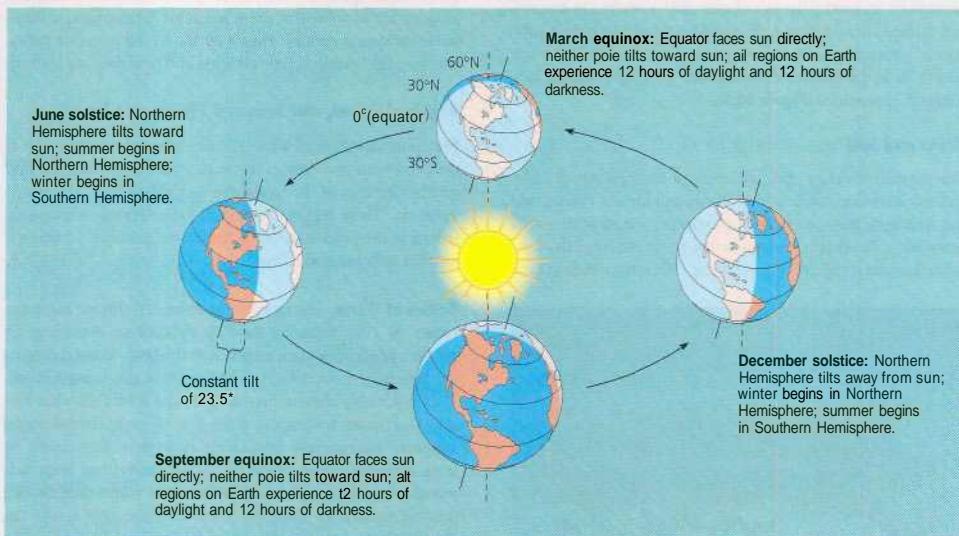

Earth's curved shape causes latitudinal variation in the intensity of sunlight. Because sunlight strikes the equator perpendicularly, the most heat and light per unit of surface area are delivered there. At higher latitudes, sunlight strikes Earth at an oblique angle, and thus the light energy is more diffuse on Earth's surface,

SEASONAL VARIATION IN SUNLIGHT INTENSITY

Earth's tilt causes seasonal variation in the intensity of solar radiation. Because the planet is tilted on its axis by 23.5° relative to its plane of orbit around the sun, the tropics (those regions that lie between 23.5° north latitude and 23.5° south latitude) experience the greatest

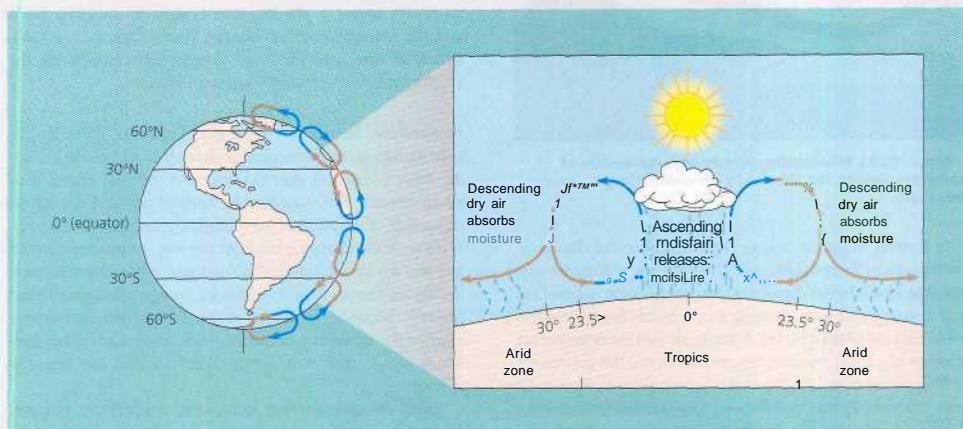

annual input of solar radiation and the least seasonal variation. The seasonal variation of light and temperature increases steadily toward the poles.

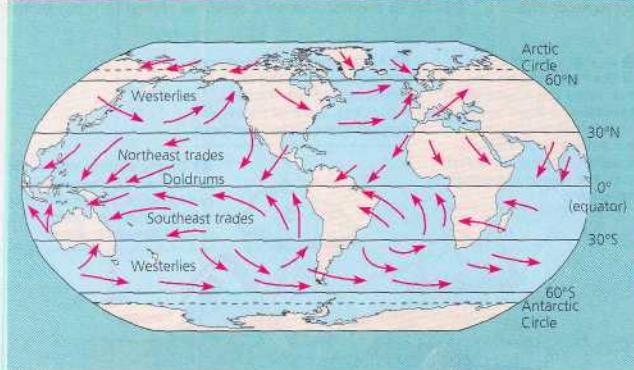

GLOBAL AIR CIRCULATION AND PRECIPITATION PATTERNS

Intense solar radiation near the equator initiates a global pattern of air circulation and precipitation. High temperatures in the tropics evaporate water from Earth's surface and cause warm, wet air masses to rise (blue arrows) and flow toward the poles. The rising air masses release much of their water content, creating abundant precipitation in tropical regions. The high-altitude air masses, now dry, descend (brown arrows) toward Earth, absorbing moisture from the land and creating an arid climate conducive to the development of

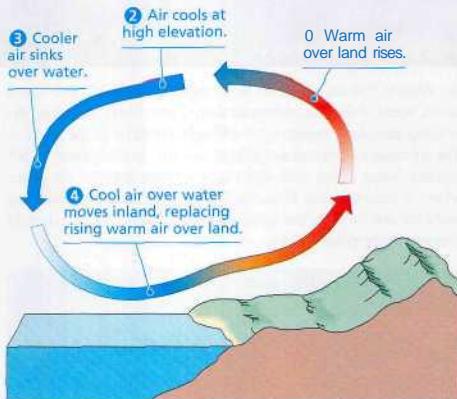

the deserts that are common at latitudes around 30° north and south. Some of the descending air then flows toward the poles, depositing abundant precipitation (though less than in the tropics). The air masses again rise and release moisture in the vicinity of 60° latitude. Some of the cold, dry rising air then flows to the poles, where it descends and flows back toward the equator, absorbing moisture and creating the comparatively rainless and bitterly cold climates of the polar regions,

GLOBAL WIND PATTERNS

Air flowing close to Earth's surface creates predictable global wind patterns. As Earth rotates on its axis, land near the equator moves faster than that at the poles, deflecting the winds from the vertical paths shown above and creating more easterly and westerly flows. Cooling trade winds blow from east to west in the tropics; prevailing westerlies blow from west to east in the temperate zones, the regions between the tropics and the Arctic Circle or the Antarctic Circle.

A Figure 50.11 Moderating effects of large bodies of water on climate. This figure illustrates what happens on a warm summer day.

In general, oceans and large lakes moderate the climate of nearby terrestrial environments. During a warm summer day, when the land is hotter than a large lake or the ocean, air over the land heats up and rises, drawing a cool breeze from the water across the land (**Figure 50.11**). At night, air over the now warmer ocean or lake rises, reversing the circulation and drawing cooler air from the land out over the water, replacing it with warmer air from offshore. Proximity to water does not always moderate climate, however. In summer in certain regions, including the coast of central and southern California, cool, dry ocean breezes are warmed when they contact the land, absorbing moisture and creating a hot, rainless climate just a few miles inland. This climate pattern also occurs in the area around the Mediterranean Sea, which gives it the name *Mediterranean climate*.

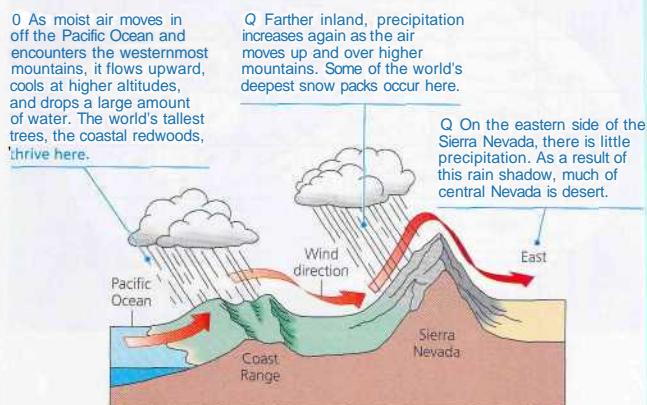

Mountains. Mountains have a significant effect on the amount of sunlight reaching an area, as well as on local temperature and rainfall. South-facing slopes in the Northern Hemisphere receive more sunlight than nearby north-facing slopes and are therefore warmer and drier. These abiotic differences influence species distribution; for example, in many mountains of western North America, spruce and other conifers occupy the north-facing slopes, whereas shrubby, drought-resistant plants inhabit the south-facing slopes. In addition, at any particular latitude, air temperature declines approximately 6°C with every 1,000-m increase in elevation,

paralleling the decline of temperature with increasing latitude. In the north temperate zone, for example, a 1,000-m increase in elevation produces a temperature change equivalent to that produced by an 880-km increase in latitude. This is one reason the biological communities of mountains are similar to those at lower elevations but farther from the equator.

When warm, moist air approaches a mountain, the air rises and cools, releasing moisture on the windward side of the peak (**Figure 50.12**). On the leeward side of the mountain, cooler, dry air descends, absorbing moisture and producing a "rain shadow." Deserts commonly occur on the leeward side of mountain ranges, a phenomenon evident in the Great Basin and the Mojave Desert of western North America, the Gobi Desert of Asia, and the small deserts that characterize the southwest corners of some Caribbean islands.

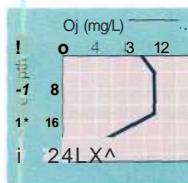

Seasonality. In addition to the global changes in day length, solar radiation, and temperature described earlier, the changing angle of the sun over the course of the year affects local environments. For example, the belts of wet and dry air on either side of the equator move slightly northward and southward with the changing angle of the sun, producing marked wet and dry seasons around 20° latitude, where many tropical deciduous forests grow. In addition, seasonal changes in wind patterns produce variations in ocean currents, sometimes causing the upwelling of nutrient-rich, cold water from deep ocean layers, thus nourishing organisms that live near the surface.

Lakes are also sensitive to seasonal temperature changes. During the summer and winter, many lakes in temperate regions are thermally stratified—that is, layered vertically according to temperature. Such lakes undergo a semiannual mixing of their waters as a result of changing temperature

A Figure 50.12 How mountains affect rainfall.

O In winter, the coldest water in the lake (0°C) lies just below the surface ice; water is progressively warmer at deeper levels of the lake, typically $4\text{--}5^{\circ}\text{C}$ at the bottom.

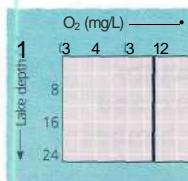

O₂ concentration

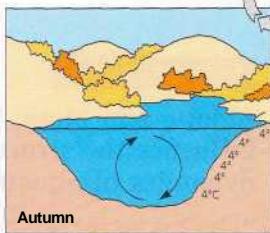

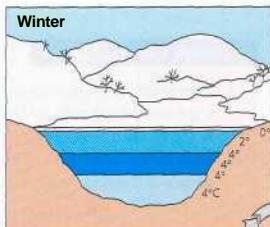

H High

M Medium

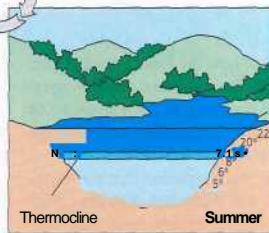

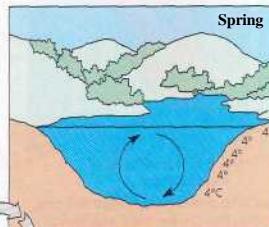

L Low

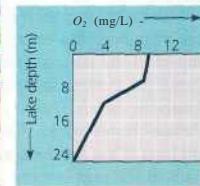

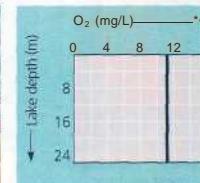

*3 In autumn, as surface water cools rapidly, it sinks below the underlying layers, remixing the water until the surface begins to freeze and the winter temperature profile is reestablished.

② In spring, as the sun melts the ice, the surface water warms to 4°C and sinks below the cooler layers immediately below, eliminating the thermal stratification. Spring winds mix the water to great depth, bringing oxygen (O₂) to the bottom waters (see graphs) and nutrients to the surface.

③ In summer, the lake regains a distinctive thermal profile, with warm surface water separated from cold bottom water by a narrow vertical zone of rapid temperature change, called a thermocline.

A Figure 50.13 Seasonal turnover in lakes with winter ice cover.

profiles (Figure 50.13). This turnover, as it is called, brings oxygenated water from a lake's surface to the bottom and nutrient-rich water from the bottom to the surface in both spring and autumn. These cyclic changes in the abiotic properties of lakes are essential for the survival and growth of organisms at all levels within this ecosystem.

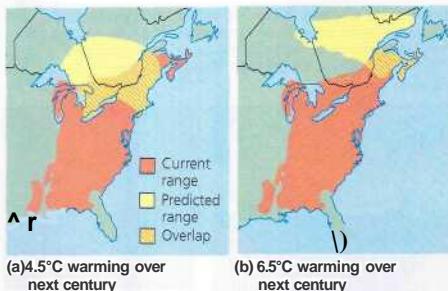

Microclimate

Many features in the environment influence microclimates by casting shade, affecting evaporation from soil, and changing wind patterns. For example, forest trees frequently moderate the microclimate below them. Consequently, cleared areas generally experience greater temperature extremes than the forest interior because of greater solar radiation and wind currents that are established by the rapid heating and cooling of open land; evaporation is generally greater in clearings as well. Within a forest, low-lying ground is usually wetter than high ground and tends to be occupied by different species of trees. A log or large stone sheltering organisms such as salamanders, worms, and insects, buffering them from the extremes of temperature and moisture. Every environment on Earth is similarly characterized by a mosaic of small-scale differences in the abiotic factors that influence the local distributions of organisms.

Long-Term Climate Change

If temperature and moisture are the master factors limiting the geographic ranges of plants and animals, the global climate change currently under way will profoundly affect the biosphere (see Chapter 54). One way to predict the possible effects is to look back at the changes that have occurred in temperate regions since the last ice age ended.

Until about 16,000 years ago, continental glaciers covered much of North America and Eurasia. As the climate warmed and the glaciers retreated, tree distribution expanded northward. A detailed record of these migrations is captured in fossil pollen deposited in lakes and ponds. (It may seem odd to think of trees "migrating," but recall from Chapter 38 that wind and animals can disperse seeds, sometimes over great distances.) If researchers can determine the climatic limits of current geographic distributions for organisms, they can make predictions about how distributions will change with climatic warming. A major question when applying this approach to plants is whether seed dispersal is rapid enough to sustain the migration of each species as climate changes. For example, fossils suggest that the eastern hemlock was delayed nearly 2,500 years in its movement north at the end of the last ice age partly because of relatively slow seed dispersal.

A Figure 50.14 Current range and predicted range for the American beech (*Fagus grandifolia*) under two scenarios of climate change.

Let's look at a specific case of how the fossil record of past migrations can inform predictions about the biological impact of the current global warming trend. **Figure 50.14** shows the current and predicted geographic ranges of the American beech (*Fagus grandifolia*) under two different climate-change models. These models predict that the northern limit of the beech's range will move 700–900 km northward in the next century, and its southern range limit will move northward an even greater distance. If these predictions are even approximately correct, the beech must move 7–9 km per year northward to keep pace with the warming climate. However, since the end of the last ice age, the beech has migrated into its present range at a rate of only 0.2 km per

year. The unhappy conclusion is clear: Without human assistance in moving into new ranges where they can survive as the climate warms, migrating species such as the American beech may become extinct.

Concept Check 50.2

- Give examples of human actions that could expand a species¹ distribution by changing its (a) dispersal or (b) biotic interactions.
- Explain how the sun's unequal heating of Earth's surface influences global climate patterns.

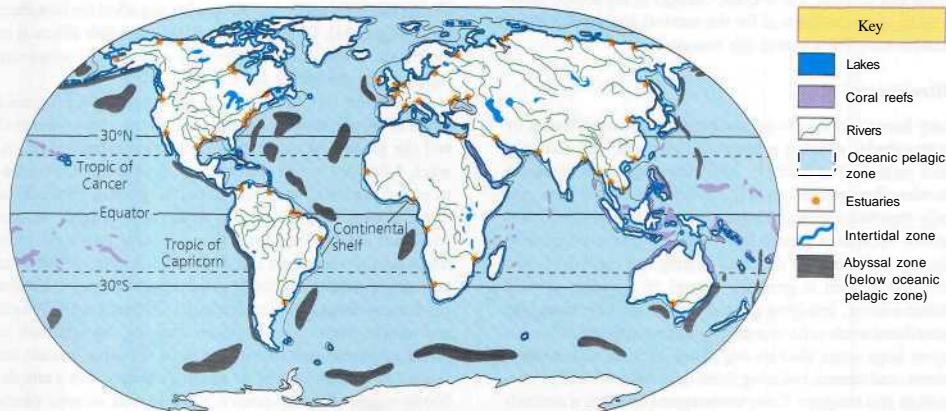

For suggested answers, see Appendix A.

Concept 50.3

Abiotic and biotic factors influence the structure and dynamics of aquatic biomes

We have seen how both biotic and abiotic factors influence the distribution of organisms on Earth. Varying combinations of these factors determine the nature of Earth's many biomes, major types of ecological associations that occupy broad geographic regions of land or water. We'll begin by examining Earth's aquatic biomes (**Figure 50.15**).

B Figure 50.15 The distribution of major aquatic biomes.

Aquatic biomes account for the largest part of the biosphere in terms of area, and all types are found around the globe. Ecologists distinguish between freshwater biomes and marine biomes on the basis of physical and chemical differences. For example, marine biomes generally have salt concentrations that average 3%, whereas freshwater biomes are usually characterized by a salt concentration of less than 1%.

The largest marine biomes, the oceans, cover about 75% of Earth's surface and thus have an enormous impact on the biosphere. The evaporation of water from the oceans provides most of the planet's rainfall, and ocean temperatures have a major effect on world climate and wind patterns. In addition, marine algae and photosynthetic bacteria supply a substantial portion of the world's oxygen and consume huge amounts of atmospheric carbon dioxide.

Freshwater biomes are closely linked to the soils and biotic components of the terrestrial biomes through which they pass or in which they are situated. The particular characteristics of a freshwater biome are also influenced by the patterns and speed of water flow and the climate to which the biome is exposed.

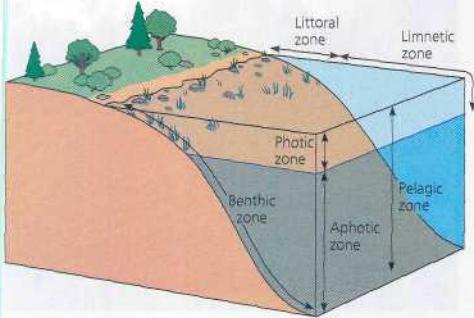

Many aquatic biomes are physically and chemically stratified, as illustrated in **Figure 50.16** for both a lake and a marine environment. Light is absorbed by both the water itself and the photosynthetic organisms in it, so its intensity decreases rapidly with depth, as mentioned earlier. Ecologists distinguish between the upper **photic zone**, where there is sufficient light for photosynthesis, and the lower **aphotic zone**, where little light penetrates. At the bottom of all aquatic biomes,

the substrate is called the **benthic zone**. Made up of sand and organic and inorganic sediments ("ooze"), the benthic zone is occupied by communities of organisms collectively called **benthos**. A major source of food for the benthos is dead organic matter called **detritus**, which "rains" down from the productive surface waters of the photic zone. The deepest regions of the ocean floor are known as the abyssal zone.

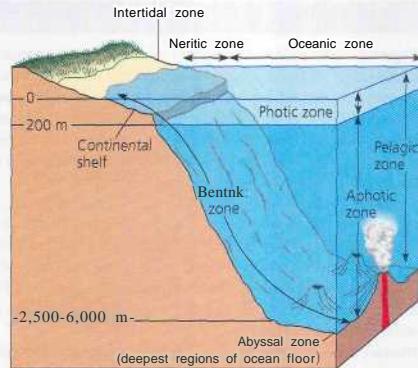

Thermal energy from sunlight warms surface waters to whatever depth the sunlight penetrates, but the deeper waters remain quite cold. As a result, water temperature in lakes tends to be stratified, especially during summer and winter (see Figure 50.13). In the ocean and in most lakes, a narrow stratum of rapid temperature change called a **thermocline** separates the more uniformly warm upper layer from more uniformly cold deeper waters.

In both freshwater and marine environments, communities are distributed according to depth of the water, degree of light penetration, distance from shore, and open water versus bottom. Marine communities illustrate the limitations on species distribution that result from these abiotic factors. Phytoplankton, zooplankton, and many fish species occur in the relatively shallow photic zone (see Figure 50.16b). Because water absorbs light so well and the ocean is so deep, most of the ocean volume is virtually devoid of light (the aphotic zone) and harbors relatively little life, except for microorganisms and relatively sparse populations of luminescent fishes and invertebrates.

Figure 50.17, on the next four pages, surveys the major aquatic biomes.

(a) Zonation in a lake. The lake environment is generally classified on the basis of three physical criteria: light penetration (photic and aphotic zones), distance from shore and water depth (littoral and limnetic zones), and whether it is open water (pelagic zone) or bottom (benthic zone).

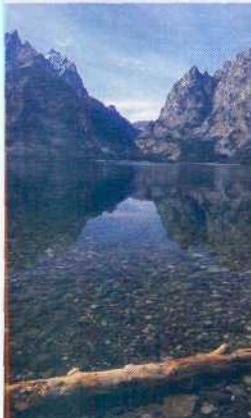

(b) Marine zonation. Like lakes, the marine environment is generally classified on the basis of light penetration (photic and aphotic zones), distance from shore and water depth (intertidal, neritic, and oceanic zones), and whether it is open water (pelagic zone) or bottom (benthic and abyssal zones).

A. Figure 50.16 Zonation in aquatic environments.

Exploring Aquatic Biomes

LAKES

Physical Environment Standing bodies of water range from ponds a few square meters in area to lakes covering thousands of square kilometers. Light decreases with depth, creating stratification (see Figure 50.16a). Temperate lakes may have a seasonal thermocline (see Figure 50.13); tropical lowland lakes have a thermocline year-round.

An oligotrophic lake in Grand Teton, Wyoming

A eutrophic lake in Okavango delta, Botswana

Chemical Environment The salinity (salt content), oxygen concentration, and nutrient content differ greatly among lakes and can vary substantially with season. **Oligotrophic lakes** are nutrient-poor and generally oxygen-rich; **eutrophic lakes** are nutrient-rich and often depleted of oxygen if ice-covered in winter and in the deepest zone during summer. The amount of decomposable organic matter in bottom sediments is low in oligotrophic lakes and high in eutrophic lakes.

Geologic Features Oligotrophic lakes tend to have less surface area relative to their depth than eutrophic lakes. Over long periods of time, an oligotrophic lake may become more eutrophic as runoff adds sediments and nutrients to the lake.

Photosynthetic Organisms Rates of photosynthesis are higher in eutrophic lakes than in oligotrophic lakes. Rooted and floating aquatic plants live in the **littoral zone**, the shallow, well-lit waters close to shore. Further away from shore, the limnetic zone, where water is too deep to support rooted aquatic plants, is inhabited by a variety of phytoplankton and cyanobacteria.

Animals In the limnetic zone, small drifting animals, or zooplankton, graze on the phytoplankton. The benthic zone is inhabited by a variety of invertebrate animals, with the species composition depending partly on oxygen levels. Fishes live in all zones in lakes with sufficient oxygen.

Human Impact Pollution by runoff from fertilized land and dumping of municipal wastes leads to nutrient enrichment, which can produce algal blooms, oxygen depletion, and fish kills.

WETLANDS

Physical Environment A **wetland** is an area covered with water for a long enough period to support aquatic plants. Wetlands range from those that are permanently inundated to those that flood infrequently.

Chemical Environment Because of the high organic production and decomposition in wetlands, both the water and the soils are periodically low in dissolved oxygen. Wetlands have a high capacity to filter dissolved nutrients and chemical pollutants.

Geologic Features *Basin wetlands* develop in shallow basins, ranging from upland depressions to filled-in lakes and ponds. *Riverine wetlands* develop along shallow and periodically flooded banks of rivers and streams. *Fringe wetlands* occur along the coasts of large lakes and seas, where water flows back and forth because of rising lake levels or tidal action. Thus, fringe wetlands include both freshwater and marine biomes.

Photosynthetic Organisms Wetlands are among the most productive biomes on Earth. Their water-saturated soils favor the growth of plants, such as floating pond lilies and emergent cattails, many sedges, tamarack, and black spruce, that have adaptations enabling them to grow in water or in soil that is periodically anaerobic owing to the presence of unaerated water. Woody plants dominate the vegetation of swamps, while bogs are dominated by sphagnum mosses.

Animals Wetlands are home to a diverse community of invertebrates, which in turn support a wide variety of birds. Herbivores,

Okefenokee National Wetland Reserve in Georgia

from crustaceans and aquatic insect larvae to muskrats, consume algae, detritus, and plants. Carnivores are also varied and may include dragonflies, otters, alligators, and owls.

Human Impact Draining and filling have destroyed up to 90% of wetlands in some regions.

STREAMS AND RIVERS

Physical Environment The most prominent physical characteristic of streams and rivers is current. Headwater streams are generally cold, clear, turbulent, and swift. Farther downstream, where numerous tributaries may have joined, forming a river, the water is generally warmer and more turbid, since rivers generally carry more sediment than their headwaters. Streams and rivers are stratified into vertical zones, extending from surface water through groundwater.

Chemical Environment The salt and nutrient content of streams and rivers increases from the headwaters to the mouth. In streams, headwaters are generally rich in oxygen. River water may also contain substantial oxygen, except where there has been organic enrichment from either natural or human sources.

Geologic Features Headwater stream channels are often narrow, with a rocky bottom alternating between riffles and pools. The downstream reaches of rivers are generally wide and meandering. River bottoms are often silty from sediments deposited over long periods of time.

Photosynthetic Organisms Headwater streams that flow through grasslands or deserts may be rich in algae or rooted aquatic plants; but in streams flowing through temperate or tropical forests, leaves and other organic matter produced by terrestrial vegetation are the primary source of food for aquatic consumers. In rivers, a large fraction of the organic matter consists of dissolved and highly fragmented material that is carried by the current from forested headwater streams.

Animals A great diversity of fishes and invertebrates inhabit unpolluted rivers and streams, distributed according to, and throughout, the vertical zones.

Human Impact Municipal, agricultural, and industrial pollution degrade water quality and kill aquatic organisms. Damming and flood control impair natural functioning of stream and river ecosystems and threaten migratory species such as salmon.

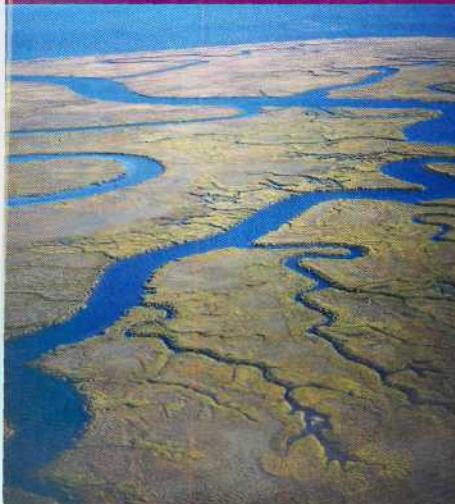

A headwater stream in the Great Smoky Mountains

The Mississippi River far from its headwaters

ESTUARIES

An estuary in a low coastal plain of Georgia

Physical Environment An estuary is a transition area between river and sea. Estuaries have very complex flow patterns. During a rising tide, seawater flows up the estuary channel, flowing back down again during the falling tide. Often higher-density seawater occupies the bottom of an estuary channel, while lower-density river water forms a surface layer that mixes little with the salty bottom layer.

Chemical Environment Salinity varies spatially within estuaries, from nearly that of fresh water to that of seawater. Salinity also varies with the rise and fall of the tides. Nutrients from the river make estuaries, like wetlands, among the most productive biomes.

Geologic Features Estuarine flow patterns combined with the sediments carried by river and tidal water create a complex network of tidal channels, islands, natural levees, and mudflats.

Photosynthetic Organisms Saltmarsh grasses and algae, including phytoplankton, are the major producers in estuaries.

Animals Estuaries support an abundance of worms, oysters, crabs, and many of the fish species that humans consume. Because of the abundant food in estuaries, many marine invertebrates and fishes use them as a breeding ground; others migrate through estuaries to freshwater habitats upstream. Estuaries are also crucial feeding areas for many semi-aquatic vertebrates, particularly waterfowl.

Human Impact Pollution from upstream, and also filling and dredging, have disrupted estuaries worldwide.

Figure 50.17 (continued)
Exploring Aquatic Biomes

INTERTIDAL ZONES

Rocky intertidal zone on the Oregon coast

Physical Environment An intertidal zone is periodically submerged and exposed by the tides, twice daily on most marine shores. Upper zones experience longer exposures to air and greater variations in physical environment. Among the physical challenges faced by intertidal organisms are variations in temperature and salinity and the mechanical forces of wave action. Changes in physical conditions from the upper intertidal zone to

the lower intertidal zone limit the distributions of many organisms to particular strata, as shown in the photograph.

Chemical Environment Oxygen and nutrient levels are generally high and are renewed with each turn of the tides.

Geologic Features The substrates of intertidal zones, which are generally either rocky or sandy, select for particular behavior and anatomy among intertidal organisms. The configuration of bays or coastlines influences the magnitude of tides and the relative exposure of intertidal organisms to wave action.

Photosynthetic Organisms A high diversity and biomass of attached marine algae inhabit rocky intertidal zones, especially in the lower zone. Because of the instability of the substrate, sandy intertidal zones exposed to vigorous wave action generally lack attached plants or algae, while sandy intertidal zones in protected bays or lagoons often support rich beds of sea grass and algae.

Animals Many of the animals of rocky intertidal environments have structural adaptations that enable them to attach to the hard substrate. The composition, density, and diversity of intertidal animals change markedly from the upper to lower intertidal zones. Many of the animals in sandy or muddy intertidal environments, such as suspension-feeding worms and clams and predatory crustaceans, bury themselves in sand or mud, feeding as the tides bring sources of food. Other common animals are sponges, sea anemones, molluscs, echinoderms, and small fishes.

Human Impact Oil pollution has disrupted many intertidal areas. Recreational use has caused a severe decline in the numbers of beach-nesting birds and sea turtles.

OCEANIC PELAGIC BIOME

Physical Environment The oceanic pelagic biome is a vast realm of open blue water, constantly mixed by wind-driven oceanic currents. The surface waters of temperate ocean areas turn over during fall through spring. Because of higher water clarity, the photic zone extends to greater depths than in coastal marine waters.

Chemical Environment Oxygen levels are generally high. Nutrient concentrations are generally lower than in coastal waters. Because they are thermally stratified year-round, some tropical areas of the oceanic pelagic biome have lower nutrient concentrations than temperate oceans. Turnover during fall through spring renews nutrients in the photic zones of temperate and high-latitude ocean areas.

Geologic Features The most prominent geologic characteristic of the oceanic pelagic biome is its vastness and the great depth of the ocean basins. This biome covers approximately 70% of Earth's surface and has an average depth of nearly 4,000 m. The deepest point in the ocean is more than 10,000 m beneath the surface.

Photosynthetic Organisms The dominant photosynthetic organisms are phytoplankton, including photosynthetic bacteria, that drift with the oceanic currents. Spring turnover and renewal of nutrients in temperate oceans produces a surge of phytoplankton growth. Despite the large extent of their biome, photosynthetic

plankton account for less than half of the photosynthetic activity on Earth.

Animals The most abundant animals and other heterotrophs in this biome are zooplankton. These protozoans, worms, copepods, shrimp-like krill, jellies, and the small larvae of invertebrates and fishes graze on photosynthetic plankton. The oceanic pelagic biome also includes free-swimming animals, such as large squids, fishes, sea turtles, and marine mammals.

Human Impact Overfishing has depleted fish stocks in all Earth's oceans, which have also been polluted by waste dumping and oil spills.

Open ocean off the island of Hawaii

Physical Environment Reef-building corals are limited to the photic zone of relatively stable tropical marine environments with high water clarity. They are sensitive to temperatures below about 18°–20°C and above 30°C.

Chemical Environment Corals require high oxygen levels and are excluded by high inputs of fresh water and nutrients.

(Geologic Features) Corals require a solid substrate for attachment. A coral reef, which is formed largely from the calcium carbonate skeletons of corals, develops over a long time on oceanic islands. It begins as a fringing reef on young high islands, forming an offshore barrier reef later in the history of the island and becoming a coral atoll [as the older oceanic island submerges].

Photosynthetic Organisms Dinoflagellate algae live within the tissues of the corals, forming a mutualistic, symbiotic relationship that provides the corals with organic molecules. Diverse red and green marine algae also contribute substantial amounts of photosynthesis on coral reefs.

Animals Corals, a diverse group of cnidarians (see Chapter 33), are themselves the predominant animals on coral reefs. However, fish and invertebrate diversity is exceptionally high. Overall animal diversity on coral reefs rivals that of tropical forests.

Human Impact Collecting of coral skeletons, often using poisons and explosives, as well as overfishing for food and for the aquarium

A coral reef in the Red Sea

trade, have reduced populations of corals and reef fishes. Global warming and pollution may be contributing to large-scale coral mortality.

MARINE BENTHIC ZONE

Physical Environment The marine benthic zone consists of the seafloor below the surface waters of the coastal, or neritic, zone and the offshore, pelagic zone (see Figure 50.16b). Although in shallow, near-coastal waters the benthic zone receives enough sunlight to support photosynthetic organisms, most of the ocean's benthic zone receives no sunlight. Water temperatures decline with depth, while pressure increases. As a result, organisms in the very deep benthic, or abyssal, zone are adapted to continuous cold (about 3°C) and extremely high water pressure.

Chemical Environment Except in some areas of organic enrichment, oxygen is present at sufficient concentrations to support a diversity of animals.

A deep-sea hydrothermal vent community

Geologic Features Soft sediments cover most of the benthic zone. However, there are areas of rocky substrate on reefs, submarine mountains, and new oceanic crust created by seafloor volcanoes.

Food-Producing Organisms Photosynthetic organisms, mainly seaweeds and filamentous algae, are limited to shallow benthic areas with sufficient light to support them. Unique assemblages of organisms, such as those shown in the photo, are associated with deep-sea hydrothermal vents of volcanic origin on mid-ocean ridges. In this lifeless, not oxygen-deficient environment, the food producers are chemoautotrophic prokaryotes (see Chapter 27) that obtain energy by oxidizing H_2S formed by a reaction of the hot water with dissolved sulfate (SO_4^{2-}).

Animals Neritic benthic communities include numerous invertebrates and fishes. Beyond the photic zone, most consumers depend entirely on organic matter raining down from above. Among the animals of the deep-sea hydrothermal vent communities are giant tube-dwelling worms (pictured at left), some more than 1 m long. They are apparently nourished by chemosynthetic prokaryotes that live as symbionts within the worms. Many other invertebrates, including arthropods and echinoderms, are also abundant around the hydrothermal vents.

Human Impact Overfishing has decimated important benthic fish populations such as the cod of the Grand Banks off Newfoundland. Dumping of organic wastes has created oxygen-deprived benthic areas.

Concept Check 50.3

The following questions refer to Figure 50.17.

1. Are stoneflies, benthic aquatic insects that require relatively high concentrations of oxygen, more likely to live in oligotrophic lakes or eutrophic lakes? Why?
2. Why are phytoplankton, and not benthic algae or rooted aquatic plants, the dominant photosynthetic organisms of the oceanic pelagic biome?

For suggested answers, see Appendix A.

Concept 50.4

Climate largely determines the distribution and structure of terrestrial biomes

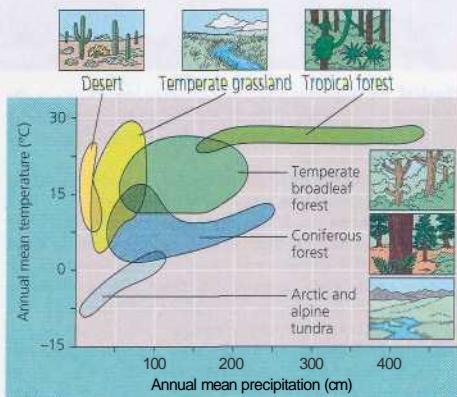

All the abiotic factors discussed in this chapter, but especially climate, are important in determining why a particular terrestrial biome is found in a certain area. Because there are latitudinal patterns of climate over Earth's surface (see Figure 50.10), there are also latitudinal patterns of biome distribution.

Climate and Terrestrial Biomes

We can see the great impact of climate on the distribution of organisms by constructing a climograph, a plot of the temperature and precipitation in a particular region. For example, **Figure 50.18** is a climograph denoting annual mean temperature and precipitation for some of the biomes found in North America. Notice that the range of precipitation in northern coniferous forests is similar to that in temperate forests, but the temperature ranges are different. Grasslands are generally drier than either kind of forest, and deserts are drier still.

Annual means for temperature and rainfall are reasonably well correlated with the biomes that exist in different regions. However, it is important to distinguish *correlation* from *causation*. Although the climograph provides circumstantial evidence that temperature and rainfall are important to the distribution of biomes, it does not confirm that these variables govern the biomes' location. Only a detailed analysis of the water and temperature tolerances of individual species could establish the controlling effects of these variables.

As Figure 50.18 shows, there are regions where biomes overlap. Thus factors other than mean temperature and precipitation must play a role in determining where biomes exist. For example, certain areas in North America with a particular temperature and precipitation combination support a temperate broadleaf forest, but other areas with similar values for these variables support a coniferous forest. How do we explain this variation? First, remember that the climograph is based on annual averages. Often it is not only the mean or average climate

A. Figure 50.18 A climograph for some major types of biomes in North America. The areas plotted here encompass the range of annual mean temperature and precipitation in the biomes.

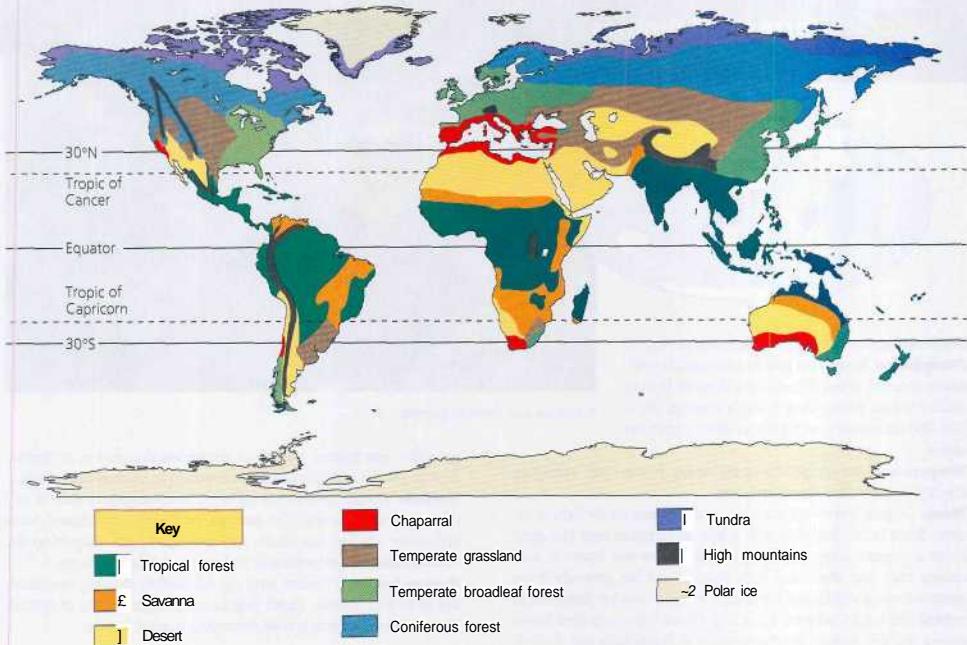

that is important but also the *pattern* of climatic variation. For example, some areas may receive regular precipitation throughout the year, whereas other areas with the same amount of annual precipitation have distinct wet and dry seasons. A similar phenomenon may occur with respect to temperature. Other factors, such as the bedrock in an area, may greatly affect mineral nutrient availability and soil structure, which in turn affect the kind of vegetation that will develop.

The general distribution of the major terrestrial biomes is shown in **Figure 50.19**.

General Features of Terrestrial Biomes

Most terrestrial biomes are named for major physical or climatic features and for their predominant vegetation. Temperate grasslands, for instance, are generally found in middle latitudes, where the climate is more moderate than in the tropics or polar regions, and are dominated by various grass species. Each biome is also characterized by microorganisms, fungi, and animals adapted to that particular environment. For example, temperate grasslands are more likely than forests to be populated by large grazing mammals.

Vertical stratification is an important feature of terrestrial biomes, and the shapes and sizes of plants largely define the layering. For example, in many forests, the layers consist of the upper canopy, then the low-tree stratum, the shrub understory, the ground layer of herbaceous plants, the forest floor (litter layer), and finally the root layer. Nonforest biomes have similar, though usually less pronounced, strata. Grasslands have an herbaceous layer of grasses and forbs (small broadleaf plants), a litter layer, and a root layer. Stratification of vegetation provides many different habitats for animals, which often occupy well-defined feeding groups, from the

A Figure 50.19 The distribution of major terrestrial biomes. Although terrestrial biomes are mapped here with sharp boundaries, biomes actually grade into one another, sometimes over relatively large areas.

insectivorous and carnivorous birds and bats that feed above canopies to the small mammals, numerous worms, and arthropods that forage in the litter and root layers for food.

Although Figure 50.19 shows distinct boundaries between the biomes, in actuality, terrestrial biomes usually grade into each other, without sharp boundaries. The area of intergradation, called an ecotone, may be wide or narrow.

The actual species composition of any one kind of biome varies from one location to another. For instance, in the northern coniferous forest (taiga) of North America, red spruce is common in the east but does not occur in most other areas, where black spruce and white spruce are abundant. Although the vegetation of African deserts superficially resembles that of North American deserts, the plants are actually in different families. Such "ecological equivalents" can arise because of convergent evolution (see Figure 25.5).

Biomes are dynamic, and disturbance rather than stability tends to be the rule. For example, hurricanes create openings for new species in tropical and temperate forests. In northern coniferous forests, old trees die and fall over, or snowfall may break branches, producing gaps that allow deciduous species, such as aspen and birch, to grow. As a result, biomes usually

exhibit extensive patchiness, with several different communities represented in any particular area.

In many biomes, the dominant plants depend on periodic disturbance. For example, natural wildfires are an integral component of grasslands, savannas, chaparral, and many coniferous forests. Before agricultural and urban development, much of the southeastern United States was dominated by a single conifer species, the longleaf pine. Without periodic burning, broadleaf trees tended to replace the pines. Forest managers now use fire as a tool to help maintain many coniferous forests.

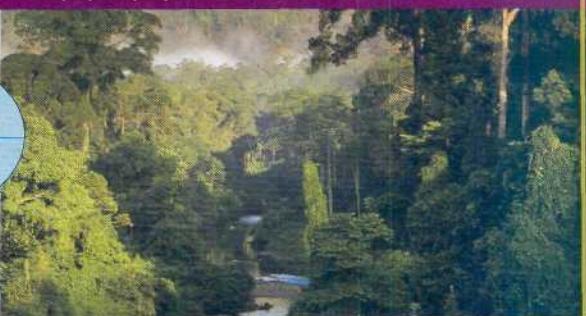

In many biomes today, extensive human activity has radically altered the natural patterns of periodic physical disturbance. Fires, which used to be part of life on the Great Plains, are now controlled for the sake of agricultural land use. Humans have altered much of Earth's surface, replacing original biomes with urban and agricultural ones. Most of the eastern United States, for example, is classified as temperate broadleaf forest, but human activity has eliminated all but a tiny percentage of the original forest.

Figure 50.20, on the next four pages, surveys the major terrestrial biomes.

Figure 50.20

Exploring Terrestrial Biomes

TROPICAL FOREST

▲ tropical rain forest in Borneo

Distribution Equatorial and subequatorial regions.

Precipitation In tropical rain forests, rainfall is relatively constant, about 200–400 cm annually. In tropical dry forests, precipitation is highly seasonal, about 150–200 cm annually with a six- to seven-month dry season.

Temperature Air temperatures are warm year-round, averaging 25–29°C with little seasonal variation.

Plants Tropical forests are stratified, and competition for light is intense. Strata in rain forests include a layer of emergent trees that grow above a closed canopy of canopy trees, one or two layers of subcanopy trees, and shrub and herb layers. There are generally fewer strata in tropical dry forests. Broadleaf evergreen trees are dominant in tropical rain forests, whereas tropical dry forest trees drop their leaves during the dry season. Epiphytes such as bromeliads and orchids

generally cover tropical forest trees, but are less abundant in dry forest. Thorny shrubs and succulents are common in tropical dry forests.

Animals Animal diversity is higher in tropical forests than in any other terrestrial biome. The animals, including amphibians, birds and other reptiles, mammals, and arthropods, are adapted to the three-dimensional environment and are often inconspicuous.

Human Impact Humans long ago established thriving communities in tropical forests. Rapid population growth leading to agriculture and development is now destroying tropical forests.

DESERT

Distribution Deserts occur in a band near 30° north and south latitude or at other latitudes in the interior of continents (for instance, the Gobi Desert of north central Asia).

Precipitation Precipitation is low and highly variable, generally less than 30 cm per year.

Temperature Temperature is variable seasonally and daily. Maximum air temperature in hot deserts may exceed 50°C; in cold deserts air temperature may fall below -30°C.

Plants Desert landscapes are dominated by low, widely scattered

vegetation; the proportion of bare ground is high compared with other terrestrial biomes. The plants include succulents such as cacti, deeply rooted shrubs, and herbs that grow during the infrequent moist periods. Desert plant adaptations include heat and desiccation tolerance, water storage, and reduced leaf surface area. Physical defenses, such as spines, and chemical defenses, such as toxins in the leaves of shrubs, are common. Many of the plants exhibit C₄ or CAM photosynthesis (see Chapter 10).

Animals Common desert animals include many kinds of snakes and lizards, scorpions, ants, beetles, migratory and resident birds, and seed-eating rodents. Many species are nocturnal. Water conservation is a common adaptation, with some species surviving on water from metabolic breakdown of carbohydrates in seeds.

Human Impact Long-distance transport of water and deep groundwater wells have allowed humans to maintain substantial populations in deserts. Conversion to irrigated agriculture and urbanization have reduced the natural biodiversity of deserts.

The Sonoran Desert in southern Arizona

A typical savanna in Kenya

Distribution Equatorial and subequatorial regions.

Precipitation Rainfall, which is seasonal, averages 30–50 cm per year. The dry season can last up to eight or nine months.

Temperature The savanna is warm year-round, averaging 24–29°C, but with somewhat more seasonal variation than in tropical forests.

Plants The scattered trees found in the savanna are often thorny with reduced leaf surface area, an apparent adaptation to the relatively dry conditions. Fires are common in the dry season, and the dominant plant species are fire-adapted and tolerant of seasonal

drought. Grasses and forbs, which make up most of the ground cover, grow rapidly in response to seasonal rains and are tolerant of grazing by large mammals and other herbivores.

Animals Large herbivorous mammals, such as wildebeests and zebras, and their predators, including lions and hyenas, are common inhabitants. However, the dominant herbivores are actually insects, especially termites. During seasonal droughts, grazing mammals must migrate to other parts of the savanna with more forage and scattered watering holes.

Human Impact The earliest humans appear to have lived on savannas. Fires set by humans may help maintain this biome. Cattle ranching and overhunting have led to declines in large-mammal populations.

CHAPARRAL

Distribution This biome occurs in midlatitude coastal regions on several continents, and its many names reflect its far-flung distribution: chaparral in North America, matorral in Spain and Chile, garigue and maquis in southern France, and fynbos in South Africa.

Precipitation Precipitation is highly seasonal, with rainy winters and long, dry summers. Annual precipitation generally falls within the range of 30–50 cm.

Temperature Fall, winter, and spring are cool, with average temperatures ranging from 10–12°C. Average summer temperature can reach 30°C, and daytime maximum temperature can exceed 40°C.

Plants The chaparral is dominated by shrubs and small trees, along with a high diversity of grasses and herbs. Plant diversity is high, with many species confined to a specific, relatively small geographic area. Adaptations to drought include the tough evergreen leaves of woody plants that reduce water loss. Adaptations to fire are also prominent. Some of the shrubs produce seeds that will germinate only

after a hot fire; food reserves stored in their fire-resistant roots enable them to resprout quickly and use nutrients released by the fire.

Animals Native mammals include browsers, such as deer and goats, that feed on twigs and buds of woody vegetation and a high diversity of small mammals. Chaparral areas also support a high diversity of amphibians, birds and other reptiles, and insects.

Human Impact Chaparral areas have been heavily settled and reduced through conversion to agriculture and urbanization. Humans contribute to the fires that sweep across chaparral.

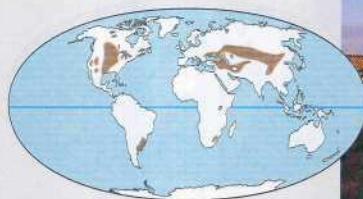

An area of chaparral in California

Exploring Terrestrial Biomes

TEMPERATE GRASSLAND

Sheyenne National Grassland in North Dakota

Distribution The veldts of South Africa, the puszta of Hungary, the pampas of Argentina and Uruguay, the steppes of Russia, and the plains and prairies of central North America are all temperate grasslands.

Precipitation Precipitation is highly seasonal, with relatively dry winters and wet summers. Annual precipitation generally averages between 30 and 100 cm. Periodic drought is common.

Temperature Winters are generally cold, with average temperatures frequently falling well below -10°C . Summers, with average temperatures frequently approaching 30°C , are hot.

Plants The dominant plants are grasses and forbs, which vary in height from a few centimeters to 2 meters in tallgrass prairie. Some of the main adaptations of plants are to periodic, protracted droughts

and to fire. The grasses of temperate grassland sprout quickly following fire. Grazing by large mammals helps prevent establishment of woody shrubs and trees.

Animals Native mammals include large grazers such as bison and wild horses. Temperate grasslands are also inhabited by a wide variety of burrowing mammals, such as prairie dogs in North America.

Human Impact Deep, fertile soils make temperate grasslands ideal places for agriculture, especially for growing grains. As a consequence, most grassland in North America and much of Eurasia has been converted to farmland.

CONIFEROUS FOREST

Distribution Extending in a broad band across northern North America and Eurasia to the edge of the arctic tundra, the northern coniferous forest, or *taiga*, is the largest terrestrial biome on Earth.

Precipitation Precipitation generally ranges from 30 to 70 cm, and periodic droughts are common. However, some coastal coniferous forests of the United States Pacific Northwest are temperate rain forests that may receive over 300 cm of annual precipitation.

Temperature Winters are usually cold and long; summers may be hot. Some areas of coniferous forest in Siberia range in temperature from -70°C in the winter to over 30°C in summer.

Plants Cone-bearing trees, such as pine, spruce, fir, and hemlock dominate coniferous forests. The conical shape of many conifers prevents too much snow from accumulating and breaking their branches. The diversity of plants in the shrub and herb layers of coniferous forests is lower than in temperate broadleaf forests.

Animals While many migratory birds nest in coniferous forests, many species reside there year-round. The mammals of coniferous forests, which include moose, brown bears, and Siberian tigers, are diverse. Periodic outbreaks of insects that feed on the dominant tree can kill vast tracts of trees.

Human Impact Although they have not been heavily settled by human populations, coniferous forests are being logged at an alarming rate, and the old-growth stands of these trees may soon disappear.

Rocky Mountain National Park in Colorado

TEMPERATE BROADLEAF FOREST

Great Smoky Mountains National Park in North Carolina

Distribution Found mainly at midlatitudes in the Northern Hemisphere, with smaller areas in New Zealand and Australia.

Precipitation Precipitation can average from about 70 to over 200 cm annually. Significant amounts fall during all seasons, including summer rain and winter snow.

Temperature Winter temperatures average around 0°C. Summers, with maximum temperatures near 30°C, are hot and humid.

Plant A mature temperate broadleaf forest has distinct, highly diverse, vertical layers, including a closed canopy, one or two strata of understory trees, a shrub layer, and an herbaceous stratum.

There are few epiphytes. The dominant plants in the Northern Hemisphere are deciduous trees, which drop their leaves before winter,

when low temperatures would reduce photosynthesis and make water uptake from frozen soil difficult. In Australia, evergreen eucalyptus dominate these forests.

Animals In the Northern Hemisphere, many mammals hibernate in winter, while many bird species migrate to warmer climates. The mammals, birds, and insects make use of all vertical layers of the forest.

Human Impact Temperate broadleaf forest has been heavily settled on all continents. Logging and land clearing for agriculture and urban development destroyed virtually all the original deciduous forests in North America. However, owing to their capacity for recovery, these forests are returning over much of their former range.

TUNDRA

Distribution Tundra covers expansive areas of the Arctic, amounting to 20% of Earth's land surface. High winds and cold temperatures create similar plant communities, called *alpine tundra*, on very high mountaintops at all latitudes, including the tropics.

Precipitation Precipitation averages from 20 to 60 cm annually in arctic tundra but may exceed 100 cm in alpine tundra.

Temperature Winters are long and cold, with averages in some areas below -30°C. Summers are short with cool temperatures, generally averaging less than 10°C.

Plants The vegetation of tundra is mostly herbaceous, consisting of a mixture of lichens, mosses, grasses, and forbs, along with some dwarf shrubs

and trees. A permanently frozen layer of soil called permafrost generally prevents water infiltration.

Animals Large grazing musk ox are resident, while caribou and reindeer are migratory. Predators include bears, wolves, and foxes. Migratory birds use tundra intensely during the summer as nesting grounds.

Human Impact Tundra is sparsely settled but has become the focus of significant mineral and oil extraction in recent years.

Denali National Park, Alaska, in autumn

Throughout your exploration in this chapter of Earth's varied aquatic and terrestrial biomes, you have seen many examples of the considerable impact of the abiotic factors in an organism's environment. In die next chapter, we will look more closely at organisms themselves, examining how behavioral mechanisms and adaptations play key roles in the interactions between an organism and both the nonliving and living parts of its environment.

Concept Check 50.4

- judging from the climograph in Figure 50.18, what mainly differentiates dry tundra and deserts?
- Identify the natural biome in which you live and summarize its abiotic and biotic characteristics. Do these reflect your actual surroundings? Explain.

For suggested answers, see Appendix A.

Chapter 50 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 50.1

Ecology is the study of interactions between organisms and the environment

- Ecology and Evolutionary Biology** (p. 1081) Events that occur in ecological time affect life on the scale of evolutionary time.
- Organisms and the Environment** (p. 1081) Examples of questions that ecologists ask are, Who lives where? Why do they live there? and How many are there? Ecologists use observations and experiments to test explanations for the distribution and abundance of species and other ecological phenomena. The environment of any organism includes both abiotic and biotic components.
- Subfields of Ecology** (pp. 1082-1083) Ecology can be divided into several subfields of study, ranging from the ecology of organisms to the dynamics of ecosystems, landscapes, and the biosphere. Modern ecological studies cross boundaries between traditionally separate areas.
- Ecology and Environmental Issues** (p. 1083) Ecology provides the scientific understanding underlying environmental issues. Many ecologists favor the precautionary principle of "Look before you leap."

Activity *Science, Technology, and Society: DDT*

Concept 50.2

Interactions between organisms and the environment limit the distribution of species

- Dispersal and Distribution** (pp. 1084-1085) The dispersal of organisms results in broad patterns of geographic distribution. Natural range expansions and species transplants suggest hypotheses to explain why species are found where they are. Transplanted species may disrupt the ecosystem at the new site.
- Behavior and Habitat Selection** (p. 1085) Some organisms do not occupy all of their potential range. Species distribution may be limited by habitat selection behavior.
- Biotic Factors** (pp. 1085-1086) Biotic factors that affect the distribution of organisms include interactions with other species, such as predation and competition.

- Abiotic Factors** (pp. 1086-1087) Among important abiotic factors affecting species distribution are temperature, water, sunlight, wind, and rocks and soil.

Activity *Adaptations to Biotic and Abiotic Factors*
Investigation *How Do Abiotic Factors Affect Distribution of Organisms?*

- Climate** (pp. 1087-1092) Global climate patterns are largely determined by the input of solar energy and Earth's rotation around the sun. Regional, local, and seasonal effects on climate are influenced by bodies of water, mountains, and the changing angle of the sun over the year. Fine-scale differences in abiotic factors determine microclimates.

Concept 50.3

Abiotic and biotic factors influence the structure and dynamics of aquatic biomes

- Aquatic biomes account for the largest part of the biosphere in terms of area and are generally stratified with regard to light penetration, temperature, and community structure. Marine biomes have a higher salt concentration than freshwater biomes (pp. 1092-1098).

Activity *Aquatic Biomes*

Concept 50.4

Climate largely determines the distribution and structure of terrestrial biomes

- Climate and Terrestrial Biomes** (p. 1098) Climographs show that temperature and precipitation are correlated with biomes, but because biomes overlap, other abiotic factors must play a role in biome location.
- General Features of Terrestrial Biomes** (pp. 1098-1103) Terrestrial biomes are often named for major physical or climatic factors and for their predominant vegetation. Stratification is an important feature of terrestrial biomes.

Activity *Terrestrial Biomes*

TESTING YOUR KNOWLEDGE

Evolution Connection

Discuss how the concept of time applies to ecological situations and evolutionary changes. Do ecological time and evolutionary time ever correspond? If so, what are some examples?

Scientific Inquiry

Hiking up a mountain, you notice a plant species that has one growth form at low elevations and a very different growth form at high elevations. You wonder if these represent two genetically distinct populations of this species, each adapted to the prevailing conditions, or if this species has developmental flexibility and can assume either growth form, depending on local conditions. What experiments could you design to test these two hypotheses?

Investigation How Do Abiotic Factors Affect Distribution of Organisms?

Science, Technology, and Society

In pet shops throughout North America, you can purchase a variety of nonnative fishes, birds, and reptiles. Describe some scenarios in which such pet trade could endanger native plants and animals. Should governments regulate the pet trade? Are there currently any restrictions on what species a pet shop can sell in your city? How would you balance such regulation against a person's individual rights?

51

Behavioral Ecology

A Figure 51.1 A courting pair of East Asian red-crowned cranes (*Grus japonicus*).

Key Concepts

- 51.1 Behavioral ecologists distinguish between proximate and ultimate causes of behavior
- 51.2 Many behaviors have a strong genetic component
- 51.3 Environment, interacting with an animal's genetic makeup, influences the development of behaviors
- 51.4 Behavioral traits can evolve by natural selection
- .1, 5 Natural selection favors behaviors that increase survival and reproductive success
- 51.6 The concept of inclusive fitness can account for most altruistic social behavior

Overview

Studying Behavior

Humans have probably studied animal behavior for as long as we have lived on Earth. As hunters—and sometimes the hunted—knowledge of animal behavior was essential to human survival. But other animals are also a source of fascination beyond the need for practical information. For instance, cranes are animals that have long captivated people's interest, perhaps because cranes are large and their behavior is easily observed (Figure 51.1). Male and female cranes engage in elaborate courtship rituals involving graceful dance-like movements and synchronized vocalizations. Observing these rituals, many people have viewed the birds as symbols of fidelity and devotion. Some of the most conspicuous crane behaviors are associated with their annual migrations. Each spring, thousands of cranes fly from wintering grounds in southern Eurasia, North Africa, and North America to northern nesting grounds. Various species of cranes fly

hundreds or thousands of kilometers, stopping periodically to rest and feed. Because migrating cranes fly at high altitudes and call as they fly, some cultures have traditionally viewed them as messengers between Earth and the heavens.

The modern scientific discipline of behavioral ecology extends such observations of animal behavior by studying how such behavior is controlled and how it develops, evolves, and contributes to survival and reproductive success. For example, a behavioral ecologist might ask how similarities or differences in courtship displays may be related to genetic similarities or differences among crane species and how learning contributes to the development of courtship displays. Questions about migration might include why migrating cranes call, what environmental cues trigger migration, or how migration contributes to the reproductive success of cranes. Behavioral ecology is essential to solving critically important problems ranging from the conservation of endangered species to the control of emerging infectious diseases. This chapter focuses on such questions and others in a quest to understand how behavior is related to genetics, environment, and evolution.

Concept 51.1

Behavioral ecologists distinguish between proximate and ultimate causes of behavior

The questions that can be posed about any behavior can be divided generally into two classes: those that focus on the immediate stimulus and mechanism for the behavior and those that explore how the behavior contributes to survival and reproduction. First, however, let's consider an even more fundamental question: what the term *behavior* encompasses.

>What Is Behavior?

Behavioral traits are as much a part of an animal's phenotype as the length of its appendages or the color of its fur. Most of what we call behavior is the visible result of an animal's muscular activity, as when a predator chases its prey or a fish raises its fins as part of a territorial display (**Figure 51.2**). In some behaviors, muscular activity is involved but less obvious, as when a bird uses muscles to force air from its lungs and shape the sounds in its throat, producing a song. Some nonmuscular activities are also considered behaviors, as when an animal secretes a hormone that attracts members of the opposite sex. Furthermore, we can consider learning to be a behavioral process. For example, a juvenile bird may learn to reproduce a song that it hears an adult of its species singing, even though the muscular activity based on this memory may not occur until months later, when the young bird itself begins to sing the song. Thus, in addition to studying observable behaviors, mainly in the form of muscle-powered activities, behavioral ecologists also study the mechanisms underlying those behaviors, which may not involve muscles at all. Put more simply, we can think of behavior as everything an animal does and how it does it.

Proximate and Ultimate Questions

When we observe a certain behavior, we may ask both proximate and ultimate questions. **Proximate questions** about behavior focus on the environmental stimuli, if any, that trigger a behavior, as well as the genetic, physiological, and anatomical mechanisms underlying a behavioral act. Proximate questions are often referred to as "how" questions. For example, the red-crowned cranes in Figure 51.1, like many animals, breed in spring and early summer. A proximate question about the timing of breeding by this species might be, How does day length influence breeding by red-crowned cranes? A reasonable hypothesis for the proximate cause of this behavior is that breeding is triggered by the effect of increased day

i. Figure 51.2 A male African cichlid (*Neolamprologus tetracanthus*) with erect fins. Muscular contraction that raises the fins is a behavioral response to a threat to the fish's territory.

length on an animal's production of and responses to particular hormones. Indeed, experiments with various animals demonstrate that lengthening daily exposure to light produces neural and hormonal changes that induce behavior associated with reproduction, such as singing and nest building in birds.

In contrast to proximate questions, **ultimate questions** address the evolutionary significance of a behavior. Ultimate questions take such forms as, Why did natural selection favor this behavior and not a different one? Hypotheses addressing "why" questions propose that the behavior increases fitness in some particular way. A reasonable hypothesis for why the red-crowned crane reproduces in spring and early summer is that breeding is most productive at that time of year. For instance, at that time, parent birds can find ample food for rapidly growing offspring, providing an advantage in reproductive success compared to birds that breed in other seasons.

Although proximate causation is distinct from ultimate causation, the two concepts are nevertheless connected. Proximate mechanisms produce behaviors that have evolved because they reflect fitness in some particular way. For instance, increased day length itself has little adaptive significance for red-crowned cranes, but since it corresponds to seasonal conditions that increase reproductive success, such as the availability of food for feeding young birds, breeding when days are longer is a proximate mechanism that has evolved in cranes.

Ethology

In the mid-20th century, a number of pioneering behavioral biologists developed the discipline of **ethology**, the scientific study of how animals behave, particularly in their natural environments. Ethologists such as Niko Tinbergen, of the Netherlands, and Karl von Frisch and Konrad Lorenz, of Austria, who shared a Nobel Prize in 1973, established the conceptual foundations on which modern behavioral ecology is based. In a 1963 paper, Tinbergen suggested four questions that must be answered to fully understand any behavior. His questions, which remain at the core of behavioral ecology today, can be summarized as follows:

1. What is the mechanistic basis of the behavior, including chemical, anatomical, and physiological mechanisms?
2. How does development of the animal, from zygote to mature individual, influence the behavior?
3. What is the evolutionary history of the behavior?
4. How does the behavior contribute to survival and reproduction (fitness)?

Tinbergen's list includes both proximate and ultimate questions. The first two, which concern mechanism and development of the behavior, are proximate questions, while the second two are ultimate, or evolutionary, questions. The complementary nature of proximate and ultimate perspectives can be demonstrated with behaviors frequently studied by the classical ethologists, such as fixed action patterns and imprinting.

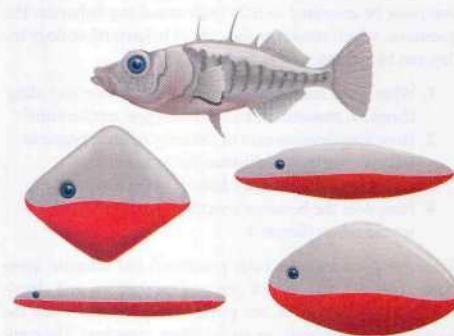

Fixed Action Patterns

A type of behavior studied extensively by the ethologists is the **fixed action pattern (FAP)**, a sequence of unlearned behavioral acts that is essentially unchangeable and, once initiated, is usually carried to completion. A FAP is triggered by an external sensory stimulus known as a **sign stimulus**. Tinbergen studied what has become a classic example of sign stimuli and FAPs in the male three-spined stickleback fish, which attacks other males that invade its nesting territory. The stimulus for the attack behavior is the red underside of the intruder; the stickleback will not attack an intruding fish lacking a red belly (note that female sticklebacks never have red bellies), but will readily attack unrealistic models as long as some red is present (**Figure 51.3**). In fact, Tinbergen was inspired to look into the matter by his casual observation that his fish responded aggressively when a red truck passed their tank. As a consequence of his research, which was first reported in 1937, Tinbergen discovered that the color red is a key component of the sign stimulus releasing aggression in male sticklebacks.

V **Figure 51.3** Sign stimuli in a classic fixed action pattern.

(a) A male three-spined stickleback fish shows its red underside.

(b) The realistic model at the top, without a red underside, produces no aggressive response in a male three-spined stickleback fish. The other models, with red undersides, produce strong responses.

BEHAVIOR: A male stickleback fish attacks other male sticklebacks that invade its nesting territory.

PROXIMATE CAUSE: The red belly of the intruding male acts as a sign stimulus that releases aggression in a male stickleback.

ULTIMATE CAUSE: By chasing away other male sticklebacks, a male decreases the chance that eggs laid in his nesting territory will be fertilized by another male.

4 **Figure 51.4** Proximate and ultimate perspectives on aggressive behavior by male sticklebacks.

Figure 51.4 offers both proximate and ultimate explanations for this particular FAP among male stickleback fish.

Imprinting

Another phenomenon studied by the classical ethologists is **imprinting**, a type of behavior that includes both learning and innate components and is generally irreversible. Imprinting is distinguished from other types of learning by having a **sensitive period**, a limited phase in an animal's development that is the only time when certain behaviors can be learned. An example of imprinting is young geese following their mother. In species that provide parental care, parent-offspring bonding is a critical part of the life cycle. During the period of bonding, the young imprint on their parent and learn the basic behaviors of their species, while the parent learns to recognize its offspring. Among gulls, for instance, the sensitive period for parental bonding in young lasts one to two days. If bonding does not occur, the parent will not initiate care of the infant, leading to certain death for the offspring and a decrease in reproductive success for the parent.

But how do the young know whom—or what—to imprint? How do young geese know that they should follow the mother goose? The tendency to respond is innate in the birds; the outside world provides the **imprinting stimulus**, something to which the response will be directed. Experiments with many species of waterfowl indicate that they have no innate recognition of "mother." They respond to and identify with the first object they encounter that has certain key characteristics. In classic experiments done in the 1930s, Konrad Lorenz showed that the most important imprinting stimulus in graylag geese is movement of an object away from the young. When incubator-hatched goslings spent their first few

hours with Lorenz rather than with a goose, they imprinted on him, and from then on, they steadfastly followed him and showed no recognition of their biological mother or other adults of their own species. Again, there are both proximate and ultimate explanations, as outlined in **Figure 51.5**.

Cranes also imprint as hatchlings, creating both problems and opportunities in captive rearing programs designed to save endangered crane species. For instance, a group of 77 endangered whooping cranes hatched and raised by sandhill cranes imprinted on the sandhill foster parents; none of these whooping cranes ever formed a mating pair-bond with another Vs whooping crane. As a consequence, captive breeding programs now isolate young cranes and expose them to the sights and sounds of members of their own species. But imprinting can also be used to aid crane conservation (**Figure 51.6**). Young

BEHAVIOR: Young geese follow and imprint on their mother.

PROXIMATE CAUSE: During an early, critical developmental stage, the young geese observe their mother moving away from them and calling.

ULTIMATE CAUSE: On average, geese that follow and imprint on their mother receive more care and learn necessary skills, and thus have a greater chance of surviving than those that do not follow their mother.

Figure 51.5 Proximate and ultimate perspectives on imprinting in graylag geese.

i Figure 51.6 Imprinting for conservation. Conservation biologists have taken advantage of imprinting by young whooping cranes as a means to teach the birds a migration route. A pilot wearing a crane suit in an ultralight plane acts as a surrogate parent.

whooping cranes imprinted on humans in "crane suits" have been taught to follow these "parents" flying ultralight aircraft along new migration routes. And importantly, such cranes have formed mating pair-bonds with other whooping cranes.

While research on imprinting and fixed action patterns is much less active than it once was, the early study of these behaviors helped to make the distinction between proximate and ultimate causes of behavior. These studies also helped establish a strong tradition of experimental approaches in behavioral ecology.

Concept Check 51.1

1. A ground squirrel that sees a predator may utter a brief, loud call. List four questions about this behavior, one for each of Tinbergen's four questions. State whether each is a proximate or an ultimate question.
2. If an egg rolls out of the nest, a mother graylag goose will retrieve it by nudging with her beak and head. If researchers remove the egg or substitute a ball during this process, the goose will not alter her response. What type of behavior is this? Suggest a proximate and an ultimate explanation.

For suggested answers, see Appendix A.

Concept 51.2

Many behaviors have a strong genetic component

Extensive research shows that behavioral traits, like anatomical and physiological aspects of a phenotype, are the result of complex interactions between genetic and environmental factors. This conclusion contrasts sharply with the popular conception that behavior is due *either* to genes (nature) *or* to environment (nurture). In biology, nature versus nurture is not a debate. Rather, biologists study how *both* genes *and* the environment influence the development of phenotypes, including behavioral phenotypes. Though we first discuss genetic influences on behavior and defer the discussion of environmental influences, you should bear in mind that all behaviors are affected by both genes and environment.

One approach to studying the influence of different factors on a particular behavior is to view the behavior in terms of the norm of reaction (see Figure 14.13). For instance, we might measure the behavioral phenotypes for a particular genotype that develop in a range of environments. In some cases, the behavior is variable, depending on environmental experience. In other cases, nearly all individuals in a population exhibit virtually the same behavior, despite internal and external

environmental differences during development and throughout life. Behavior that is *developmentally fixed* in this way is called innate behavior. Innate behaviors are under strong genetic influence, as we will discuss in the following examples.

Directed Movements

Many animal movements, ranging from simple ones that take place within a few millimeters to complex movements that span hundreds or thousands of kilometers, are under substantial genetic influence. Because of the clear role of genes in the control of these animal movements, we may refer to them as *directed movements*.

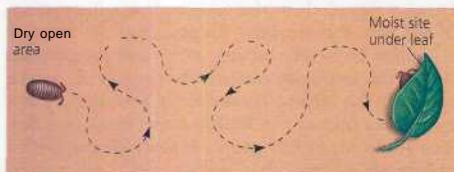

Kinesis

A kinesis is a simple change in activity or turning rate in response to a stimulus. For example, sow bugs (also called wood lice), terrestrial crustaceans that survive best in moist environments, exhibit a kinesis in response to variation in humidity (**Figure 51.7a**). The sow bugs become more active in dry areas and less active in humid areas. Though sow bugs do not move toward or away from specific conditions, their increased movement under dry conditions increases the chance that they will leave a dry area and encounter a moist area. And since they slow down in a moist area, they tend to stay there once they encounter it.

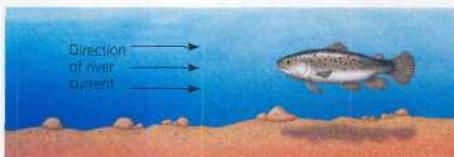

Taxis

In contrast to a kinesis, a taxis is a more or less automatic, oriented movement toward (a positive taxis) or away from (a

• Figure 51.7 A kinesis and a taxis.

(a) Kinesis increases the chance that a sow bug will encounter and stay in a moist environment.

(b) Positive rheotaxis keeps trout facing into the current, the direction from which most food comes.

negative taxis) some stimulus. For example, many stream fish, such as trout, exhibit positive rheotaxis (from the Greek rheos, current); they automatically swim or orient themselves in an upstream direction (toward the current). This taxis keeps the fish from being swept away and keeps them facing the direction from which food will come (**Figure 51.7b**).

Migration

It is easy to assume that a simple behavior, such as kinesis shown by sow bugs or positive rheotaxis by trout, is under strong genetic control. However, genetic influence can be substantial even for more complex behaviors. For example, ornithologists have found that many features of migratory behavior in birds are genetically programmed (**Figure 51.8**).

One of the most thoroughly studied migratory birds is the blackcap (*Sylvia atricapilla*), a small warbler that ranges from the Cape Verde Islands off the coast of West Africa to northern Europe. The migratory behavior of blackcaps differs greatly among populations; for instance, while all blackcaps in the northern portion of the range migrate, usually at night, those in the Cape Verde Islands do not migrate at all. During the normal season for migration, captive migratory blackcaps spend their nights hopping restlessly about their cages or rapidly flapping their wings while sitting on a perch.

Peter Berthold and his colleagues at the Max Planck Research Center for Ornithology in Radolfzell, Germany, studied the genetic basis of this behavior, known as "migratory restlessness," in several populations of blackcaps. In one study, the research team crossed (mated) migratory blackcaps from southern Germany with nonmigratory blackcaps from Cape Verde and subjected their offspring to environments simulating one location or the other. Approximately 40% of the offspring raised in both conditions showed migratory restlessness,

& Figure 51.8 Bird migration, a behavior that is largely under genetic control. Each spring, migrating western sandpiper (*Calidris mauri*), such as those shown here, migrate from their wintering grounds, which may be as far south as Peru, to their breeding grounds in Alaska. In the autumn, they return to the wintering grounds.

leading Berthold to conclude that migratory restlessness is under genetic control and follows a polygenic inheritance pattern (see Chapter 14). Other breeding experiments in Berthold's laboratory have demonstrated genetic influences on many components of blackcap migration, as we will see later in this chapter.

Animal Signals and Communication

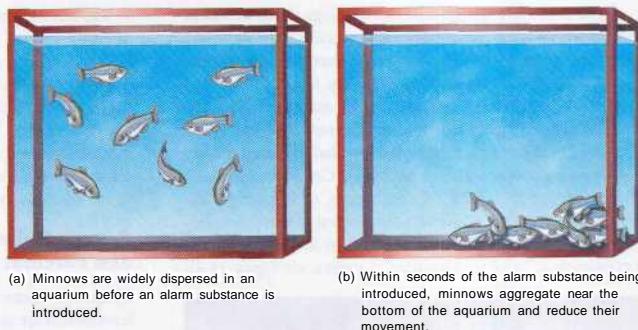

Much of the social interaction between animals involves transmitting information through specialized behaviors called signals (also known as displays). In behavioral ecology, a signal is a behavior that causes a change in another animal's behavior. The transmission of, reception of, and response to signals constitute animal communication, an essential element of interactions between individuals. Though the environment makes significant contributions to all communication systems, some of their features are under strong genetic control.

Many signals are very efficient in energy costs. For instance, a common signal between territorial fish is to erect their fins, which gives them a larger profile and is generally enough to drive off an intruding individual (see Figure 51.2); it takes less energy to erect fins than it does to push an intruding male from a territory.

Animals communicate using visual, auditory, chemical (olfactory), tactile, and electrical signals. The type of signal used to transmit information is closely related to an animal's lifestyle and environment. For example, most terrestrial mammals are nocturnal, which makes visual displays relatively ineffective. But olfactory and auditory signals work as well in the dark as in the light, and most mammalian species signal by these means. Birds, by contrast, are mostly diurnal and have a relatively poor olfactory sense; they communicate primarily by visual and auditory signals. Unlike most mammals, humans are diurnal and, like birds, use mainly visual and auditory communication. Therefore, we can detect the songs and bright colors that birds use to communicate with each other. If humans had the well-developed olfactory abilities of most mammals and could detect the rich world of chemical cues, we would have a very different perspective of nature.

Chemical Communication

Many animals that communicate through odors emit chemical substances called pheromones. In most cases, both the production of pheromones and animal responses to them are controlled genetically. Pheromones are especially common among mammals and insects and often relate to reproductive behavior. Many moths, for example, emit pheromones that can

A Figure 51.9 Minnows responding to the presence of an alarm substance.

attract mates from several kilometers away. Once the moths are together, pheromones also trigger specific courtship behaviors.

The context of a chemical signal can be as important as the chemical itself. In a honeybee colony, pheromones produced by the queen and her daughters, the workers, maintain the hive's very complex social order. When male honeybees (drones) are outside the hive, where they can mate with a queen, they are attracted to her pheromone; when drones are inside the hive, they are unaffected by the queen's pheromone.

Pheromones also function in nonreproductive behavior. For example, when a minnow or catfish is injured, an alarm substance that is stored in glands in the fish's skin disperses in the water, inducing a fright response among other fish in the area. These nearby fish become more vigilant and group together in tightly packed schools, often near the bottom, where they are safer from attack (Figure 51.9). Pheromones can be very effective at low concentrations. For instance, just 1 cm^2 of skin from a fathead minnow contains sufficient alarm substance to induce an alarm reaction even when diluted by 58,000 L of water.

Auditory Communication

The songs of most bird species are at least partly learned. By contrast, in many species of insects, mating rituals include characteristic songs that are generally under direct genetic control. In *Drosophila* species, males produce a song by vibrating their wings, and females are able to recognize the songs of males of their species through such details as the intervals between pulses of wing vibrations, the rhythm of the song, and the length of song pulses. A variety of evidence indicates that song structure in *Drosophila* males is controlled genetically and is under strong selective pressure. For instance, males reared in isolation produce a characteristic song for their species despite having no exposure to other singing males. In addition, the male song shows very little variation among individuals within a *Drosophila* species.

While *Drosophila* species differ morphologically as well as in their courtship songs, some other insect species can be identified only through their courtship songs or behavior. For example, morphologically identical green lacewings found throughout central to northern Eurasia and North America were once thought to belong to a single species, *Chrysoperla carnea*. However, studies of their courtship songs by Charles Henry and his colleagues and students at the University of Connecticut revealed the presence of at least 15 different species, each singing a different courtship song (Figure 51.10). Several of these morphologically identical species may occur together in the same habitat (an example of behavioral isolation of species; see Figure 24.4).

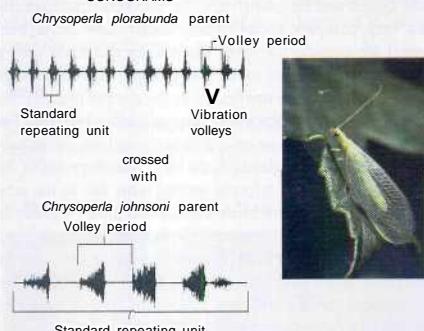

Figure 51.10

It'syiry Are the different songs of closely related green lacewing species under genetic control?

EXPERIMENT

Charles Henry, Lucia Martinez, and Kent Holsinger crossed males and females of *Chrysoperla plorabunda* and *Chrysoperla johnsoni*, two morphologically identical species of lacewings that sing different courtship songs.

SONOGRAMS

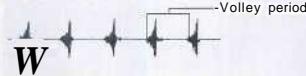

The researchers recorded and compared the songs of the male and female parents with those of the hybrid offspring that had been raised in isolation from other lacewings.

RESULTS

The F1 hybrid offspring sing a song in which the length of the standard repeating unit is similar to that sung by the *Chrysoperla plorabunda* parent, but the volley period, that is, the interval between vibration volleys, is more similar to that of the *Chrysoperla johnsoni* parent.

F, hybrids, typical phenotype

CONCLUSION

The results of this experiment indicate that the songs sung by *Chrysoperla plorabunda* and *Chrysoperla johnsoni* are under genetic control.

Though they never observed hybrids of the different green lacewing species in the wild during more than 20 years of fieldwork, Henry and his colleagues have been able to produce hybrids between different species under laboratory conditions. While all individuals in each species sing the same song, laboratory-raised hybrid offspring sing songs that contain elements of the songs of both parental species. These data led the researchers to conclude that the various songs sung by the different green lacewing species are genetically controlled.

Genetic Influences on Mating and Parental Behavior

Behavioral research has uncovered a variety of mammalian behaviors that are under relatively strong genetic control, as well as the physiological mechanisms for these behaviors. One of the most striking lines of research concerns mating and parental behavior by male prairie voles (*Microtus ochrogaster*).

Prairie voles and a few other vole species are monogamous as a social trait found among only about 3% of mammalian species. Male prairie voles also help their mates care for young another relatively uncommon trait among male mammals. In contrast with most other vole species, a male prairie vole forms a strong pair-bond with a single female after they mate, associating closely with his mate and engaging in grooming and huddling behaviors (Figure 51.11). Further, though an unmated male prairie vole shows little aggression toward other prairie voles, whether male or female, a mated male becomes intensely aggressive toward any strange male or female prairie voles while remaining nonaggressive toward his mate. A few days following the birth of pups, a male prairie vole will spend a great deal of time hovering over them, licking them, and carrying them around, while remaining vigilant for intruders.

The genetic and physiological controls on the complex social and parental behaviors of prairie voles have been revealed over the past decade by the research of Thomas R. Insel and his colleagues at Emory University. Early research suggested

Figure 51.11 A pair of prairie voles (*Microtus ochrogaster*) huddling. North American prairie voles are monogamous, with males associating closely with their mates, as shown here, and contributing substantially to the care of young.

that arginine-vasopressin (AVP), a nine-amino-acid neurotransmitter released during mating, might mediate both pair bond formation and aggression by male prairie voles. In the central nervous system, AVP binds with a receptor called the V_{1a} receptor. The Emory researchers found significant differences between the distribution of V_{1a} receptors in the brains of monogamous prairie voles and their distribution in promiscuous montane voles (which live in the mountainous regions of western North America).

To test whether the distribution of V_{1a} receptors is a key factor controlling the mating and parental behavior of prairie voles, Iissel and his colleagues inserted the prairie vole V_{1a} receptor gene into laboratory mice. Not only did the transgenic mice develop brains in which the distribution of V_{1a} receptors was remarkably similar to the distribution found in prairie voles, but they also showed many of the same mating behaviors as monogamous male prairie voles. In contrast, male wild-type mice did not have the same V_{1a} receptor distribution and did not show such behavior. Thus, though many genes influence the mating behavior of these voles, it appears that a single gene may mediate a considerable amount of the complex mating behavior (and perhaps parental behavior) that occurs in prairie voles. It remains to be seen whether other complex behaviors are under similarly simple genetic influences. In addition, although genes influence behaviors in a multitude of ways, environment also has major effects on behaviors, as we shall see in the next section.

Concept Check 51.2

- Which has greater influence on the development of behaviors, "nature" or "nurture"? Explain.
- Use an example to explain how researchers study whether a particular behavior has a strong genetic component.

For suggested answers, see Appendix A.

Concept 51.3

"Environment, interacting with an animal's genetic makeup, influences the development of behaviors

While experimental demonstrations of genetic influences on behaviors accumulate, research also reveals that environmental conditions modify many of the same behaviors. Environmental actors, such as the quality of the diet, the nature of social interactions, and opportunities for learning can influence the development of behaviors in every group of animals.

Dietary Influence on Mate Choice Behavior

One example of environmental influence on behavior is the role of diet in mate selection by *Drosophila mojavensis*, which mates and lays its eggs on the rotting tissues of cactus. *D. mojavensis* populations in Baja California, Mexico, breed almost entirely on agave cactus, whereas most populations in Sonora, Mexico, and in Arizona use organ pipe cactus. These cacti serve as food for the developing larvae.

When *D. mojavensis* from Baja and Sonora were raised on an artificial banana-based medium in the laboratory, researchers noticed that females from the Sonoran population tended to avoid mating with Baja males. Following up on these initial observations, William Etges and Mitchell Ahrens, of the University of Arkansas, showed that the food eaten by *D. mojavensis* larvae strongly influences later mate selection by females, especially those from Sonoran populations (Figure 51.12).

Figure 51.12

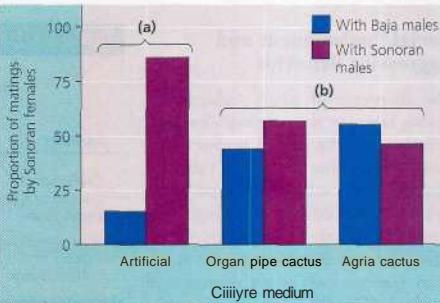

Inquiry How does dietary environment affect mate choice by female *Drosophila mojavensis*?

EXPERIMENT

William Etges raised a *D. mojavensis* population from Baja California and a *D. mojavensis* population from Sonora on three different culture media: artificial medium, agave cactus (the Baja host plant), and organ pipe cactus (the Sonoran host plant). From each culture medium, Etges collected 15 male and female Baja *D. mojavensis* pairs and 15 Sonoran pairs and observed the numbers of matings between males and females from the two populations.

RESULTS

When *D. mojavensis* had been raised on artificial medium, females from the Sonoran population showed a strong preference for Sonoran males (a). When *D. mojavensis* had been raised on cactus medium, the Sonoran females mated with Baja and Sonoran males in approximately equal frequency (b).

CONCLUSION

The difference in mate selection shown by females that developed on different diets indicates that mate choice by females of Sonoran populations of *D. mojavensis* is strongly influenced by the dietary environment in which larvae develop.

< Figure 51.13
Therese Markow (right) and a colleague collecting *Drosophila mojavensis* from a cactus.

Bu why do Sonoran females avoid Baja males that develop on some diets but not those that develop on other diets? In other words, what is the proximate cause of the behavior? Therese Markow, of Arizona State University, and Eric Toolson, of the University of New Mexico, proposed that the physiological basis for the observed mate preferences was differences in hydrocarbons in the exoskeletons of the flies (Figure 51.13). This was a reasonable hypothesis, since in addition to using courtship songs and other sensory information, *Drosophila* use their sense of taste to assess the hydrocarbons in the exoskeleton of possible mates. To test the influence of exoskeleton hydrocarbons, Etges and Ahrens raised Baja males on artificial medium and then perfumed them with hydrocarbons extracted from the exoskeletons of males from the Sonoran population. Instead of rejecting these Baja males, Sonoran females accepted them as frequently as they accepted Sonoran males.

Etges and Ahrens's study showed how the effects of the nutritional environment can modify a critical behavior. Next we will see how social environment has been found to modify the behavior of at least one species.

Social Environment and Aggressive Behavior

The discoveries of genetic influence on mating behaviors in male prairie voles are complemented by parallel studies of another monogamous rodent, the California mouse (*Peromyscus californicus*). Like prairie voles, male California mice are highly aggressive toward other mice and provide extensive parental care. In contrast to prairie voles, however, even male California mice that have not mated are already aggressive.

Janet Bester-Meredith and Catherine Marler, of the University of Wisconsin at Madison, studied what influence the social environment might have on the behavior

of male California mice. To manipulate the early social environment, they placed newborn California mice in the nests of white-footed mice (*Peromyscus leucopus*), a species in which males are not monogamous and engage in little parental care. They also placed newborn white-footed mice in the nests of California mice. This "cross-fostering," in which the young of each species were placed in the nests of the other species, altered the behavior of both species (Table 51.1). For instance, when male California mice raised by white-footed mice crawled away from the nest, they were not retrieved as frequently as those raised by their own species. When these cross-fostered California mice became parents, they, too, spent less time retrieving their pups. The cross-fostered California mice were also less aggressive toward intruders. In contrast, male white-footed mice raised by California mice were more aggressive than those raised by white-footed mice. In one study by Bester-Meredith and Marler, the brains of California mice raised by white-footed mice were found to contain reduced levels of the same neurotransmitter (AVP) associated with elevated aggression and parental care in male prairie voles.

The fact that cross-fostered California and white-footed mice adopted some of the behaviors of their foster parent suggests that experience during development can lead to changes in parental and aggressive behaviors in these rodents that can be passed from one generation to the next.

Learning

One of the most powerful ways that environmental conditions can influence behavior is through learning, the modification of behavior based on specific experiences. Learned behaviors range from the very simple, such as imprinting, which results in a young bird following a particular individual it has learned to recognize as its parent, to the highly complex. Before we consider some complex forms of learning, let's look briefly at another very simple one: habituation.

Table 51.1 Influence of Cross-Fostering on Male Mice*

| Species | Aggression Toward an Intruder | Aggression in Neutral Situation | Paternal Behavior | Arginine-Vasopressin (AVP) Content in Brain |
|---|-------------------------------|---------------------------------|-------------------|---|
| California mice fostered by white-footed mice | Reduced | No difference* | Reduced | Reduced |
| White-footed mice fostered by California mice | No difference | Increased | No difference | No difference |

*Comparisons are with mice raised by parents of their own species.

Data from J. K. Bester-Meredith and C. A. Marler, Vasopressin and the transmission of paternal behavior across generations in mated, cross-fostered *Peromyscus* mice. *Behavioral Neuroscience* 117(2003):455–463.

Habituation

Habituation is a loss of responsiveness to stimuli that convey little or no information. Examples are widespread. A hydra contracts when disturbed by a slight touch; if it is repeatedly disturbed by such a stimulus without any further consequences, it stops responding. Many mammals and birds recognize alarm calls of members of their species, but they eventually stop responding if these calls are not followed by an actual attack (the "cry-wolf effect"). In terms of ultimate causation, habituation may increase fitness by allowing an animal's nervous system to focus on stimuli that signal the presence of food, mates, or real danger instead of wasting time or energy on a vast number of other stimuli that are irrelevant to the animal's survival and reproduction. Next, let's shift our attention to some more complex forms of learning.

Initial Learning

Every natural environment shows some degree of spatial variation. For instance, sites suitable for nesting may be more common in some places than in others. As a consequence, the fitness of an organism may be enhanced by the capacity for **spatial learning**, which is the modification of behavior based on experience with the spatial structure of the environment, including the locations of nest sites, hazards, food, and prospective mates.

In a classic experiment done in 1932, Niko Tinbergen studied how digger wasps find their nest entrances. Tinbergen moved a circle of pinecones that had previously surrounded a nest entrance and observed that the wasp landed in the center of the pinecones, even though the nest entrance was no longer there (Figure 51.14). The wasp was using the pinecones as a **landmark**, or location indicator. The use of landmarks is a more complex cognitive mechanism than a taxis or kinesis, since it involves learning. The wasp flies toward a stimulus (in his case, the center of the pinecones), as in a taxis, but the stimulus is an arbitrary landmark the animal must learn rather than a constant stimulus such as light. One nest entrance may have pinecones around it, while another may be next to a pile of stones. Each wasp has to learn the unique landmarks of each individual nest site.

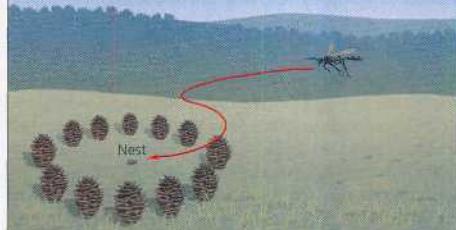

Tinbergen's experiment reveals that for spatial learning to be a reliable way to navigate through the environment, the landmarks used must be stable (within the time frame of a particular activity). For example, the pinecones that indicate the presence of the wasp's nest should have a low probability of moving. Using unreliable information for learning may result in a significant cost to the animal. If a nesting wasp learns to locate its nest using objects that might blow away, for instance, the cost may be an inability to locate and provision the nest and, consequently, reduced reproductive success for the wasp.

Figure 51.14

Inquiry Does a digger wasp use landmarks to find her nest?

EXPERIMENT

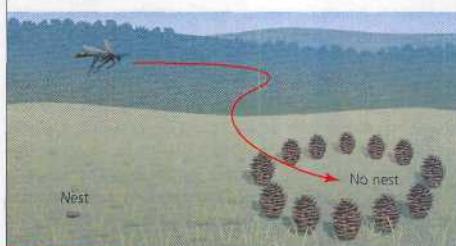

A female digger wasp excavates and cares for four or five separate underground nests, flying to each nest daily with food for the single larva in the nest. To test his hypothesis that the wasp uses visual landmarks to locate the nests, Niko Tinbergen marked one nest with a ring of pinecones.

After the mother visited the nest and flew away, Tinbergen moved the pinecones a few feet to one side of the nest.

RESULTS

When the wasp returned, she flew to the center of the pinecone circle instead of to the nearby nest. Repeating the experiment with many wasps, Tinbergen obtained the same results.

CONCLUSION

The experiment supported the hypothesis that digger wasps use landmarks to keep track of their nests.

Because some environments are more stable than others, animals may use different kinds of information for spatial learning in different environments. Lucy Odling-Smeet and Victoria Braithwaite, of the University of Edinburgh, hypothesized that three-spined stickleback fish from stable pond environments would rely more on landmarks than would sticklebacks from more changeable river environments. Odling-Smeet and Braithwaite trained 20 sticklebacks from rivers and 20 from ponds to navigate a T-shaped maze to reach a reward (a combination of food and other fish the sticklebacks could school with). In the first phase of the experiment, the researchers placed the reward at one end of the maze and marked the correct direction to turn for the reward with landmarks in the form of two plastic plants.

Fish that learned to find the reward were given a second set of trials., in which Odling-Smee and Braithwaite put rewards at both ends of the maze and switched the location of the landmarks. The results showed that the sticklebacks from stable pond environments located the rewards using a combination of learning which direction to turn and landmarks, while most river fish learned simply to turn in a particular direction. These results suggest that the degree of environmental variability influences the spatial learning strategies of animals.

Cognitive Maps

An animal can move around its environment in a flexible and efficient manner using landmark orientation alone. Honeybees, for instance, might learn ten or so landmarks and locate their hive and flowers in relation to those landmarks. A more powerful mechanism is a cognitive map, an internal representation, or code, of the spatial relationships between objects in an animal's surroundings.

It is very difficult to distinguish experimentally between an animal that is using landmarks and one that is using a true cognitive map. Researchers have collected evidence that specifically supports the use of cognitive maps by corvids, a family of birds that includes ravens, crows, jays, and nutcrackers. Many corvids store food in caches, from which the birds can retrieve the food later. For instance, pinyon jays (*Gymnorhinus cyanocephalus*) and Clark's nutcrackers (*Nucifraga caryocatactes*) store nuts in as many as thousands of caches that may be widely dispersed. The birds not only relocate each cache, but also keep track of food quality, bypassing caches in which the food was relatively perishable and would have decayed since it was stored. Research by Alan Kamil, of the University of Nebraska, suggests that pinyon jays and Clark's nutcrackers use cognitive maps to memorize the locations of their food caches. In one experiment with Clark's nutcrackers, Kamil varied the distance between landmarks and discovered that the birds could learn to find the halfway point between them. Such behavior suggests that the birds are capable of using a general abstract geometric rule for locating a seed cache. In Kamil's experiment, the rule was something like, "Seed caches are found halfway between particular landmarks." Such rules form the basis of cognitive maps, which benefit the organism by reducing the amount of detail that must be remembered to relocate an object.

Associative Learning

As we have seen, in learning, an animal modifies its behavior based on information from the environment. For instance, an inexperienced white-footed mouse may readily attack a brightly colored, slow-moving caterpillar, such as the larva of a monarch butterfly, only to find its mouth full of a distasteful poisonous fluid. Following this experience, the white-footed mouse may avoid attacking insects with similar coloration and behavior. The ability of many animals to associate one feature

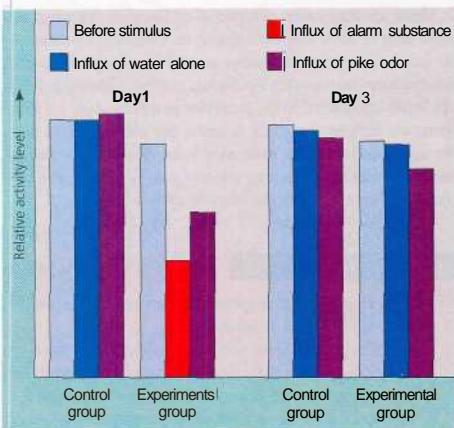

of the environment (a stimulus, such as color) with another (bad taste) is called associative learning.

Associative learning and its genetic and neurological bases have been extensively studied in the fruit fly *Drosophila melanogaster*. William Quinn, William Harris, and Seymour Benzer, of the California Institute of Technology, published the first demonstration of associative learning by *Drosophila* over 30 years ago. The research team trained *Drosophila* flies to avoid air carrying a particular scent by coupling exposure to the odor with an electric shock. This is an example of a type of associative learning called classical conditioning, in which an arbitrary stimulus, in this case an odor, is associated with a reward or punishment, the electric shock. *Drosophila* individuals trained in this way would avoid the particular odor for as long as 24 hours. Further research over the past three decades has revealed a surprising capacity for learning by *Drosophila*, which has become a model for the study of this component of behavior.

The laboratory study of associative learning has been extended to natural environments. The role that associative learning may play in helping animals avoid predators has been particularly well studied in fishes and aquatic insects.¹ Recall our earlier discussion about the alarm substance in the skins of minnows and related fishes that induces an automatic fright response in nearby fish. Nichole Korpi and Briar Wisenden, of Minnesota State University at Moorhead, conducted a study to determine whether this alarm substance might be involved in a process of associative learning through which fish learn to avoid predators.

Korpi and Wisenden studied the zebrafish (*Danio rerio*), a common aquarium fish. For the predator they chose a pike. Zebrafish, a minnow from southern Asia, and pike, a fish of northern lakes, do not occur together in nature. Would the zebrafish learn to associate the scent of this unfamiliar predator with their alarm substance if there were a delay between exposure to the alarm substance and exposure to the odor of the predator? Korpi and Wisenden proposed that a delay of 5 minutes would realistically model a possible delay between the occurrence of an alarm and encountering an actual predator.

The researchers exposed zebrafish in an experimental group to an influx of 20 mL of water containing an alarm substance and then, 5 minutes later, to 20 mL of water with pike odor. Zebrafish in a control group were exposed to an influx of water alone (without alarm substance) and then to water containing pike odor. On day 1 of the experiment, the zebrafish in the control group did not change their activity in response to the influx of either water alone or pike odor (Figure 51.15). This lack of response by the control group is critical to the interpretation of the results, because it indicates that the zebrafish had no innate negative reaction to pike odor. As expected, the zebrafish in the experimental group reduced their activity markedly in response to the alarm substance. When pike odor was added 5 minutes later, their activity actually increased

k Figure 51.15 Associative learning in zebrafish. Changes in activity indicated that the experimental group of zebrafish had learned to associate the odor of pike with the presence of alarm substance.

somewhat, a difference from the typical alarm response. Three days later, the zebrafish in the control group still showed no response to the influx of either water alone or pike odor (see Figure 51.15). The experimental fish also showed no significant response to an influx of water alone. However, they did reduce their activity somewhat in response to pike odor. Korpi and Wisenden concluded that the zebrafish in the experimental group had learned to associate pike odor with the alarm substance, even though their exposure to pike odor on the first day of the study was delayed for 5 minutes. In terms of classical conditioning, the zebrafish had been *conditioned* to associate pike odor with the alarm substance. The experimental results show that this association was retained for three days.

Another type of associative learning is operant conditioning, also called trial-and-error learning. Here, an animal learns to associate one of its own behaviors with a reward or punishment and then tends to repeat or avoid that behavior (Figure 51.16). As in the example of a mouse eating a distasteful caterpillar, or instance, predators quickly learn to associate certain kinds of potential prey with painful experiences and modify their behavior accordingly.

Cognition and Problem Solving

The study of cognition connects behavior with nervous system function. The term *cognition* is variously defined. In a narrow sense, it is synonymous with consciousness, or awareness. In a broad sense—the way we use the term in this book—cognition is the ability of an animal's nervous system to perceive, store, process, and use information gathered by sensory receptors.

A Figure 51.16 Operant conditioning. Having received a face full of quills, a young coyote has probably learned to avoid porcupines.

The study of animal cognition, called cognitive ethology, examines the connection between an animal's nervous system and its behavior.

One area of research in cognitive ethology investigates how an animal's brain represents objects in the environment. For example, researchers have discovered that many animals, including insects, are capable of categorizing objects according to concepts such as "same" and "different." Martin Giurfa, of the Centre of Animal Cognition Research in Toulouse, France, and his team trained honeybees to match a sample color to the same color marking one of two arms in a Y-maze. Later, the trained bees were able to match black-and-white patterns in the same orientation on the maze, indicating that they recognized the "sameness" of the problem.

Watching an animal solve a problem makes us aware that its nervous system has a substantial ability to process information. For example, if a chimpanzee is placed in a room with a banana hung high out of reach and several boxes on the floor, the chimp can "size up" the situation and stack the boxes, enabling it to reach the food. Such novel problem-solving behavior is highly developed in some mammals, especially primates and dolphins, and notable examples have also been observed in some bird species, especially crows, ravens, and jays. Behavioral ecologist Bernd Heinrich, of the University of Vermont, performed an experiment in which ravens had to obtain food hanging from a string. Several ravens solved the problem by using one foot to pull up the string in increments and the other foot to secure the string so the food did not drop down again; other ravens showed great individual variation in their problem-solving attempts.

One powerful source of information used by many animals to solve problems is the behavior of other individuals. Long-term research by Tetsuro Matsuzawa, of the Primate Research Institute of Kyoto University, Japan, has revealed that chimpanzees learn to solve problems by copying the behavior of other chimpanzees. Matsuzawa and his research team have shown that

A Figure 51.17 Young chimpanzees learning to crack oil palm nuts by observing older chimpanzees.

young wild chimpanzees at Bossou, Guinea, learn how to use two stones as a hammer and anvil to crack oil palm nuts by observing and copying experienced chimpanzees (Figure 51.17).

Genetic and Environmental Interaction in Learning

Considerable research on the development of bird songs has revealed varying degrees of genetic and environmental influence on the learning of complex behavior. In some species, learning appears to play only a small part in song development. For instance, New World flycatchers that are reared away from adults of their species will develop the song characteristic of their own species without ever having heard it: In other words, their songs are innate. In contrast, among the songbirds—a group that includes the sparrows, robins, and canaries—learning plays a key role in song development.

Techniques for learning songs vary from species to species. Some have a sensitive period for developing their songs. For example, if a white-crowned sparrow is isolated for the first 50 days of life and unable to hear either real sparrows or recordings of sparrow songs, it fails to develop the adult song of its species. Although the young bird does not sing during the sensitive period, it memorizes the song of its species by listening to other white-crowned sparrows sing. During the sensitive period, fledglings seem to be stimulated more by the songs of their own species than by songs of other species, chirping more in response. Thus, young white-crowned sparrows *learn* the songs they will sing as adults, but the learning appears to be bounded by genetically controlled preferences.

The sensitive period when a white-crowned sparrow memorizes its species' song is followed by a second learning phase, when the juvenile bird sings some tentative notes that researchers call a subsong. The juvenile bird hears its own singing and compares it with the song that it memorized during the sensitive period. Once a sparrow's own song matches the one it memorized, it "crystallizes" as the final song, and the bird sings only this adult song for the rest of its life.

There are important exceptions to the song-learning scenario seen in white-crowned sparrows. Canaries, for example do not have a single sensitive period for song learning. A young canary begins with a subsong, but the full song it develops is not crystallized in the same way as it is in white-crowned sparrows. Between breeding seasons, the song becomes flexible again, and an adult male may learn new song "syllables each year, adding to the song it already sings. Each year, a new plastic song stage allows the learning of new syllables.

Concept Check 51.3

- How can cognitive maps increase an animal's capacity to learn spatial relationships?
- Describe three ways in which an animal's environment can influence the development of its behavior.
- How might associative learning explain why unrelated distasteful or stinging insects have similar colors?

For suggested answers, see Appendix A.

Concept 51.4

Behavioral traits can evolve by natural selection

Because of the influence of genes on behavior, natural selection can result in the evolution of behavioral traits in populations. One of the primary sources of evidence for this evolution is behavioral variation between and within species.

Behavioral Variation in Natural Populations

Behavioral differences between closely related species are common. As you have already seen, the males of different species of *Drosophila* sing different courtship songs. Another example is found in voles: In some species, both males and females care for young, while in other species, the young receive only maternal care. Though often less obvious, significant differences in behavior can also be found *within* animal species. When behavioral variation within a species corresponds to variation in environmental conditions, it may be evidence of past evolution.

Variation in Prey Selection

One of the best-known examples of genetically based variation in behavior within a species is prey selection by the garter snake *Thamnophis elegans* (Figure 51.18a). Stevan Arnold, of the University of Chicago, discovered that the natural diet of this species differs widely across its range in California. Coastal populations feed on salamanders, frogs, and toads, but predominantly on slugs. Inland populations feed on frogs.

a) A garter snake (*Thamnophis elegans*)

b) A banana slug (*Ariolimax californicus*); not to scale

bees, and fish, but not on slugs. In fact, slugs are rare or absent in the inland habitats of *T. elegans*.

The contrast in prey availability led Arnold to compare the responses of coastal and inland populations of *T. elegans*. When offered bits of banana slug (Figure 51.18b), which is found throughout the coastal habitats of *T. elegans* but is absent from the inland habitats Arnold studied. In a first test, Arnold offered banana slugs to *T. elegans* from both wild populations. Whereas most of the coastal snakes readily ate the slugs, the inland snakes tended to refuse them.

Because the contrast in feeding behavior may have been conditioned by experience in their natural habitat, Arnold tested the responses of young snakes born in the laboratory. He found that 73% of the young snakes from coastal mothers attacked the slugs they were offered, while only 35% of the young snakes from inland mothers attacked the slugs.

Arnold proposed that when inland snakes colonized coastal habitats more than 10,000 years ago, a fraction of the population had the ability to recognize slugs by chemoreception. Because these snakes took advantage of the abundant food source, they had higher fitness than snakes in the population that ignored slugs; thus, the capacity to recognize slugs as prey increased in frequency in the population over hundreds or thousands of generations. The variation in behavior today between the two populations is evidence of this evolution.

Variation in Aggressive Behavior

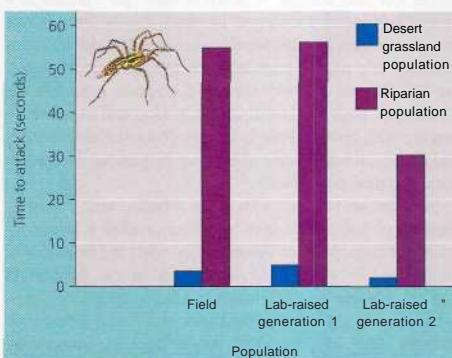

Although the differences in feeding behavior documented by Arnold occur over hundreds of kilometers, such distances are not necessary for intraspecific variation. In arid regions, the presence of water can produce striking environmental contrast over small distances, particularly where a desert

meets a riparian (riverside) woodland. The obvious contrast in vegetation is only one of many differences, which extend to the behavioral ecology of species inhabiting riparian zones and the surrounding arid environments.

Agelenopsis aperta is a species of funnel web spider that lives in both riparian zones and the surrounding arid environments in the western United States. The web of *A. aperta* consists of a silken sheet ending in a funnel hidden in some sheltering feature of the habitat. While foraging (behavior associated with recognizing, searching for, capturing, and consuming food), the spider sits in the mouth of the funnel. When prey strikes the web, the spider runs out to make its capture.

Susan RiecherL, of the University of Tennessee at Knoxville, and several colleagues found a striking contrast in the behavior of *A. aperta* spiders inhabiting riparian forests and those in arid and semi-arid habitats in Arizona and New Mexico. In arid, food-poor habitats, *A. aperta* is more aggressive toward potential prey and toward other spiders, and it returns to foraging more quickly following disturbance.

Ann Hedrick and Riechert tested whether the higher aggressiveness of arid-habitat *A. aperta* spiders reflects a genetic difference between the two populations or a learned response to living in food-poor environments (Figure 51.19). The researchers compared each spider's time to attack, the time that elapsed between a prey's first contact with the web and the point at which the spider first touched it. They found that in their natural environments, the spiders from desert grassland attacked all 15 prey types more quickly than did the riparian spiders. Hedrick and Riechert then brought female spiders from the two habitats into the laboratory, where the spiders laid eggs. Again using attack time as a measure, the researchers compared the aggressiveness of laboratory-raised

A Figure 51.19 Aggressiveness of funnel web spiders (*Agelenopsis aperta*) living in two environments. Field-collected and lab-raised funnel web spiders from desert grasslands delay less before attacking potential prey compared to *A. aperta* from riparian environments.

spiders from desert grassland and riparian habitats and repeated the experiment with the laboratory-raised offspring of each population.

The experiments revealed a strikingly consistent difference between desert grassland and riparian *A. aperta* in their time to attack prey. The highly productive riparian sites are rich in prey for the spiders, but the density of potential predators, particularly birds, is high. Riechert had proposed that, this higher risk of predation was the cause of the more timid behavior of *A. aperta* in riparian habitats. Based on their results, Hedrick and Riechert concluded that the difference in aggressiveness between desert grassland and riparian *A. aperta* spiders is genetically based and is the product of natural selection for differences in foraging and territorial behavior—a genetically determined rather than a learned response. Their findings were reinforced by later experiments with *A. aperta* transplanted from one environment to the other.

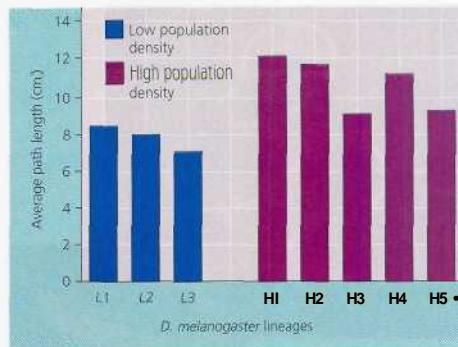

Experimental Evidence for Behavioral Evolution

Looking for more direct ways to demonstrate the evolution of behavior, researchers are increasingly turning to laboratory and field experiments using organisms with short lifespans, enabling the observation of change over many generations.

Laboratory Studies of *Drosophila* Foraging Behavior

In a few cases, researchers have been able to link behaviors to specific genes. For instance, Maria Sokolowski, of the University of Toronto, studied a polymorphism in a gene for foraging in *Drosophila melanogaster* called *jor*. One allele, *jor^s*, results in a behavioral phenotype called "sitter," in which the fly larva moves less than average. A different allele, *jor^r*, results in a "rover" behavioral phenotype, in which the fly larva moves about more than average. Sokolowski found that the allele frequencies in a natural population of *Drosophila melanogaster* are 70% *jor^r* and 30% *jor^s*. She noted, however, that while the mechanistic basis for the differences in rover and sitter behaviors are well known, little is known about the evolutionary and ecological significance of different frequencies of these alleles in natural populations.

Sokolowski teamed with Sofia Pereira and Kimberly Hughes, of York University Ontario, to conduct a laboratory study of how population density might affect the frequency of the *or/or^s* and *or/or^r* alleles in *Drosophila* populations. Sokolowski and her colleagues raised *Drosophila* at both high and low densities, starting with equal frequencies of *or/or^s* and *or/or^r* in both lineages. After 74 generations, larvae from the low-density and high-density lineages showed a clear divergence in behavior, as measured by differences in average foraging path length (Figure 51.20). The researchers concluded that the *or/or^s* allele had increased in frequency in the low-density populations, in which short-distance foraging would yield sufficient

A Figure 51.20 Evolution of foraging behavior by laboratory populations of *Drosophila melanogaster*. After 74 generations of living at low population density, *D. melanogaster* followed a foraging path significantly shorter than that of *D. melanogaster* populations that had lived at high density.

food, while long-distance foraging would result in unnecessary energy expenditure. Meanwhile, the *jor^r* allele had increased in frequency in the high-density lineage, where long-distance foraging could enable larvae to move beyond areas of food depletion. In other words, they had observed an evolutionary change in behavior in their laboratory populations.

Migratory Patterns in Blackcaps

An example of evolutionary change in the behavior of a wild population comes from studies on migratory behavior in a population of blackcaps, which we introduced in our earlier discussion of migration. The migratory patterns of blackcaps are well known in western Europe because of a great interest in bird study and a long history of bird banding. Blackcaps that breed in northwestern Europe generally migrate to the western Mediterranean region for the winter. As a consequence, blackcaps in Germany have historically migrated in a southwest direction, while those in Britain have migrated south. In the 1950s, a few blackcaps began to spend their winters in Britain, and over time, the population of blackcaps wintering in Britain has grown to many thousands. Surprisingly, these wintering birds are not birds that bred in Britain and then stayed for the winter. Leg bands on some of the birds show that they had come from continental Europe and migrated westward to Britain instead of south to the Mediterranean.

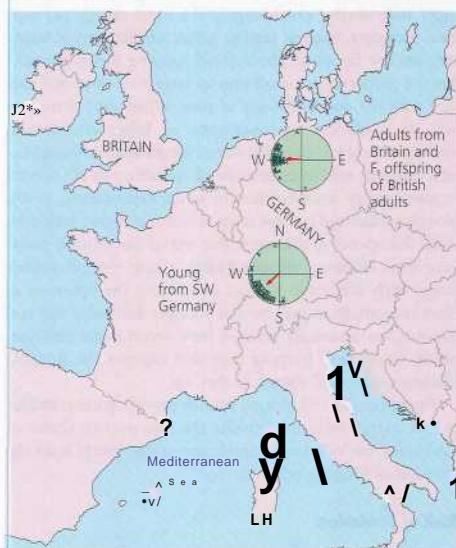

Peter Berthold and his colleagues captured 20 male and 20 female blackcaps wintering in Britain and transported them back to their laboratory in southwestern Germany. They compared the migratory orientation of these birds and their F₁ offspring to that of young birds originally from southwestern Germany. Behavioral ecologists have long known that the migratory restlessness that Berthold had studied previously is not

random activity but rather is directed. That is, caged birds showing migratory restlessness orient their activity in the direction that they would migrate if they were not caged. In the autumn when the birds were showing migratory restlessness, Berthold's team placed the blackcaps from their three study groups in large

f Figure 51.21 Evidence of a genetic basis for migratory orientation.

(a) Blackcaps placed in a funnel cage left marks indicating the direction in which they were trying to migrate.

(b) Wintering blackcaps captured in Britain and their laboratory-raised offspring had a migratory orientation toward the west, while young birds from Germany were oriented toward the southwest.

glass-covered funnel cages lined with carbon-coated paper for 1.5–2 hours. As the birds moved around the funnels, the marks they made on the paper indicated the direction in which they were trying to "migrate" (Figure 51.21a). The results showed that the migratory orientation of wintering adult birds captured in Britain was very similar to the orientation of their laboratory-raised offspring (Figure 51.21b). That similarity contrasted sharply with the migratory orientation of the young birds originally from Germany. This study indicates a genetic basis for migratory orientation, since the young of the British blackcaps and the young birds from Germany were raised under similar conditions but showed very different migratory orientations.

But has the behavior actually evolved over time? Berthold's study also indicates that the change in migratory behavior in western European blackcaps is both recent and rapid, having taken place over the past 50 years. Before 1960, there were no known westward-migrating blackcaps in Germany, but by the 1990s, westward migrants made up 7–11% of the blackcap populations of Germany and parts of Austria. Berthold suggests that once westward migration began, it persisted and increased in frequency as a result of several factors, including milder winter climate in Britain and improved winter food partly due to the widespread use of winter bird feeders in Britain. These hypotheses touch on the subject of the next section, which concerns how behavior can influence survival and reproduction and thus lead to evolution.

Concept Check 51.4

- Explain why geographic variation in garter snake foraging behavior might demonstrate that the behavior evolved by natural selection.
- Why did Hedrick and Riechert examine behavioral variation in laboratory-raised spiders rather than wild ones?
- What conclusions did Berthold and his colleagues draw from their studies of blackcap migratory patterns?

For suggested answers, see Appendix A.

Concept 51.5

Natural selection favors behaviors that increase survival and reproductive success

The genetic components of behavior, like all aspects of phenotype, evolve through natural selection for traits that enhance

survival and reproductive success in a population. Two of the most direct ways a behavior can affect fitness are through its influences on foraging and mate choice behavior.

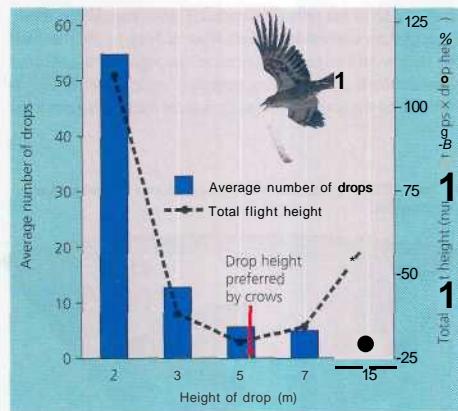

Foraging Behavior

Because adequate nutrition is essential to an animal's survival and reproductive success, we should expect natural selection to refine behaviors that enhance the efficiency of feeding. Food-obtaining behavior, or foraging, includes not only eating, but also any mechanisms an animal uses to recognize, search for, and capture food items. Optimal foraging theory views foraging behavior as a compromise between the benefits of nutrition and the costs of obtaining food, such as the energy expenditure or the risk of being eaten by a predator while foraging. According to this theory, natural selection should favor foraging behavior that minimizes the costs of foraging and maximizes the benefits. Some behavioral ecologists are applying cost-benefit analysis to study the proximate and ultimate causes of diverse foraging strategies.

Energy Costs and Benefits

Reto Zach, of the University of British Columbia, conducted a cost-benefit analysis of feeding behavior in crows of the Pacific Northwest. Northwestern crows (*Corvus caurinus*), like other crow species, are opportunistic feeders that eat a variety of food items. On Mandarte Island, off British Columbia, crows search the rocky tide pools for gastropod molluscs called whelks. A bird grasps a whelk in its beak, then flies upward and drops it onto the rocks to break the shell. If the drop is successful, the crow can dine on the mollusc's soft parts. If the shell doesn't break, the crow flies up and drops the whelk again and again until the shell breaks. The higher the bird flies before dropping a whelk, the fewer drops are required to break the shell. But there is an energy cost correlated with the height of the crows' ascent. Zach predicted that crows would, on average, fly to a height that would provide the most food relative to the amount of total energy required to break the whelk shells.

To determine the optimal height, Zach erected a 15-m pole and then dropped shells of relatively uniform size onto rocks from different heights along the pole. He recorded the number of drops required to break a shell from each height and multiplied it by the drop height to arrive at the *total flight height*. He then calculated the *average total height* required to break shells as the average number of drops from a particular height times the drop height. Zach's experiments indicated that a drop height of about 5 m is optimal, breaking the shells with the least total flight height—in other words, with the least amount of work. When Zach measured the actual average flight height for crows in their whelk-eating behavior, it was 5.23 m, very close to the prediction based on an optimal trade-off between energy gained (food) versus energy expended (Figure 51.22).

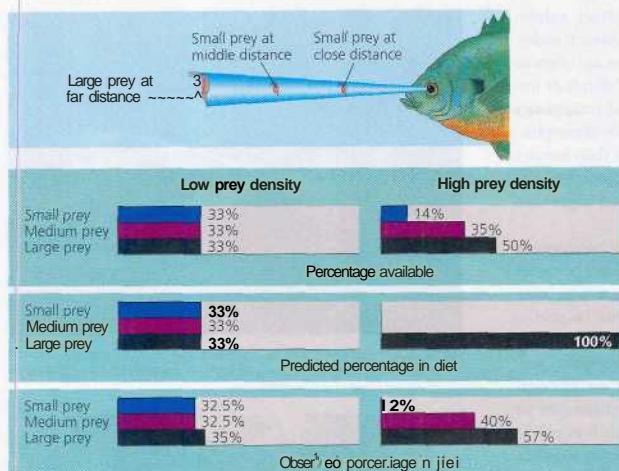

A Figure 51.22 Energy costs and benefits in foraging behavior. Experimental results indicate that dropping shells from a height of 5 m results in breakage with the least amount of work. The actual drop height preferred by crows corresponds almost exactly to the height that minimizes total flight height.

The feeding behavior of the bluegill sunfish provides further support for the optimal foraging theory. These animals feed on small crustaceans called *Daphnia*, generally selecting larger individuals, which supply the most energy per unit time. However, bluegill sunfish select smaller prey if larger prey are too far away. The optimal foraging theory predicts that the proportion of small prey to large prey eaten will also vary with the overall density of prey. When prey density is high, it is efficient to concentrate on larger crustaceans, whereas at very low prey densities, bluegill sunfish should exhibit little size selectivity, because all available prey are needed to meet energy requirements. In actual experiments, young bluegill sunfish did become more selective at higher prey densities, though not to the extent that would theoretically maximize their efficiency (Figure 51.23). Young bluegill sunfish forage fairly efficiently but not as close to the optimum as older individuals. It may be that younger fish judge size and distance less accurately because their vision is not yet completely developed; learning may also improve the foraging efficiency of bluegill sunfish as they age.

Though crows and bluegill sunfish provide good examples of how energy costs and benefits affect an animal's choice of food items, the following example shows that energy is not the only cost of foraging behavior.

Risk of Predation

One of the most significant potential costs to a forager is risk of predation. Clearly, an animal that feeds in a way that maximizes energy benefits and minimizes energy costs without regard to its

K> Figure 51.23 Feeding by bluegill sunfish. In feeding on *Daphnia* (water fleas), the fish do not feed randomly but select prey based on both size and distance, tending to pursue prey that looks largest. Small prey (low energy yield) at the middle distance may be ignored. But small prey at close distances may be taken with a relatively small energy expenditure. In the experiments described here, when prey was at low density, young bluegill foraged nonselectively, as predicted by optimal foraging theory.

risk of becoming a meal for some predator has not optimized its foraging behavior. Researchers have investigated the influence of predation risk on foraging behavior for a number of species, including the mule deer (*Odocoileus hemionus*). A major predator of mule deer throughout their range in the mountainous regions of western North America is the mountain lion (*Puma concolor*). A team of researchers from several institutions studied populations of mule deer in Idaho to determine if the mule deer forage in a way that reduces their risk of falling prey to mountain lions. The team investigated how food availability and risk of predation varied across the study landscape, which consisted of both patches of forest and open, nonforested areas. The researchers found that the food available to mule deer was fairly uniform across the potential foraging areas, though somewhat lower in open areas. In contrast, risk of predation differed greatly; mountain lions killed most mule deer at forest edges and only a small number in open areas and forest interiors (Figure 51.24).

How does mule deer feeding behavior respond to the dramatic differences in predation risk in different foraging areas? The researchers found that the mule deer in their study area feed predominantly in open areas, avoiding both forest edges and forest interiors (see Figure 51.24). In addition, when deer are at Forest edges, they spend significantly more time scanning their surroundings than when they are in either open areas or forest interiors. The evidence indicates that mule deer foraging

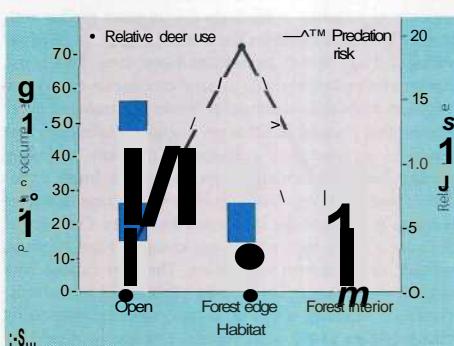

behavior reflects variation in predation risk more than variation in food availability. This result, like the results of the bluegill sunfish study, underscores the fact that behavior often reflects a compromise among competing selective pressures.

Mating Behavior and Mate Choice

Mating behavior, which includes seeking or attracting mates, choosing among potential mates, and competing for mates, is the product of a form of natural selection called sexual selection (see Chapter 23). How mating behavior enhances reproductive success varies, depending on the species' mating system.

Mating Systems and Parental Care

The mating relationship between males and females varies a great deal from species to species. In many species, mating is promiscuous, with no strong pair-bonds or lasting relationships. In species in which the mates remain together for a longer period, the relationship may be monogamous (one male mating with one female) or polygamous (an individual of one sex mating with several of the other). Polygamous relationships most often involve a single male and many females,

A Figure 51.24 Risk of predation and use of foraging areas by mule deer. Optimal foraging theory predicts that prey will forage in a way that minimizes the risk of predation. The risk of predation by mountain lions is lowest in open areas and forest interiors and highest at forest edges. Mule deer feed preferentially in open areas, avoiding both forest edges and interiors.

a system called polygyny, though some species exhibit polyandry, in which a single female mates with several males. Among monogamous species, males and females are often so much alike morphologically that they may be difficult or impossible to distinguish based on external characteristics (**Figure 51.25a**). Potygynous species are generally dimorphic, with males being more showy and often larger than females (**Figure 51.25b**). Polyandrous species are also dimorphic, but in this case, females are generally ornamented and larger than males (**Figure 51.25c**).

The needs of the young are an important factor constraining the evolution of mating systems. Most newly hatched birds, for instance, cannot care for themselves and require a large, continuous food supply that a single parent may not be able to provide. In such cases, a male may ultimately leave more viable offspring by helping a single mate than by going off to seek more mates. This may explain why most birds are monogamous. In contrast, birds with young that can feed and care for themselves almost immediately after hatching, such as pheasants and quail, have less need for their parents to stay together. Males of such species can maximize their reproductive success by seeking other mates, and polygyny is relatively common in such birds. In the case of mammals, the lactating female is often the only food source for the young; males usually play no role in raising the young. In mammalian species where males protect the females and young, such as lions, a male or small group of males typically takes care of many females at once in a harem.

Another factor influencing mating behavior and parental care is certainty of paternity. Young born or eggs laid definitely contain the mother's genes. But even within a normally monogamous relationship, these young may have been fathered by a male other than the female's usual mate. The certainty of paternity is relatively low in most species with internal fertilization because the acts of mating and birth (or mating and egg laying) are separated over time. This could explain why exclusively male parental care occurs in very few species of birds and mammals. However, the males of many species with internal fertilization engage in behaviors that appear to increase their certainty of paternity, including guarding females, removing any sperm from the female reproductive tract before copulation, and introducing large quantities of sperm to displace the sperm of other mates. Certainty of paternity is much higher when egg laying and mating occur together, as in external fertilization. This may explain why parental care in aquatic invertebrates, fishes, and amphibians, when it occurs at all, is at least as likely to be by males as by females (**Figure 51.26**). Male parental care occurs in only 7% of fish and amphibian families with internal fertilization, but in 69% of families with external fertilization. In fishes, even when parental care is provided exclusively by males, the mating system is often polygynous, with several females laying eggs in a nest tended by one male.

(a) Since monogamous species, such as these trumpeter swans, are often monomorphic, males and females are difficult to distinguish using external characteristics only.

(b) Among polygynous species, such as elk, the male (left) is often highly ornamented.

(c) In polyandrous species, such as these Wilson's phalaropes, females (top) are generally more ornamented than males.

& **Figure 51.25 Relationship between mating system and male and female forms.**

Figure 51.26 Paternal care by a male jawfish. Male jawfish, which live in tropical marine environments, hold the eggs they have fertilized in their mouths, keeping them aerated and protecting them from egg predators until the young hatch.

It is important to point out that when behavioral ecologists use the expression *certainty of paternity*, they do not mean that animals are aware of those factors when they behave a certain way. Parental behavior correlated with certainty of paternity exists because it has been reinforced over generations by natural selection. The relationship between certainty of paternity and male parental care remains an area of active research, enlivened by controversy.

Sexual Selection and Mate Choice

As you read in Chapter 23, the degree of sexual dimorphism within a species results from sexual selection, a form of natural selection in which differences in reproductive success among individuals are a consequence of differences in mating success. Recall from that chapter that sexual selection can take the form of *intersexual selection*, in which members of one sex choose mates on the basis of particular characteristics of the other sex, such as courtship songs, or *intrasexual selection*, which involves competition among members of one sex for mates. Let's look next at some experimental evidence for sexual selection.

Mate Choice by Females. Mate preferences by females may play a central role in the evolution of male behavior and anatomy through intersexual selection. Klaudia Witte and Nadia Sawka, of the University of Bielefeld, Germany, used experiments to test whether imprinting by young zebra finches on their parents may influence their choice of mates when they mature. Male zebra finches are more ornate than females, though neither have crests on their heads (Figure 51.27). Witte and Sawka taped a 2.5-cm-long red feather to the forehead feathers of both male and female parents, to the male parent only, or to the female parent only when the chicks were

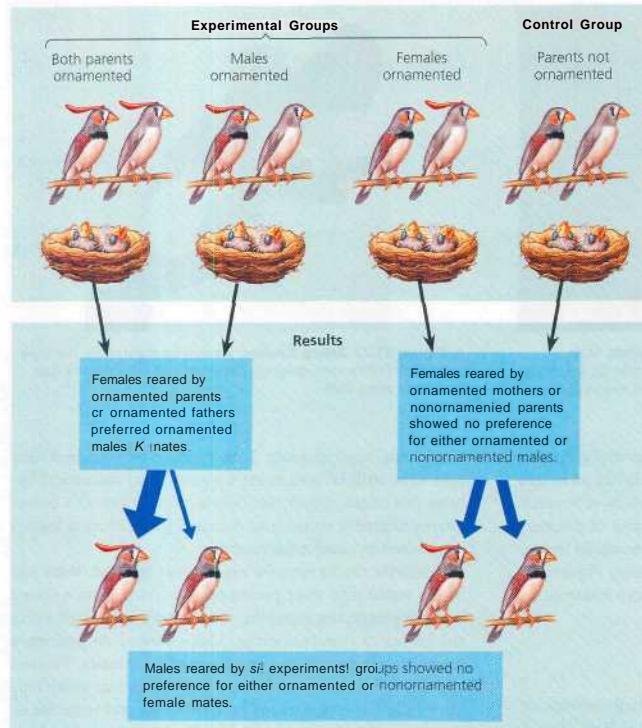

A Figure 51.27 Zebra finches, native to Australia. The male zebra finch (left) is more strikingly patterned and more colorful than the female zebra finch.

8 days old, approximately 2 days before they opened their eyes. (The artificial ornaments represent novel anatomical features that might appear naturally in populations as a consequence of genetic mutations.) A control group of zebra finches were raised by unadorned parents.

When the chicks from the experiments matured, Witte and Sawka tested their mate preferences by giving them a choice between prospective mates that were either ornamented with a red feather or nonornamented. Males showed no preference for either ornamented or nonornamented females. Females raised by nonornamented parents or by parents in which only the female was ornamented also showed no preference for either ornamented or nonornamented males (Figure 51.28, on the next page). However, females raised by parents that were both ornamented or by a pair in which the male was ornamented preferred ornamented males as their own mates. These experiments suggest that the females imprint on their fathers rather than on their mothers and that mate choice by female zebra finches has played a key role in the evolution of ornamentation in male zebra finches.

As another example of how female choice affects the evolution of males, consider the courtship behavior of stalk-eyed flies. The eyes of these insects are at the tips of stalks, which are longer in males than in females (Figure 51.29, on the next page). During courtship, a male presents himself to a female, front end on. Researchers have documented that females are more likely to mate with those males that have relatively long eyestalks; thus, female choice has been a strong selection factor in the evolution of long eyestalks in males. But why would the females favor this seemingly arbitrary trait? Behavioral ecologists have correlated certain genetic disorders in the male flies with an inability to develop long eyestalks. Such studies support the hypothesis that females are basing their mate choices on characteristics that correlate with male quality. As

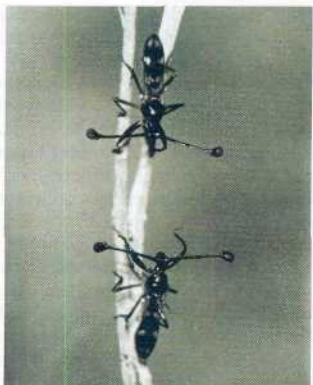

A Figure 51.28 Sexual selection influenced by imprinting. Experiments demonstrated that female zebra finch chicks that had imprinted on artificially ornamented fathers preferred ornamented males as adults.

we discussed in Chapter 23, in general, ornaments such as long eye stalks in these flies or brightly colored feathers in male birds correlate with the males' health and vitality. A female that chooses a healthy male increases the probability of producing healthy offspring.

Male Competition for Mates. The previous examples show how female choice can select for one best type of male in a given situation, resulting in low variation among males. Male competition for mates is a source of intrasexual selection that also can reduce variation among males. Such competition may involve agonistic behavior, an often ritualized contest that determines which competitor gains access to a resource, such as food or mates (Figure 51.30). The outcome of such contests may be determined by strength, size, or the form of horns, teeth, and so forth, but the victories may be psychological rather than physical. Despite the potential for such competition to select for reduced variation, male behavioral and morphological variation is extremely high in some vertebrate species ranging from fish to deer and in a wide variety of invertebrates. In some species, more than one mating behavior can result in successful reproduction; in these cases, intrasexual selection has led to the evolution of alternative male mating behavior and morphology.

One invertebrate in which alternative male mating behaviors and morphology have been well documented is the marine intertidal isopod *Paracerceis sculpta*, which lives within sponges in the Gulf of California. This species includes three genetically distinct male types (Figure 51.31). Stephen M. Shuster, of the University of New Mexico, discovered that large males defend harems of females within intertidal sponges, mainly against other males. Meanwhile, (3) males mimic female morphology and behavior and do not elicit a defensive response in a male; thus, they are able to gain access to guarded harems. Tiny 7 males invade and live within large harems, which can be inhabited by all three types of males at the same time.

Shuster reported that the mating success of each type of *Paracerceis* male depends on the relative densities of males and females within sponges. The large males father the majority of young when defending a single female. If more than one

• Figure 51.29 Male stalk-eyed flies.

female is present, 3 males sire approximately 60% of the offspring. Finally, the reproductive rate of 7 males increases linearly with harem size. Using this information and the patterns of distribution of *Paracercis* females and males in their natural environment, Shuster and Michael Wade, of the University of Chicago, concluded that a, p, and 7 males have

A Figure 51.30 Agonistic behavior. These two male polar bears (*Ursus maritimus*) are engaging in "play-fighting," ritualized contests that usually do not injure the bears. By contrast, during the spring breeding season, male polar bears fight fiercely as they compete for access to females in estrus.

A Figure 51.31 Male polymorphism in the marine intertidal isopod *Paracerceis sculpta*. Different morphology affects the mating behavior of three genetically different types.

approximately equal mating success, indicating that a diversity of mating behavior and anatomy can result from intrasexual selection due to male competition for mates. Variation among males in this species is sustained, since none of the three male types is most successful in all circumstances; each type of male has high mating success at some female densities but reduced mating success at other female densities (an example of balanced polymorphism, which we discussed in Chapter 23).

Applying Game Theory

The three types of *Paracercis* males discovered by Shuster can coexist because they have equal mating success, which likely gives them equal evolutionary fitness. However, in some other species, the fitness of different types of males appears to be unequal. How can alternative reproductive strategies exist in such a situation? Why doesn't natural selection favor one strategy to the exclusion of the others? In studying this question, behavioral ecologists use a range of tools, including game theory. Originally developed by John Nash and other mathematicians to model human economic behavior, game theory evaluates alternative strategies in situations where the outcome depends not only on each individual's strategy but also on the strategies of other individuals. Currently applied to a wide variety of problems in behavioral ecology, game theory is a way of thinking about evolution in situations where the fitness of a particular behavioral phenotype is influenced by other behavioral phenotypes in the population.

Barry Sinervo and Curt Lively, of Indiana University, used game theory to account for the coexistence of three different male phenotypes in populations of the side-blotched lizard (*Uta stansburiana*) in the inner Coast Ranges of California (Figure 51.32). Sinervo and Lively identified males with three different types of genetically controlled coloration: orange throats, blue throats, and yellow throats. Orange-throat males are the most aggressive and defend large territories that contain many females. Blue-throat males are also territorial but defend smaller territories and fewer females. Yellow-throats

A Figure 51.32 Male polymorphism in the side-blotched lizard (*Uta stansburiana*). An orange-throat male, left; a blue-throat male, center; a yellow-throat male, right.

are nonterritorial males that mimic females and use "sneaky" tactics to obtain matings. Sinervo and Lively found that the three types go through cycles of relative abundance; over a period of several years, their study population went from high frequency of blue-throats to high frequency of orange-throats to high frequency of yellow-throats and finally back to high frequency of blue-throats.

Sinervo and Lively connected their study population to game theory when they realized that the relative mating success of each male type is not fixed but changes with the relative abundance of the other male types in the populations. Sinervo and Lively suggested that the cycling of male abundance in side-blotched lizards is like the children's game of paper-rock-scissors, in which paper defeats rock, rock defeats scissors, and scissors defeats paper. When blue-throats are abundant, they can successfully defend the few females in their territories from the advances of the sneaky yellow-throat males; in terms of the game, blue-throats "defeat" yellow-throats. However, blue-throat males cannot defend their territories against the hyperaggressive orange-throat males. As a consequence, orange-throat males take over blue-throat territories and increase in abundance; orange-throats "defeat" blue throats. But the numerical dominance by orange-throat males is temporary, since they cannot defend all the females in their large territories from the sneaky yellow-throat males. So eventually orange-throat males, the most aggressive males, are replaced as the most numerous by yellow-throat males, the least aggressive males; yellow-throats "defeat" orange-throats. And then the cycle begins again; Since the blue-throat tactics of guarding small territories and few females can restrict yellow-throat access to females, blue-throat males soon replace yellow-throats as the most abundant males. Game theory gives behavioral ecologists a way to think about complex evolutionary problems in which relative performance, not absolute performance, is the key to understanding the evolution of behavior. This makes game theory an important tool, since the relative performance of one phenotype compared to others is how evolutionary⁷ biologists assess Darwinian fitness.

Concept 51.6

The concept of inclusive fitness can account for most altruistic social behavior

Many social behaviors are selfish, meaning that they benefit the individual at the expense of others, especially competitors. Even in species in which individuals do not engage in agonistic behavior, most adaptations that benefit one individual will indirectly harm others. For example, superior foraging ability by one individual may leave less food for others. It is easy to understand the pervasive nature of selfishness if natural selection shapes behavior. Behavior that maximizes an individual's survival and reproductive success is favored by selection, regardless of how much damage such behavior does to another individual, a local population, or even an entire species. How, then, can we explain observed examples of what appears to be "unselfish" behavior?

Altruism

On occasion, some animals do behave in ways that reduce their individual fitness but increase the fitness of other individuals in the population; this is our functional definition of altruism, or selflessness. Consider the Belding's ground squirrel, which lives in some mountainous regions of the western United States and is vulnerable to predators such as coyotes and hawks. If a squirrel sees a predator approach, the squirrel often gives a high-pitched alarm call, which alerts unaware individuals, who then retreat to their burrows. Field observations have confirmed that the conspicuous alarm behavior increases the risk of being killed, because it brings attention to the caller's location.

Another example of altruistic behavior occurs in bee societies, in which the workers are sterile. The workers themselves never reproduce, but they labor on behalf of a single fertile queen. Furthermore, the workers sting intruders, a behavior that helps defend the hive but results in the death of those workers.

Still another example of altruism is seen in naked mole rats (*Heterocephalus glaber*), highly social rodents that live in underground chambers and tunnels in southern and northeastern Africa (Figure 51.33). The naked mole rat, which is almost hairless and nearly blind, lives in colonies of 75 to 250 or more individuals. Each colony has only one reproducing female, the queen, who mates with one to three males, called kings. The rest of the colony consists of nonreproductive females and males who forage for underground roots and tubers and care for the queen, the kings, and new offspring still dependent on the queen. The nonreproductive individuals may sacrifice their own lives in trying to protect the queen or kings from snakes or other predators that invade the colony.

Concept Check 51.5

1. Why is male parental care more likely to evolve among species with external fertilization than among species with internal fertilization?
2. How does optimal foraging theory explain why mule deer spend more time foraging in open areas than near or in forests?
3. How is a female bird's fitness associated with her ability to choose a mate by discerning among displays and adornments that "advertise" the health of the male?

For suggested answers, see Appendix A.

Figure 51.33 Naked mole rats, a species of colonial mammal that exhibits altruistic behavior. Pictured here is a queen nursing offspring while surrounded by other members of the colony.

Iclusive Fitness

How can a naked mole rat, a worker bee, or a Belding's ground squirrel enhance its fitness by aiding other members of the population, which may be its closest competitors? How can altruistic behavior be maintained by evolution if it does not enhance—and in fact may even reduce—the survival and reproductive success of the self-sacrificing individuals? It is easiest to see how such behavior might be selected for when it applies to parents sacrificing for offspring. When parents sacrifice their own personal well-being to produce and aid offspring, this actually increases the fitness of the parents, because it maximizes their genetic representation in the population.

But individuals sometimes help others who are not their offspring. Like parents and offspring, siblings have half their genes in common. Therefore, selection might also favor helping siblings or helping one's parents produce more offspring. Evolutionary biologist William Hamilton was the first to realize that selection could result in an animal's increasing its genetic representation in the next generation by "altruistically" helping close relatives other than its own offspring. This realization led to the concept of inclusive fitness, the total effect an individual has on proliferating its genes by producing its own offspring *and* by providing aid that enables other close relatives, who share many of those genes, to produce offspring.

Hamilton's Rule and Kin Selection

Hamilton proposed a quantitative measure for predicting when natural selection would favor altruistic acts among related individuals. The three key variables in an act of altruism are the benefit to the recipient (B), the cost to the altruist (C), and the coefficient of relatedness (r). The benefit and cost measure the change in the average number of offspring produced by the recipient and altruist, respectively, resulting from the altruistic act. Thus, B , the benefit, is the average number of extra offspring that the beneficiary of an altruistic act produces; and C , the cost, is how many fewer offspring the altruist

produces. Suppose, for example, that members of a human population average two children each. Now consider two brothers who are close in age, reproductively mature, equally fertile, but not yet fathers. One of these young men is close to drowning in heavy surf, and his brother risks his own life to swim out and pull his sibling to safety. The benefit to the almost-drowned brother, the recipient of this altruistic act, is two offspring. Had he drowned, his reproductive output would have been zero; but now, if we use the average, he can father two children: $B = 2.0$. The cost to the heroic brother depends on the risk to his own life in saving his sibling. Let's say that in this kind of surf, an average swimmer has a 5% chance of drowning. Thus, the cost of the altruistic act is 5% of the number of offspring we would expect if the altruist had not taken the risky plunge. The cost is $0.05 \times 2 = 0.1$.

We now know that $B = 2.0$ and $C = 0.1$ for this hypothetical act of altruism, but what about r ? The coefficient of relatedness equals the probability that if two individuals share a common parent or ancestor, a particular gene present in one individual will also be present in the second individual. With two siblings, such as our imaginary brothers at the beach, there is a 50% chance that any gene in one brother will also be present in the other brother. Thus, for siblings, $r = 0.5$. One way to see this is in terms of the segregation of homologous chromosomes that occurs during meiosis of gametes (Figure 51.34; also see Chapter 13).

We can now use values of B , C , and r to evaluate whether natural selection would favor the altruistic act in our imaginary scenario. Natural selection favors altruism when the

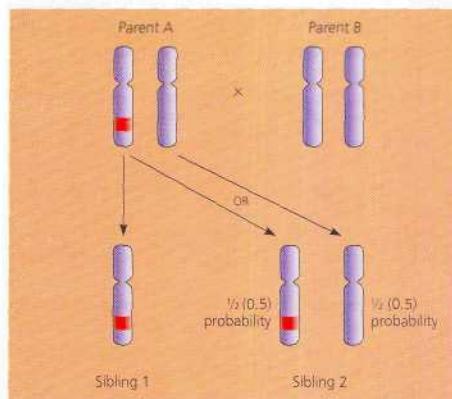

Figure 51.34 The coefficient of relatedness between siblings. The red band indicates a particular gene on a chromosome of a homologous chromosome pair in one parent. Sibling 1 has inherited the gene from parent A. There is a probability of V ; that sibling 2 will also inherit this gene from parent A. The coefficient of relatedness between the two siblings is thus V^2 , or 0.5.

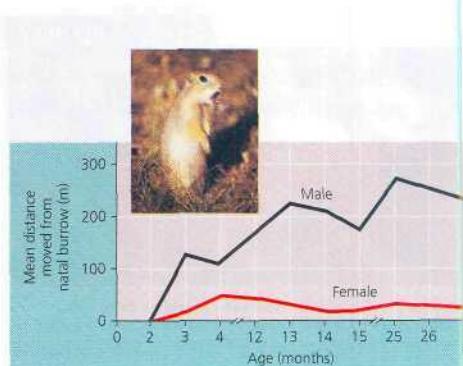

benefit to the recipient multiplied by the coefficient of relatedness exceeds the cost to the altruist—in other words, when $rB > C$. This inequality is called Hamilton's rule. For our swimming brothers, $rB = 0.5 \times 2 = 1$ and $C = 0.1$. This satisfies Hamilton's rule; thus, natural selection would favor this altruistic act of one brother saving another. Any particular gene in the altruist will, on average, be passed on to more offspring if that brother risks the rescue than if he does not. (And among those genes may be some that actually contribute to altruistic behavior, so these genes, too, are propagated.) The natural selection that favors this kind of altruistic behavior by enhancing reproductive success of relatives is called kin selection.

Kin selection weakens with hereditary distance. Siblings have an r of 0.5, but between an aunt and her niece, $r = 0.25$ (QA), and between first cousins, $r = 0.125$ (Vs). Notice that as the degree of relatedness decreases, the rB term in the Hamilton inequality also decreases. Would natural selection favor our strong swimmer rescuing his cousin? For this altruistic act, $rB = 0.125 \times 2 = 0.25$, which, luckily for the drowning cousin, is still much greater than $C = 0.1$, the cost to the altruist. Of course, the degree of risk the altruist takes comes into play, too. If the potential rescuer is a poor swimmer, he may have a 50% chance of drowning instead of the 5% chance for a strong swimmer. In this case, the cost to the altruist would be $0.5 \times 2 = 1$. That's greater than the rB of 0.25 we calculated for the drowning cousin, who'd better hope a life-guard is near.

The British geneticist J. B. S. Haldane anticipated the concepts of inclusive fitness and kin selection by jokingly saying that he would lay down his life for two brothers or eight cousins. In today's terms, we would say that he would do this because either two brothers or eight cousins would result in as much representation of Haldane's genes as would two of his own offspring.

If kin selection explains altruism, then the examples of unselfish behavior we observe among diverse animal species should involve close relatives. This is in fact the case, but often in complex ways. Like most mammals, female Belding's ground squirrels settle close to their site of birth, whereas males settle at distant sites. Since nearly all alarm calls are given by females (Figure 51.35), they are most likely aiding close relatives. If all of a female's close relatives are dead, she rarely gives alarm calls. In the case of worker bees, who are all sterile, anything they do to help the entire hive benefits the only permanent member who is reproductively active—the queen, who is their mother.

In the case of naked mole rats, DNA analyses have shown that all the individuals in a colony are closely related. Genetically, the queen appears to be a sibling, daughter, or mother of the kings, and the nonreproductive rats are the queen's direct descendants or her siblings. Hence, when a nonreproductive individual enhances a queen's or king's chances of reproducing, it increases the chances that some genes identical to its own will be passed to the next generation.

A Figure 51.35 Kin selection and altruism in Belding's ground squirrels. This graph helps explain the male-female difference in altruistic behavior of ground squirrels. After they are weaned, females are more likely than males to live near close relatives. Alarm calls that warn these relatives increase the inclusive fitness of the female altruist.

Reciprocal Altruism

Some animals occasionally behave altruistically toward others who are not relatives. A baboon may help an unrelated companion in a fight, or a wolf may offer food to another wolf even though they share no kinship. Such behavior can be adaptive if the aided individual returns the favor in the future. This sort of exchange of aid, called reciprocal altruism, is commonly invoked to explain altruism between unrelated humans. Reciprocal altruism is rare in other animals; it is limited largely to species (such as chimpanzees) with social groups stable enough that individuals have many chances to exchange aid. It is generally thought to be most likely where individuals are likely to meet again and where there would be negative consequences associated with not returning favors to individuals who had been helpful in the past, a pattern of behavior that behavioral ecologists refer to as "cheating." It is likely that all behavior that seems altruistic actually has at least the potential to increase fitness in some way.

However, because cheating may provide a large benefit to the cheater, behavioral ecologists have questioned how reciprocal altruism could evolve. To find answers to this question, many behavioral ecologists have turned to game theory. In 1981, Robert Axelrod and William Hamilton, then at the University of Michigan, proposed that reciprocal altruism can evolve and persist in a population where individuals adopt a behavioral strategy they called *tit-for-tat*. In the tit-for-tat strategy, an individual treats another in the same way it was treated the last time they met. Individuals adopting this behavior are always altruistic, or cooperative, on the first encounter with another individual and will remain so as long as their altruism is reciprocated. When their cooperation is not reciprocated,

however individuals employing tit-for-tat will retaliate immediately but return to cooperative behavior as soon as the other individual becomes cooperative. The tit-for-tat strategy has been used to explain the few apparently reciprocal altruistic interactions observed in animals—ranging from blood sharing between nonrelated vampire bats to social grooming in primates.

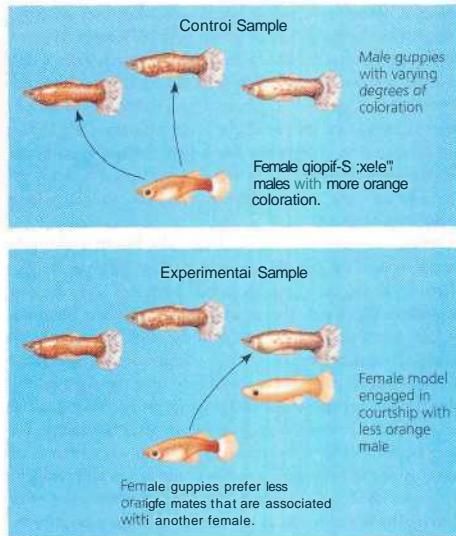

Social Learning

When we discussed learning earlier in this chapter, we focused largely on the genetic and environmental influences that lead animals to acquire new behaviors. Learning can also have a significant social component, as seen in **social learning**, which is learning through observing others (see Figure 51.17). Social learning forms the roots of **culture**, which can be defined as a system of information transfer through social learning or teaching that influences the behavior of individuals in a population. Cultural transfer of information has the potential to alter behavioral phenotypes and, in turn, to influence the fitness of individuals. Culturally based changes in the phenotype occur on a much shorter time scale than changes resulting from natural selection. Because we recognize social learning most easily in humans, we may take the process for granted or assume that social learning occurs only in humans. However, social learning can be seen among lineages of animals that diverged from ours very long ago, some of which we describe next.

Mate Choice Copying

We have seen how female mate choice can lead to intersexual selection for elaborate male ornamentation (see Figure 51.28). In many species, mate choice is strongly influenced by social learning.

Mate choice copying, a behavior in which individuals in a population copy the mate choice of others, has been extensively studied in the guppy *Poecilia reticulata*. Female wild guppies generally prefer to mate with males showing a high percentage of orange coloration. However, they are also known to copy the mate choices of other females. In other words, female guppies appear to mate with males that have been successful in attracting other females. With this background in mind, Lee Dugatkin, of the University of Louisville, designed an ingenious experiment to compare the influences of male phenotype and social learning on mate choice by female guppies. He gave female guppies a choice of mating with males with varying degrees of orange coloration. In the control samples, a female chose between males with no other females present. In the experimental treatments, males with the same range of orange coloration as the control males were present, but the experimental female also observed a model of a female engaging in courtship with a male with relatively little orange. In the control samples, females overwhelmingly chose males with higher percentages of orange

A Figure 51.36 Mate choice copying by female guppies (*Poecilia reticulata*). Female guppies generally choose the males with more orange coloration. However, when males were matched for orange or differed in amount of orange by 12% or 24%, experimental females chose the less orange male that had been presented with a model female. Females ignored the apparent choice of the model female only where the alternative male had 40% more orange coloration.

coloration (Figure 51.36). However, experimental females in most cases chose the less orange male that had been presented in association with a model female, choosing a male not associated with a model female only when he had a *much* higher percentage of orange coloration. Dugatkin concluded that below a certain threshold of difference in male color, mate choice copying by female guppies can mask genetically controlled female preference for orange males. A female that mates with males that are attractive to other females may increase the probability that her male offspring will also be attractive and have high reproductive success. Mate choice copying, one form of social learning, has also been observed in several other fish and bird species.

Social Learning of Alarm Calls

In their studies of vervet monkeys (*Cercopithecus aethiops*) in Amboseli National Park, Kenya, Dorothy Cheney and Richard Seyfarth, of the University of Pennsylvania, determined that performance of a behavior by the vervets could improve through learning. Vervet monkeys, which are about the size of a domestic cat, produce a complex set of alarm calls. The

Amboseli vervets give distinct alarm calls when they see leopards, eagles, or snakes, all of which prey on vervets. When a vulture sees a leopard, it gives a loud barking sound; when it sees an eagle, it gives a short double-syllabled cough; and the snake alarm call is a "chatter." Upon hearing a particular alarm call, other vervets in the group behave in an appropriate way: They run up a tree on hearing the alarm for a leopard (ververts are nimbler than leopards in the trees); look up on hearing the alarm for an eagle; and look down on hearing the alarm for a snake (Figure 51.37).

Infant vulturine monkeys give alarm calls, but in a relatively undiscriminating way. For example, they give the "eagle" alarm on seeing any bird, including harmless birds such as bee-eaters. With age, the monkeys improve their accuracy. In fact, adult vulturine monkeys give the eagle alarm only on seeing an eagle belonging to either of the two species that eat vervets. Infants probably learn how to give the right call by observing other members of the group and receiving social confirmation. For instance, if the infant gives the call on the right occasion—for instance, an eagle alarm when there is an eagle overhead—another member of the group will also give the eagle call. But if the infant gives the call when a bee-eater flies by, the adults in the group are silent. Thus, vulturine monkeys have an initial, unlearned tendency to give calls on seeing potentially threatening objects in the environment. Learning fine-tunes the call so that by adulthood, vervets give calls only in response to genuine danger and are prepared to fine-tune the alarm calls of the next generation. However, neither vervets nor any other species comes close to matching the social learning and cultural transmission that occurs among humans (Figure 51.38).

A Figure 51.37 Vervet monkeys learning correct use of alarm calls. On seeing a python (foreground), vulturine monkeys give a distinct "snake" alarm call (inset), and the members of the group stand upright and look down.

M Figure 51.38 Both genes and culture build human nature. Teaching of a younger generation by an older generation is one of the basic ways in which all cultures are transmitted.

Evolution and Human Culture

Human culture is related to evolutionary theory in the discipline of sociobiology, whose main premise is that certain behavioral characteristics exist because they are expressions of genes that have been perpetuated by natural selection. In his seminal 1975 book *Sociobiology: The New Synthesis*, E. O. Wilson speculated about the evolutionary basis of certain kinds of social behavior mainly in nonhuman animals, but also including human culture, sparking a debate that remains heated today.

The spectrum of possible human social behaviors may be influenced by our genetic makeup, but this is very different from saying that genes are rigid determinants of behavior. This distinction is at the core of the debate about evolutionary perspectives on human behavior. Skeptics fear that evolutionary interpretations of human behavior could be used to justify the status quo in human society, thus rationalizing current social injustices. Evolutionary biologists argue that this is a gross oversimplification and misunderstanding of what the data tell us about human biology. Evolutionary explanations of human behavior do not reduce us to robots stamped out of rigid genetic molds. Just as individuals vary extensively in anatomical features, we should expect inherent variations in behavior as well. Environment intervenes in the pathway from genotype to phenotype for physical traits and even more so for behavioral traits. And because of our capacity for learning and versatility, human behavior is probably more plastic than that of any other animal. Over our recent evolutionary history, we have built up a diversity of structured societies with governments, laws, cultural values, and religions that define what is acceptable behavior and what is not, even when unacceptable behavior might enhance an individual's Darwinian fitness.

And yet we read in the media about newly discovered genes for complex human behavioral traits, such as depression, violence, or alcoholism. Doesn't this reinforce the idea that our behavior is, in fact, "hardwired"? According to Robert Plomin, director of the Center for Developmental and Health Genetics at Pennsylvania State University, research into the heritability of behavior is the best demonstration of the importance of environment. As Plomin puts it, genes and nongenetic, environmental factors "build on each other." For instance, it might seem that the human ability to speak is completely genetic. However, the ability to learn a specific language, such as English or Spanish, is a function of a complex brain that develops in a particular environmental context under the guidance of a human genome and with the aid of social learning. If the behavior of humans, like that of other species, is the result of interactions between genes and environment, what is unique about our species? Perhaps it is our

social and cultural institutions that make us truly unique and that provide the only feature in which there is no continuum between humans and other animals.

Concept Check 51.6

- What is the ultimate cause for altruistic behavior among kin?
- What hypothesis could explain cooperative behavior among nonrelated animals? Explain.
- Could the changes in behavior produced by cross-fostering of white-footed mice and California mice (described in Concept 51.3) extend beyond one generation? Explain.

For suggested answers, see Appendix A.

Chapter 51 Review

SUMMARY OF KEY CONCEPTS

Concept 51.1

Behavioral ecologists distinguish between proximate and ultimate causes of behavior

K **What Is Behavior?** (p. 1107) Behavior, which includes muscular as well as nonmuscular activity, is everything that an animal does and how it does it. Learning is also generally considered a behavioral process.

I* **Proximate and Ultimate Questions** (p. 1107) Proximate, or "how," questions focus on the environmental stimuli, if any, that trigger a behavior, as well as the genetic, physiological, and anatomical mechanisms underlying a behavioral act. Ultimate, or "why," questions address the evolutionary significance of a behavior.

E* **Ethology** (pp. 1107–1109) Ethology is the scientific study of animal behavior, particularly in natural environments. The mid-20th-century ethologists developed a conceptual framework defined by a set of questions that highlight the complementary nature of proximate and "ultimate" perspectives.

Investigation How Can Pill Bug Responses to Environments Be Tested?

Concept 51.2

Many behaviors have a strong genetic component

• Biologists study the ways both genes and the environment influence the development of behavioral phenotypes (pp. 1109–1110).

A **Directed Movements** (pp. 1110–1111) Kinesis, a behavior involving a change in activity or turning rate, and taxis, an

oriented movement toward or away from some stimulus, are examples of innate behaviors that are under strong genetic influence. Experiments have demonstrated that bird migration is one complex behavior that is at least partly under genetic control.

• **Animal Signals and Communication** (pp. 1111–1112)

The transmission, reception of, and response to signals constitute animal communication. Animals communicate using visual, auditory, chemical (olfactory), tactile, and electrical signals.

Activity Honeybee Waggle Dance Video

• **Genetic Influences on Mating and Parental Behavior**

(pp. 1112–1113) A variety of mammalian behaviors are under relatively strong genetic control. For instance, research has revealed the genetic and neural basis for the mating and parental behavior of male prairie voles.

Concept 51.3

Environment, interacting with an animal's genetic makeup, influences the development of behaviors

• **Dietary Influence on Mate Choice Behavior** (pp. 1113–1114) Laboratory experiments have demonstrated that the type of food eaten during larval development strongly influences later mate selection by *Drosophila mojavensis* females.

• **Social Environment and Aggressive Behavior** (p. 1114)

Cross-fostering studies of California mice and white-footed mice have uncovered an influence of social environment on the aggressive and parental behaviors of these mice.

• **Learning** (pp. 1114–1118) Learning is the modification of behavior based on specific experiences. Types of learning include habituation, spatial learning, use of cognitive maps, and associative learning. Studies of cognition and problem solving are revealing levels of mental sophistication in animals ranging from insects and birds to primates. Environment and genetics can interact in influencing the learning process.

Concept 51.4

Behavioral traits can evolve by natural selection

- **Behavioral Variation in Natural Populations** (pp. 1118-1120) When behavioral variation within a species corresponds to variation in environmental conditions, it may be evidence of past evolution.
- **Experimental Evidence for Behavioral Evolution** (pp. 1120-1121) Laboratory studies of *Drosophila* populations raised in high- and low-density conditions show a clear divergence in behavior linked to specific genes. Field and laboratory studies have documented a change in migratory behavior in western European blackcaps over a period of 40 years.

Concept 51.5

Natural selection favors behaviors that increase survival and reproductive success

- **Foraging Behavior** (pp. 1122-1123) Several studies provide support for optimal foraging theory, which posits that natural selection should favor foraging behavior that minimizes the costs of foraging and maximizes the benefits.
- **Mating Behavior and Mate Choice** (pp. 1123-1127) How mate choice enhances reproductive success varies, depending on the species' mating system. The mating relationship between males and females, which includes monogamous, polygynous, and polyandrous mating systems, varies a great deal from species to species. Certainty of paternity has a significant influence on mating behavior and parental care. Mate preferences by females may play a central role in the evolution of male behavior and anatomy through intersexual selection. Male competition for mates is a source of intrasexual selection that also can reduce variation among males. Intrasexual selection can lead to the evolution of alternative male mating behavior and morphology.
- **Applying Game Theory** (pp. 1127-1128) Applied to problems in behavioral ecology, game theory provides a way of thinking about evolution in situations where the fitness of a particular behavioral phenotype is influenced by other behavioral phenotypes in the population.

Concept 51.6

The concept of inclusive fitness can account for most altruistic social behavior

- **Altruism** (pp. 1128-1129) On occasion, animals behave in altruistic ways that reduce their individual fitness but increase the fitness of the recipient of the behavior.
- **Inclusive Fitness** (pp. 1128-1131) Altruistic behavior can be explained by the concept of inclusive fitness, the total effect an individual has on proliferating its genes by producing its own offspring and by providing aid that enables other close relatives to produce offspring. Kin selection favors altruistic behavior by enhancing the reproductive success of relatives. Altruistic behavior toward unrelated individuals can be adaptive if the aided individual returns the favor in the future, an exchange of aid called reciprocal altruism.
- **Social Learning** (pp. 1131-1132) Social learning forms the roots of culture, which can be defined as a system of information transfer through observation or teaching that influences the behavior of individuals in a population.
- **Evolution and Human Culture** (pp. 1132-1133) Human behavior, like that of other species, is the result of interactions between genes and environment. However, our social and cultural institutions may provide the only feature in which there is no continuum between humans and other animals.

TESTING YOUR KNOWLEDGE

Evolution Connection

In human affairs, we often explain our behavior in terms of subjective feelings, motives, or reasons; but evolutionary explanations for behavior are based on reproductive fitness. What is the relationship between the two kinds of explanation? For instance, is a human explanation for behavior, such as "falling in love," incompatible with an evolutionary explanation? Does falling in love become more meaningful or less meaningful (or neither) if it has an evolutionary basis?

Scientific Inquiry

Scientists studying scrub jays found that it is common for "helpers" to assist mated pairs of birds in raising their young. The helpers lack territories and mates of their own. Instead, they help the territory owner gather food for their offspring. Propose a hypothesis to explain what advantage there might be for the helpers to engage in this behavior instead of seeking their own territories and mates. How would you test your hypothesis? If your hypothesis is correct, what kind of results would you expect your tests to yield?

Investigation *How Can Pill Bug Responses to Environments Be Tested?*

Biological Inquiry: *A Workbook of Investigative Cases* Explore the behavior of a large gull population in a marina, and human attempts to control the population, in the case "Back to the Bay."

Science, Technology, and Society

Researchers are very interested in studying identical twins who were separated at birth and raised apart. So far, the data suggest that such twins are much more alike than researchers would have predicted; they frequently have similar personalities, mannerisms, habits, and interests. What general question do you think researchers hope to answer by studying twins that have been raised apart? Why do identical twins make good subjects for this kind of research? What are the potential pitfalls of this research? What abuses might occur if the studies are not evaluated critically and if the results are carelessly cited in support of a particular social agenda?

neither good nor bad

an individual's innate self-referencing tendencies, a bit enough to make it be aware only the positive traits are his/her own.

Another way to interpret a leader's self-referencing tendency is to view it as a kind of cognitive bias that can either help or hurt an organization's performance. In particular, research has shown that individuals who have strong self-referencing tendencies tend to perceive their own strengths more accurately than do others. This means that self-referencing leaders are more likely to identify their own strengths and weaknesses and to evaluate their performance more accurately than other leaders. Thus, self-referencing leaders tend to be more successful than other leaders. However, this pattern of behavior may also lead to overconfidence and complacency. For example, when leaders are less self-referencing, they tend to be more open to feedback from others and are more likely to make changes in their behavior based on that feedback. Thus, self-referencing leaders may be less effective than other leaders because they are less open to change and less willing to accept feedback from others.

Overall, self-referencing tendencies can be both positive and negative,

depending on how they are used. For example, if a leader uses self-referencing to focus on his/her own strengths, he/she may be more successful and less likely to make mistakes. However, if a leader uses self-referencing to focus on his/her own weaknesses, he/she may be less successful and more likely to make mistakes. Thus, the key to effective self-referencing is to use it in a balanced way, acknowledging both one's strengths and weaknesses, and using them to guide one's behavior and decision-making.

emotional intelligence

Emotional intelligence (EI) is a concept that has been developed in recent years to describe the ability to recognize and manage one's own emotions and those of others. EI is often seen as a key component of leadership effectiveness, as leaders who are emotionally intelligent are better able to connect with their followers and inspire them. EI is also important for managing conflicts and resolving disputes. In general, EI involves the ability to understand and regulate one's own emotions, as well as the emotions of others. EI includes the ability to recognize and manage one's own stress and anxiety, as well as the stress and anxiety of others. EI also involves the ability to recognize and manage one's own biases and prejudices, as well as the biases and prejudices of others. EI is a complex concept, but it is an essential part of effective leadership.

the power of positive thinking

Positive thinking is a concept that refers to the practice of focusing on the good things in life and avoiding negative thoughts and feelings. Positive thinking is often used as a tool for improving mental health and well-being, as well as for achieving success in various areas of life.

Positive thinking is based on the idea that our thoughts and beliefs about ourselves and the world around us can have a significant impact on our behavior and outcomes. For example, if we believe that we are capable of achieving our goals, we are more likely to work hard and persevere in the face of challenges. Conversely, if we believe that we are incapable of achieving our goals, we are more likely to give up easily and feel defeated.

Positive thinking is often used in conjunction with other techniques, such as goal setting and time management, to achieve specific goals. For example, if you want to lose weight, you might set a goal to eat healthier and exercise more, and then use positive thinking to stay motivated and focused on your goal.

Positive thinking is a powerful tool for achieving success, but it is important to remember that it is just one part of a larger picture. Other factors, such as hard work, persistence, and good luck, also play a role in achieving success.

In conclusion, positive thinking is a valuable tool for achieving success, but it is important to remember that it is just one part of a larger picture. Other factors, such as hard work, persistence, and good luck, also play a role in achieving success.

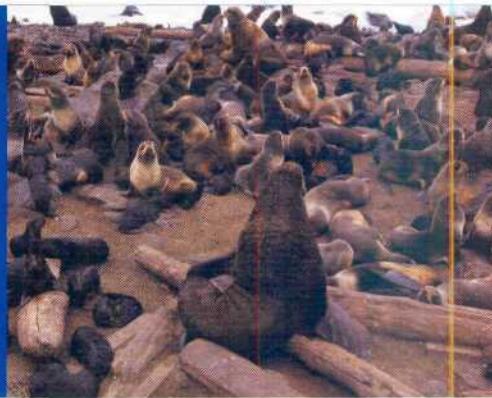

In conclusion, positive thinking is a valuable tool for achieving success, but it is important to remember that it is just one part of a larger picture. Other factors, such as hard work, persistence, and good luck, also play a role in achieving success.

Key Concepts

- 52.1 Dynamic biological processes influence population density, dispersion, and demography
- 52.2 Life history traits are products of natural selection
- 52.3 The exponential model describes population growth in an idealized, unlimited environment
- 52.4 The logistic growth model includes the concept of carrying capacity
- 52.5 Populations are regulated by a complex interaction of biotic and abiotic influences
- 52.6 Human population growth has slowed after centuries of exponential increase

Overview

Earth's Fluctuating Populations

The size of the human population and its impact are now among Earth's most significant problems. With a population of more than 6 billion individuals¹, our species requires vast amounts of materials and space, including places to live, land to grow our food, and places to dump our waste. By rapidly expanding our presence on Earth, we have devastated the environment for many other species and now threaten to make it unfit for ourselves.

To understand human population growth, we must consider the general principles of population ecology. No population, including the human population, can continue to grow indefinitely. Though many species exhibit population explosions, their numbers inevitably decline. In contrast to such

radical booms and busts, other populations are relatively stable over time, with only minor changes in size.

Our earlier study of populations in Chapter 23 emphasized the relationship between population genetics—the structure and dynamics of gene pools—and evolution. Evolution remains our central theme as we now view populations in the context of ecology. **Population** ecology, the subject of this chapter, is the study of populations in relation to the environment, including environmental influences on population density and distribution, age structure, and variations in population size. The fur seal population of St. Paul Island (Figure 52.1), off the coast of Alaska, is one population that has experienced dramatic fluctuations in size. Reduced to low numbers by hunting early in the 20th century, the seal population grew rapidly once it was protected. In this case, the population had been reduced by human predation, but there are many reasons why populations grow or decline.

Later in this chapter, we will apply the basic population concepts we develop to the human population. Let's begin by exploring some of the structural and dynamic aspects of populations that apply to all species.

Concept 52.1

Dynamic biological processes influence population density, dispersion, and demography

A **population** is a group of individuals of a single species living in the same general area. Members of a population rely on the same resources, are influenced by similar environmental factors, and have a high likelihood of interacting with and

breeding with one another. Populations can evolve through natural selection acting on heritable variations among individuals and changing the frequencies of various traits over time (see Chapter 23).

Density and Dispersion

At any given moment, every population has specific boundaries and a specific size (the number of individuals living within those boundaries). Ecologists usually begin investigating a population by defining boundaries appropriate to the organisms under study and to the questions being asked. A population's boundaries may be natural ones, as in the case of terns nesting on a particular island in Lake Superior, or they may be arbitrarily defined by an investigator, as in the case of oak trees within a specific county in Minnesota. Once defined, the population can be described in terms of its density and its dispersion. Density is the number of individuals per unit area or volume—the number of oak trees per square kilometer in the Minnesota county, for example, or the number of *Escherichia coli* bacteria per milliliter in a test tube. Dispersion is the pattern of spacing among individuals within the boundaries of the population.

Density: A Dynamic Perspective

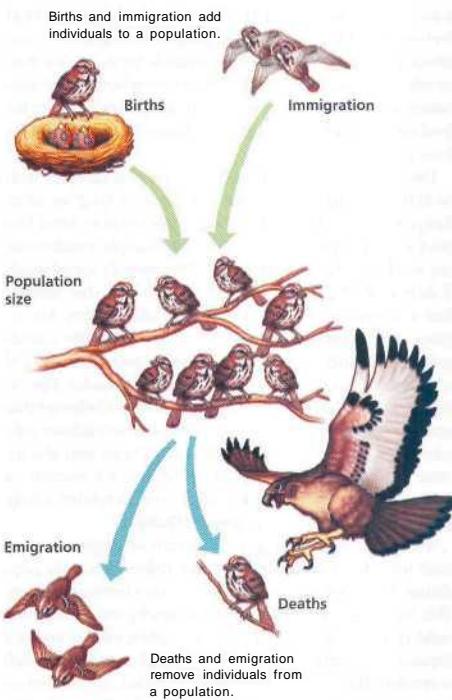

In rare cases, it is possible to determine population size and density by actually counting all individuals within the boundaries of the population. We could count all the sea stars in a tide pool, for example. Herds of large mammals, such as buffalo or elephants, can sometimes be counted accurately from airplanes. In most cases, however, it is impractical or impossible to count all individuals in a population. Instead, ecologists use a variety of sampling techniques to estimate densities and total population sizes. For example, they might count the number of oak trees in several randomly located 10×100 m plots (samples), calculate the average density in the samples, and then extrapolate to estimate the population size in the entire area. Such estimates are most accurate when there are many sample plots and when the habitat is homogeneous. In some cases, instead of counting individual organisms, population ecologists estimate density from some index of population size, such as the number of nests, burrows, tracks, or fecal droppings.

Another sampling technique commonly used to estimate wildlife populations is the mark-recapture method. The researchers place traps within the boundaries of the population under study. Captured animals are marked with tags, collars, bands, or spots of dye, and then released. After a few days or weeks—enough time for the marked individuals to mix with unmarked members of the population—traps are set again. This second capture yields both marked and unmarked individuals. From these data, researchers can estimate the

total number of individuals in the population. Note that the mark-recapture method assumes that each marked individual has the same probability of being trapped as each unmarked individual. This is not always a safe assumption, because an animal that has been trapped once may be wary of traps in the future.

Density is not a static property of a population, but is rather the result of a dynamic interplay between processes that add individuals to a population and those that remove individuals from it (Figure 52.2). Additions to populations occur through birth (which we will define here to include all forms of reproduction) and immigration, the influx of new individuals from other areas. The factors that remove individuals from a population are death (mortality) and emigration, the movement of individuals out of a population.

While birth and death rates have obvious influences on the density of all populations, immigration and emigration can

A Figure 52.2 Population dynamics.

also make important contributions to the density of local populations. For instance, long-term studies of Beldings ground squirrels (*Spermophilus beldingi*) in the vicinity of Tioga Pass, in the Sierra Nevada mountains of California, show that some of the squirrels move nearly 2 km from where they are born, making them immigrants to other populations. Paul Sherman and Martin Morton, at that time at Cornell University and Occidental College, respectively, estimated that immigrants made up 1–8% of the males and 0.7–6% of the females in the study population. While these may seem like small percentages, over time such rates represent biologically significant exchanges between populations.

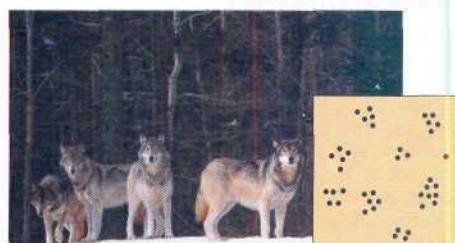

Patterns of Dispersion

Within a population's geographic range, local densities may vary substantially. Variations in local density are among the most important characteristics that a population ecologist might study, since they provide insight into the environmental associations and social interactions of individuals in the population. Environmental differences—even at a local level—contribute to variation in population density; some habitat patches are simply more suitable for a species than are others. Social interactions between members of the population, which may maintain patterns of spacing between individuals, can also contribute to variation in population density.

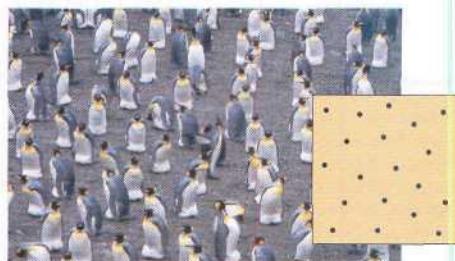

The most common pattern of dispersion is *clumped*, with the individuals aggregated in patches. Plants or fungi are often clumped where soil conditions and other environmental factors favor germination and growth. For example, mushrooms may be clumped on a rotting log. Many animals spend much of their time in a particular microenvironment that satisfies their requirements. Forest insects and salamanders, for instance, are frequently clumped under logs, where the humidity tends to be higher than in more exposed areas. Clumping of animals may also be associated with mating behavior. For example, mayflies often swarm in great numbers, a behavior that increases mating chances for these insects, which survive only a day or two as reproductive adults. Group living may also increase the effectiveness of certain predators; for example, a wolf pack is more likely than a single wolf to subdue a large prey animal, such as a moose (Figure 52.3a).

A *uniform*, or evenly spaced, pattern of dispersion may result from direct interactions between individuals in the population. For example, some plants secrete chemicals that inhibit the germination and growth of nearby individuals that could compete for resources. Animals often exhibit uniform dispersion as a result of antagonistic social interactions, such as territoriality—the defense of a bounded physical space against encroachment by other individuals (Figure 52.3b). Uniform patterns are not as common in populations as clumped patterns.

Random dispersion (unpredictable spacing) occurs in the absence of strong attractions or repulsions among individuals of a population or where key physical or chemical factors are relatively homogeneous across the study area; the position of each individual is independent of other individuals. For example,

(a) **Clumped.** For many animals, such as these wolves, living in groups increases the effectiveness of hunting, spreads the work of protecting and caring for young, and helps exclude other individuals from their territory.

(b) **Uniform.** Birds nesting on small islands, such as these king penguins on South Georgia Island in the South Atlantic Ocean, often exhibit uniform spacing, maintained by aggressive interactions between neighbors.

(c) **Random.** Dandelions grow from windblown seeds that land at random and later germinate.

A **Figure 52.3** Patterns of dispersion within a population's geographic range.

plants established by windblown seeds, such as dandelions, are sometimes randomly distributed in a fairly consistent habitat (**Figure 52.3c**). Random patterns are not as common in nature as one might expect; most populations show at least a tendency toward a clumped distribution.

Demography

The factors that influence population density and dispersion patterns—ecological needs of a species, structure of the environment, and interactions between individuals within the population—also influence other characteristics of populations. Demography is the study of the vital statistics of populations and how they change over time. Of particular interest to demographers are birth rates and how they vary among individuals (specifically among females) and death rates. A useful way of summarizing some of the vital statistics of a population is with a life table.

Life Tables

About a century ago, when life insurance first became available, insurance companies needed to estimate how long, on average, individuals of a given age could be expected to live. To do this, demographers developed **life tables**, age-specific summaries of the survival pattern of a population. Population ecologists adapted this approach to the study of nonhuman populations and developed quantitative demography as a branch of population ecology.

Table 52.1 Life Table for Belding's Ground Squirrels (*Spermophilus beldingi*) at Tioga Pass, in the Sierra Nevada Mountains of California*

| Age (years) | FEMALES | | | | | MALES | | | | |
|----------------|--|--|---------------------------------------|----------------|--|--|--|---------------------------------------|----------------|--|
| | Number Alive at Start of Year | Proportion Alive at Start of Year | Number of Deaths During Year | Death Rate* | Average Additional Life Expectancy (years) | Number Alive at Start of Year | Proportion Alive at Start of Year | Number of Deaths During Year | Death Rate* | Average Additional Life Expectancy (years) |
| 0-1 | 337 | 1.000 | 207 | 0.61 | 1.33 | 349 | 1.000 | 227 | 0.65 | 1.07 |

Males and Females have different mortality. ^aIncludes =0 tri. ^bIncludes separately.

The death rate is the proportion of individuals dying in the specific time interval.

^cIncludes 122 females and 126 males first entered as one-year-olds and therefore not included in the cohort of squirrels age 0-1.

Source: Data from V. W. Sherman and M. L. Morton, "Demography of Belding's Ground Squirrel," *Foxley* 65(1984): 1617-1628.

The best way to construct a life table is to follow the fate of a **cohort**, a group of individuals of the same age, from birth until all are dead. To build the life table, we need to determine the number of individuals that die in each age group and calculate the proportion of the cohort surviving from one age to the next. Cohort life tables are difficult to construct for wild animals and plants and are available for only a limited number of species. Sherman and Morton's studies of the Tioga Pass Belding's ground squirrels resulted in the life table in **Table 52.1**. The table reveals many things about the population. For instance, the third and eighth columns list, respectively, the proportions of females and males in the cohort that are still alive at each age. A comparison of the fifth and tenth columns reveals that males have higher death rates than females.

Survivorship Curves

A graphic way of representing the data in a life table is a **survivorship curve**, a plot of the proportion or numbers in a cohort still alive at each age. Let's use the data for Belding's ground squirrels in Table 52.1 to construct a survivorship curve for this population. Generally, a survivorship curve is constructed beginning with a cohort of 1,000 individuals from a population. We can do this for the Belding's ground squirrel population by multiplying the proportion alive at the start of each year (third and eighth columns of Table 52.1) by 1,000 (the hypothetical beginning cohort). The result is the

number alive at the start of each year. Plotting these numbers versus age for female and male Belding's ground squirrels yields **Figure 52.4**. The relatively straight lines of the plots indicate relatively constant rates of death; however, males have a lower survival rate overall than females.

Figure 52.4 represents just one of many patterns of survivorship exhibited by natural populations. Though diverse, survivorship curves can be classified into three general types (**Figure 52.5**). A Type I curve is flat at the start, reflecting low death rates during early and middle life, then drops steeply as death rates increase among older age groups. Humans and many other large mammals that produce few offspring but provide them with good care often exhibit this kind of curve. In contrast, a Type III curve drops sharply at the start, reflecting very high death rates for the young, but then flattens out as death rates decline for those few individuals that have survived to a certain critical age. This type of curve is usually associated

with organisms that produce very large numbers of offspring but provide little or no care, such as long-lived plants, many fishes, and marine invertebrates. An oyster, for example, may release millions of eggs, but most offspring die as larvae from predation or other causes. Those few that survive long enough to attach to a suitable substrate and begin growing a hard shell will probably survive for a relatively long time. Type II curves are intermediate, with a constant death rate over the organism's life span. This kind of survivorship occurs in Belding's ground squirrels (see Figure 52.4) and some other rodents, various invertebrates, some lizards, and some annual plants.

Many species fall somewhere between these basic types of survivorship or show more complex patterns. In birds, for example, mortality is often high among the youngest individuals (as in a Type III curve) but fairly constant among adults (as in a Type II curve). Some invertebrates, such as crabs, may show a "stair-stepped" curve, with brief periods of increased mortality during molts, followed by periods of lower mortality when the exoskeleton is hard.

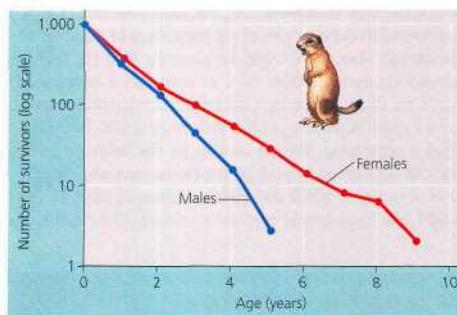

In populations without immigration or emigration, survivorship is one of the two key factors determining changes in population size. In such populations, the other key factor determining population trends is reproductive rate.

Reproductive Rates

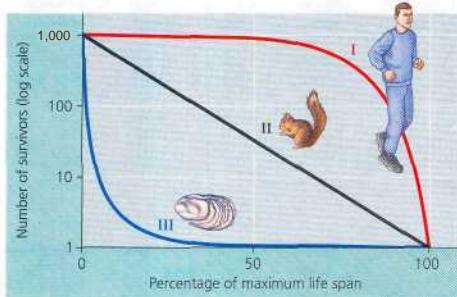

Demographers who study sexually reproducing species generally ignore males and concentrate on females in a population because only females produce offspring. Demographers view populations in terms of females giving rise to new females; males are important only as distributors of genes. The simplest way to describe the reproductive pattern of a population is to ask how reproductive output varies with the ages of females.

A reproductive table, or fertility schedule, is an age-specific summary of the reproductive rates in a population. The best way to construct a fertility schedule is to measure the reproductive output of a cohort from birth until death. For sexual species, the reproductive table tallies the number of female offspring produced by each age group. **Table 52.2** illustrates a reproductive table for Belding's ground squirrels. Reproductive output for sexual species such as birds and mammals is the product of the proportion of females of a given age that are breeding and the number of female offspring of those breeding females. Multiplying these numbers gives the average number of female offspring for each female in a given age class (the last column in Table 52.2). For Belding's ground squirrels, which begin to reproduce at age 1 year, reproductive output rises to a peak at 4 years and then falls off in older females.

Reproductive tables vary greatly, depending on the species. Squirrels have a litter of two to six young once a year for less than a decade, whereas oak trees drop thousands of acorns each year for tens or hundreds of years. Mussels and other invertebrates may release hundreds of thousands of eggs in a

A Figure 52.4 Survivorship curves for male and female Belding's ground squirrels. The logarithmic scale on they-axis makes changes in number of survivors visible across the entire range (2 to 1,000 individuals) on the graph.

A Figure 52.5 Idealized survivorship curves: Types I, II, and III. The y-axis is logarithmic and the x-axis is on a relative scale, so species with widely varying life spans can be compared on the same graph.

Table 52.2 Reproductive Table for Belding's Ground Squirrels at Tioga Pass

| Age (years) | Proportion of Females Weaning a Litter | Mean Size of Litters (Males + Females) | Mean Number of Females in a Litter | Average Number of Female Offspring* |
|-------------|--|--|------------------------------------|-------------------------------------|
| 0-1 | 0.00 | 0.00 | 0.00 | 0.00 |
| 1-2 | 0.65 | 3.30 | 1.65 | 1.07 |
| 2-3 | 0.92 | 4.05 | 2.03 | 1.87 |
| 3-4 | 0.90 | 4.90 | 2.45 | 2.21 |
| 4-5 | 0.95 | 5.45 | 2.73 | 2.59 |
| 5-6 | 1.00 | 4.15 | 2.08 | 2.08 |
| 6-7 | 1.00 | 3.40 | 1.70 | 1.70 |
| 7-8 | 1.00 | 3.85 | 1.93 | 1.93 |
| 8-9 | 1.00 | 3.85 | 1.93 | 1.93 |
| 9-10 | 1.00 | 3.15 | 1.58 | 1.58 |

*The average number of offspring per litter multiplied by the mean number of females in a litter.

Data from P. W. Sherman and M. L. Morton, "Demography of Belding's Ground Squirrel," *Ecology* 65 (1984): 1617-1628.

spawning cycle. Why a particular type of reproductive pattern evolves in a particular population is one of the many questions at the interface of population ecology and evolutionary biology. This is the subject of life history studies.

1 Concept Check 52.1

- One species of forest bird is highly territorial, while a second lives in flocks. What is each species' likely pattern of dispersion? Explain.
- Each female of a particular fish species produces millions of eggs per year. What is its likely survivorship pattern? Explain.
- What is the average proportion of females born into the population of Belding's ground squirrels described by Table 52.2?

For suggested answers, see Appendix A.

1 Concept 52.2

Life history traits are products of natural selection

Natural selection favors traits that improve an organism's chances of survival and reproductive success. In every species,

there are trade-offs between survival and traits such as frequency of reproduction, the number of offspring produced (the number of seeds produced by plants and litter or clutch size for animals), and investment in parental care. The traits that affect an organism's schedule of reproduction and survival (from birth through reproduction to death) make up its life history. Life histories entail three basic variables: when reproduction begins (the age at first reproduction or age at maturity), how often the organism reproduces, and how many offspring are produced during each reproductive episode.

Keep in mind that, with the important exception of humans (which we will consider later in the chapter), organisms do not choose consciously when to reproduce or how many offspring to have. Life history traits are evolutionary outcomes reflected in the development, physiology, and behavior of an organism.

Life History Diversity

Life histories are very diverse. Pacific salmon, for example, hatch in the headwaters of a stream, then migrate to open ocean, where they require one to four years to mature. The salmon eventually return to freshwater streams to spawn, producing thousands of small eggs in a single reproductive opportunity, and then they die. This "one-shot" pattern of big-bang reproduction, or semelparity (from the Latin *semei*, once, and *parito*, to beget), also occurs in some plants, such as the agave (Figure 52.6). Agaves, or century plants, generally grow in arid climates with sparse and unpredictable rainfall. Agaves grow for several years, then send up a large flowering stalk, produce seeds, and die. The shallow roots of agaves catch water after rain showers but are dry during droughts. This irregular water supply may prevent seed production or seedling establishment for several years at a time. By growing and storing nutrients until an unusually wet year and then putting all its resources into reproduction, the agave's life history is an adaptation to erratic climate.

In contrast to semelparity is iteroparity (from the Latin *item*, to repeat), or repeated reproduction. For example, some lizards produce a few large eggs during their second year of life, then repeat the reproductive act annually for several years.

What factors contribute to the evolution of semelparity

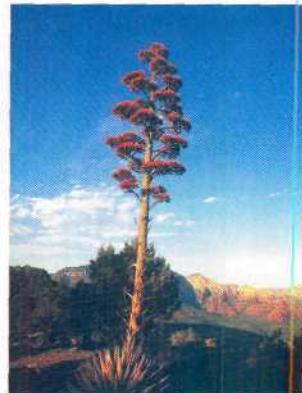

Figure 52.6 An agave, or century plant, an example of big-bang reproduction.

individual gain in reproductive success through one pattern versus the other? The critical factor is survival rate of the offspring. Where the survival rate of offspring is low, as in highly variable or unpredictable environments, big-bang reproduction (semelparity) is favored. Production of large numbers of offspring in such environments increases the probability that at least some will survive. Repeated reproduction (iteroparity) will be favored in more dependable environments where competition for resources may be intense. In such environments, a few relatively large, well-provisioned offspring will have a better chance of surviving to reproductive age.

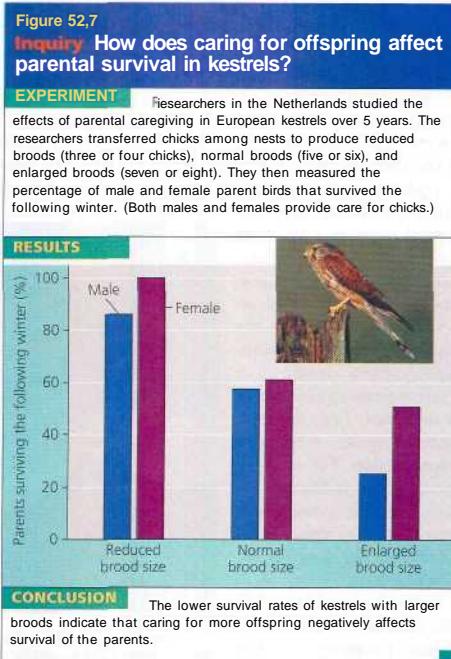

"Trade-offs" and Life Histories

We might imagine an organism that could produce as many offspring as a semelparous species, provision them well like an iteroparous species, and do so repeatedly, but such organisms do not exist. Time, energy, and nutrients that are used for one thing cannot be used for something else. As a consequence, natural selection cannot maximize all these reproductive variables simultaneously. Organisms have finite resources, and limited resources mean trade-offs, in the broadest sense, there is a trade-off between reproduction and survival, as

demonstrated by studies of a number of organisms. For example, a study of red deer in Scotland showed that females that reproduced in one summer suffered higher mortality over the next winter than females that did not reproduce. And a study of European kestrels demonstrated the survival cost to parents of caring for young (Figure 52.7).

Selective pressures also influence the trade-off between the number and size of offspring. Plants and animals whose young are subject to high mortality rates often produce large numbers of relatively small offspring. Plants that colonize disturbed environments, for example, usually produce many small seeds, only a few of which may reach a suitable habitat. Small size may also increase the chance of seedling establishment by enabling the seeds to be carried longer distances to a broader range of habitats (Figure 52.8a). Animals that suffer high predation rates, such as quail, sardines, and mice, also tend to produce large numbers of offspring.

In other organisms, extra investment on the part of the parent greatly increases the offspring's chances of survival. Oak,

(a) Most weedy plants, such as this dandelion, grow quickly and produce a large number of seeds, ensuring that at least some will grow into plants and eventually produce seeds themselves.

(b) Some plants, such as this coconut palm, produce a moderate number of very large seeds. The large endosperm provides nutrients for the embryo, an adaptation that helps ensure the success of a relatively large fraction of offspring.

A **Figure 52.8** Variation in seed crop size in plants.

walnut, and coconut trees all have large seeds with a large store of energy and nutrients that help the seedlings become established (Figure 52.8b). In animals, parental investment in offspring does not always end after incubation or gestation. For instance, primates generally bear only one or two offspring at a time. Parental care and an extended period of learning in the first several years of life are very important to offspring fitness in these species.

(Concept Check 52.2

- Consider two rivers: One is spring fed and is constant in water volume and temperature year-round; the other drains a desert landscape and floods and dries out at unpredictable intervals. Which is more likely to support many species of iteroparous animals? Why?

For suggested answers, see Appendix A.

I Concept 52.3

The exponential model describes population growth in an idealized, unlimited environment

The concepts of life history provide a biological foundation for a quantitative understanding of population growth. To appreciate the potential for population increase, consider a single bacterium that can reproduce by fission every 20 minutes under ideal laboratory conditions. There would be 2 bacteria after 20 minutes, 4 after 40 minutes, 8 after 60 minutes, and so on. If reproduction continued at this rate, with no mortality, for only a day and a half—a mere 36 hours—there would be enough bacteria to form a layer a foot deep over the entire globe. At the other life history extreme, an elephant may produce only 6 offspring in a 100-year life span. Still, Charles Darwin once estimated that the descendants of a single pair of mating elephants would number 19 million within only 750 years. Though Darwin's estimate may not have been precisely correct, such analyses led him to recognize the tremendous capacity for growth in all populations. However, unlimited population increase does not occur indefinitely for any species, either in the laboratory or in nature. A population that begins at a small size in a favorable environment may increase rapidly for a while, but eventually, as a result of limited resources and other factors, its numbers must stop growing. Nevertheless, it is useful to study population growth in an idealized, unlimited environment because such studies reveal the capacity of species for increase and the conditions in which that capacity may be expressed.

Per Capita Rate of Increase

Imagine a hypothetical population consisting of a few individuals living in an ideal, unlimited environment. Under these conditions, there are no restrictions on the abilities of individuals to harvest energy, grow, and reproduce, aside from the inherent biological limitations of their life history traits. The population will increase in size with every birth and with the immigration of individuals from other populations, and it will decrease in size with every death and with the emigration of individuals out of the population. For simplicity here, we will ignore the effects of immigration and emigration (a more complex formulation would certainly include these factors). We can thus define a change in population size during a fixed time interval with the following verbal equation:

$$\frac{\text{Change in population}}{\text{size during time interval}} = \frac{\text{Births during time interval}}{\text{time interval}} - \frac{\text{Deaths during time interval}}{\text{time interval}}$$

We can use mathematical notation to express this relationship more concisely. If N represents population size and t represents time, then ΔN is the change in population size and Δt is the time interval (appropriate to the life span or generation time of the species) over which we are evaluating population growth. (The Greek letter delta, Δ , indicates change, such as change in time.) We can now rewrite the verbal equation as

$$\frac{\Delta N}{\Delta t} = B - D$$

where B is the number of births in the population during the time interval and D is the number of deaths.

Next, we can convert this simple model into one in which births and deaths are expressed as the average number of births and deaths per individual during the specified time interval. The *per capita birth rate* is the number of offspring produced per unit time by an average member of the population. If, for example, there are 34 births per year in a population of 1,000 individuals, the annual per capita birth rate is $34/1,000$, or 0.034. If we know the annual per capita birth rate (expressed as b), we can use the formula $B = bN$ to calculate the expected number of births per year in a population of any size. For example, if the annual per capita birth rate is 0.034 and the population size is 500,

$$\begin{aligned}B &= hH \\B &\approx 0.034 \times 500 \\B &= 17 \text{ per year}\end{aligned}$$

Similarly, the *per capita death rate* (symbolized as m for mortality) allows us to calculate the expected number of deaths per unit time in a population of any size. If $m = 0.016$ per year, we would expect 16 deaths per year in a population of 1,000 individuals. For natural populations or those in the laboratory, the per capita birth and death rates can be calculated from estimates of population size and data in life tables and reproductive tables (for example, Tables 52.1 and 52.2).

Now we can revise the population growth equation again, this time using per capita birth and death rates rather than the numbers of births and deaths:

$$\frac{\Delta N}{\Delta t} = bN - mN$$

One final simplification is in order. Population ecologists are most interested in the difference between the per capita birth rate and per capita death rate. This difference is the *per capita rate of increase*, or r :

$$r = b - m$$

The value of r indicates whether a given population is growing ($r > 0$) or declining ($r < 0$). Zero population growth (ZPG) occurs when the per capita birth and death rates are equal ($r = 0$). Births and deaths still occur in such a population, of course, but they balance each other exactly.

Using the per capita rate of increase, we now rewrite the equation for change in population size as

$$\frac{\Delta N}{\Delta t} = rN$$

Most ecologists use differential calculus to express population growth as growth rate at a particular instant in time;

$$\frac{dN}{dt} = rN$$

If you have not yet studied calculus, don't be intimidated by the form of the last equation; it is essentially the same as the previous one, except that the time intervals Δt are very short and are expressed in the equation as dt .

Exponential Growth

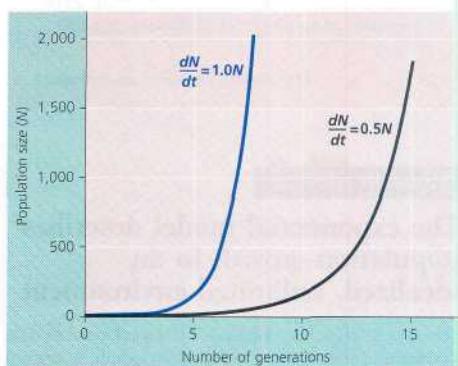

Earlier we described a population whose members all have access to abundant food and are free to reproduce at their physiological capacity. Population increase under these ideal conditions is called exponential population growth. Under these conditions, the per capita rate of increase may assume the maximum rate for the species, called the *intrinsic rate of increase* and denoted as r_{max} . The equation for exponential population growth is

$$Tt = rN$$

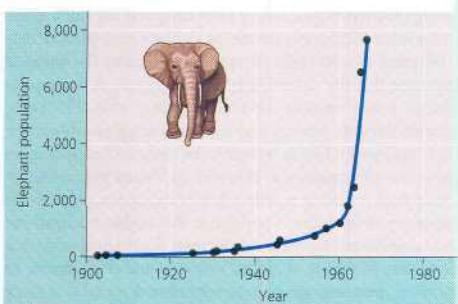

The size of a population that is growing exponentially increases at a constant rate, resulting eventually in a J-shaped growth curve when population size is plotted over time (Figure 52.9). Although the intrinsic rate of increase is constant, the population accumulates more new individuals per unit of time when it is large than when it is small; thus, the curves in Figure 52.9 get progressively steeper over time. This occurs because population growth depends on N as well as

r_{max} , and larger populations experience more births (and deaths) than small ones growing at the same per capita rate. It is also clear from Figure 52.9 that a population with a higher intrinsic rate of increase ($dN/dt = 1.0N$) will grow faster than one with a lower rate of increase ($dN/dt = 0.5N$).

The J-shaped curve of exponential growth is characteristic of some populations that are introduced into a new or unfilled environment or whose numbers have been drastically reduced by a catastrophic event and are rebounding. For example, Figure 52.10 illustrates the exponential population growth that occurred in the population of elephants in Kruger National Park, South Africa, after they were protected from hunting. After approximately 60 years of exponential growth, the large number of elephants had caused enough damage to the park vegetation

A Figure 52.9 Population growth predicted by the exponential model. This graph compares growth in two populations with different values of r_{max} . Increasing the value from 0.5 to 1.0 increases the rate of rise in population size with time, as reflected by the relative slopes of the curves.

A Figure 52.10 Exponential growth in the African elephant population of Kruger National Park, South Africa.

that a collapse in the elephant food supply was likely, leading to an end to population growth through starvation. To protect other species and the park ecosystem before that happened, park managers began limiting the elephant population by using birth control and exporting elephants to other countries.

Concept Check 52.3

- Explain why a constant rate of increase (r_{max}) for a population produces a growth graph that is j-shaped rather than a straight line.
- Where is exponential growth by a plant population more likely—on a newly formed volcanic island or in a mature, undisturbed rain forest? Why?

For suggested answers, see Appendix A.

Concept 52.4

The logistic growth model includes the concept of carrying capacity

The exponential growth model assumes resources are unlimited; never the case in the real world. As population density increases, each individual has access to fewer resources. Ultimately, there is a limit to the number of individuals that can occupy a habitat. Ecologists define carrying capacity, symbolized as K , as the maximum population size that a particular environment can support. Carrying capacity is not fixed, but varies over space and time with the abundance of limiting resources. Energy, shelters, refuges from predators, soil nutrients, water, and suitable nesting sites can all be limiting factors. For example, the carrying capacity for bats may be high in a habitat with abundant flying insects and roosting sites but lower where there is abundant food but fewer suitable shelters.

Crowding and resource limitation can have a profound effect on population growth rate. If individuals cannot obtain sufficient resources to reproduce, the per capita birth rate (b) will decline. If they cannot find and consume enough energy to maintain themselves, the per capita death rate (m) may increase. A decrease in b or an increase in m results in a lower per capita rate of increase, r .

The Logistic Growth Model

We can modify our mathematical model to incorporate changes in growth rate as the population size nears the carrying capacity. In the logistic population growth model, the per capita rate of increase declines as carrying capacity is reached.

To construct the logistic model, we start with the exponential population growth model and add an expression that reduces the per capita rate of increase as N increases (Figure 52.11). If the maximum sustainable population size (carrying capacity) is K , then $K - N$ is the number of additional individuals the environment can accommodate, and $(K - N)/K$ is the fraction of K that is still available for population growth. By multiplying the exponential rate of increase $r_{max}N$ by $(K - N)/K$, we modify the growth rate of the population as N increases:

$$\frac{dN}{dt} = r_{max}N \frac{(K-N)}{K}$$

Table 52.3 shows calculations of population growth rate at various population sizes for a hypothetical population growing

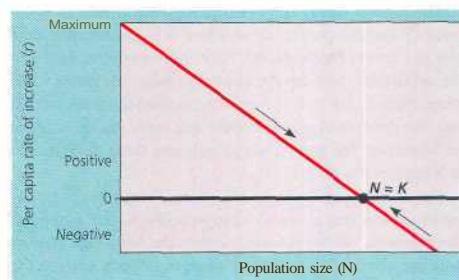

Figure 52.11 Influence of population size (N) on per capita rate of increase (r). The logistic model assumes that the per capita rate of increase decreases as N increases. If N is greater than K , then the population growth rate is negative, and population size decreases. An equilibrium is reached at the white line when $N = K$.

Table 52.3 A Hypothetical Example of Logistic Population Growth, Where $K = 1,000$ and $r_{max} = 0.05$ per Individual per Year

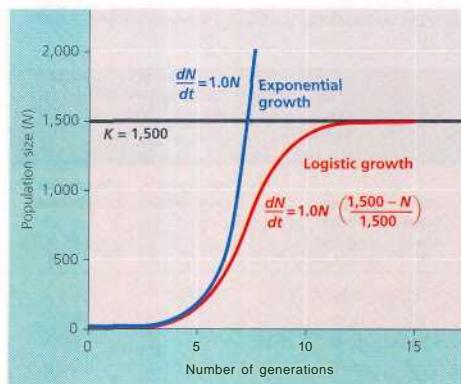

| Popu- lation Size: N | Intrinsic Rate of Increase: $\frac{(K-N)}{K} r_{max}$ | Per Capita Growth Rate: $r_{max} \frac{(K-N)}{K}$ | Population Growth Rate: $r_{max} \frac{N}{K}$ |
|---------------------------------|--|---|---|
| 20 | 0.05 | 0.98 | 0.049 |
| 100 | 0.05 | 0.90 | 0.045 |
| 250 | 0.05 | 0.75 | 0.038 |
| 500 | 0.05 | 0.50 | 0.025 |
| 750 | 0.05 | 0.25 | 0.013 |
| 1,000 | 0.05 | 0.00 | 0 |

*Rounded to the nearest whole number.

according to the logistic model. When N is small compared to K , the term $(K - N)/K$ is large, and the per capita rate of increase $r_{max}(K - N)/K$, is close to the intrinsic (maximum) rate of increase. But when N is large and resources are limiting, then $(K - N)/K$ is small, and so is the per capita rate of increase. When N equals K , the population stops growing. Notice in Table 52.3 that the overall population growth rate is highest, +13, over a year when the population size is 500, or half the carrying capacity. Why is population growth rate greatest at 500 and not at smaller population sizes? This is due to the balance between per capita rate of increase and population size. At a population size of 500, the per capita rate of increase remains relatively high (one-half the maximum rate), and there are many more reproducing individuals in the population than at lower population sizes.

The logistic model of population growth produces a sigmoid (S-shaped) growth curve when N is plotted over time (the red line in **Figure 52.12**). New individuals are added to the population most rapidly at intermediate population sizes, when there is not only a breeding population of substantial size, but also lots of available space and other resources in the environment. The population growth rate slows dramatically as N approaches K .

Notice that we haven't said anything about *why* the population growth rate slows as N approaches K . For a population's growth rate to decrease, either the birth rate b must decrease, the death rate m must increase, or both. Later in the chapter, we will consider some of the factors affecting these rates.

A Figure 52.12 Population growth predicted by the logistic model. The rate of population growth slows as population size (N) approaches the carrying capacity (K) of the environment. The red line shows logistic growth in a population where $r_{max} = 1.0$ and $K = 1,500$ individuals. For comparison, the blue line illustrates a population continuing to grow exponentially with the same r_{max} .

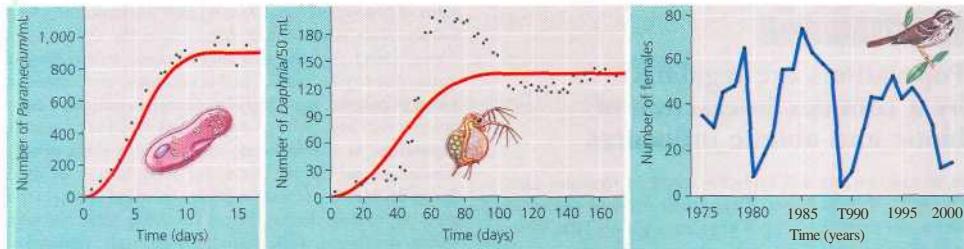

The Logistic Model and Real Populations

The growth of laboratory populations of some small animals, such as beetles and crustaceans, and of some microorganisms, such as paramecia, yeasts, and bacteria, fits an S-shaped curve fairly well (**Figure 52.13a**). These populations are grown in a constant environment lacking predators and other species that may compete for resources, conditions that rarely occur in nature.

Some of the basic assumptions built into the logistic model clearly do not apply to all populations. For example, the logistic model assumes that populations adjust instantaneously to growth and approach carrying capacity smoothly. In most natural populations, however, there is a lag time before the negative effects of an increasing population are realized. If food becomes limiting for a population, for instance, reproduction will be reduced. However, the birth rate may not decline immediately, since females may use their energy reserves to continue reproducing for a short time. This may cause the population to overshoot its carrying capacity before settling down to a relatively stable density. **Figure 52.13b** illustrates this overshoot for a laboratory population of water fleas (*Daphnia*). If the population then drops below carrying capacity, there will be a delay in population growth until the increasing number of offspring are actually born. And still other populations fluctuate greatly, making it difficult even to define carrying capacity. For example, **Figure 52.13c** shows marked population changes in the song sparrow on a small island in southern British Columbia. The population increases rapidly but suffers periodic catastrophes in winter; consequently, there is no stable population size. We will examine some possible reasons for these fluctuations later in the chapter.

The logistic model also incorporates the idea that regardless of population density, each individual added to a population has the same negative effect on population growth rate. However, some populations show an *Allee effect* (named after W. C. Allee, of the University of Chicago, who first described it), in which individuals may have a more difficult time surviving or reproducing if the population size is too small. For example, a single plant may be damaged by excessive wind if it is standing alone, but it would be protected in a clump of individuals. Conservation biologists fear that if populations of certain solitary animals, such as rhinoceroses, drop below a critical size, individuals will not be able to locate mates in the breeding season.

Although the logistic model fits few, if any, real populations closely, it is a useful starting point for thinking about how populations grow and for constructing more complex models. The model is also useful in conservation biology for estimating how rapidly a particular population might increase in numbers after it has been reduced to a small size, or for estimating sustainable harvest rates for fish and wildlife populations. And like any good starting hypothesis, the logistic model has stimulated research leading to a better understanding of the factors affecting population growth.

(a) A *Paramecium* population in the lab. The growth of *Paramecium aurelia* in small cultures (black dots) closely approximates logistic growth (red curve) if the experimenter maintains a constant environment.

(b) A *Daphnia* population in the lab. The growth of a population of *Daphnia* in a small laboratory culture (black dots) does not correspond well to the logistic model (red curve). This population overshoots the carrying capacity of its artificial environment and then settles down to an approximately stable population size.

(c) A song sparrow population in its natural habitat. The population of female song sparrows nesting on Mandarte Island, British Columbia, is periodically reduced by severe winter weather, and population growth is not well described by the logistic model.

A Figure 52.13 How well do these populations fit the logistic growth model?

The Logistic Model and Life Histories

The logistic model predicts different per capita growth rates for populations of low or high density relative to the carrying capacity of the environment. At high densities, each individual has few resources available, and the population grows slowly, if at all. At low densities, the opposite is true: Per capita resources are relatively abundant, and the population can grow rapidly. Different life history features are favored under each condition. At high population density, selection favors adaptations that enable organisms to survive and reproduce with few resources. Thus, competitive ability and efficient use of resources should be favored in populations that are at or near their carrying capacity. These are the traits we associated earlier with iteroparity. At low population density, on the other hand, even in the same species, adaptations that promote rapid reproduction, such as the production of numerous, small offspring, should be favored.

Ecologists have attempted to connect these differences in favored traits at different population densities with the logistic growth model. Selection for life history traits that are sensitive to population density is known as K-selection, or density-dependent selection. In contrast, selection for life history traits that maximize reproductive success in uncrowded environments (low densities) is called r-selection, or density-independent selection. These names follow from the variables of the logistic equation. K-selection tends to maximize population size and operates in populations living at a density near the limit imposed by their resources (the carrying capacity, K). By contrast, r-selection tends to maximize r , the rate of increase, and occurs in environments in which population densities fluctuate well below carrying capacity or individuals are likely to face little competition.

Laboratory experiments have shown that different populations of the same species may show a different balance of K-selected and r-selected traits, depending on conditions. For example, cultures of the fruit fly *Drosophila melanogaster* raised for 200 generations under crowded conditions with [minima] food are more productive at high density than other populations raised for many generations in uncrowded conditions with abundant food. Apparently, when given equal access to food, larvae from cultures selected for living in crowded conditions feed faster than larvae selected for living in uncrowded cultures. The fruit fly genotypes that are most fit at low density do not have high fitness at high density, as predicted by r- and K-selection theory.

The concepts of r- and K-selection have been criticized as an oversimplification of the variation seen in the natural histories of species. The characteristics of most species place them somewhere in between the extremes represented by r- and K-selection. The critical assessment of r- and K-selection has led ecologists to propose alternative theories of life history evolution. These alternative theories, in turn, have stimulated more thorough study of how factors such as disturbance, stress, and the frequency of opportunities for successful reproduction affect the evolution of life histories.

Concept Check 52.4

- Explain why a population that fits the logistic growth model increases more rapidly at intermediate size than at relatively small or large sizes.

For suggested answers, see Appendix A.

Concept 52.5

Populations are regulated by a complex interaction of biotic and abiotic influences

In this section, we will apply the theme of *regulation* (see Chapter 1) to populations. There are two general questions we can ask about regulation of population growth. First, what environmental factors stop a population from growing? Second, why do some populations show radical fluctuations in size over time, while others remain more stable?

These questions have many practical applications. In agriculture, the objective may be to reduce the size of a pest population. If an introduced weed is spreading rapidly, what can be done to stop its growth? Why do agricultural pests have severe effects in some areas and negligible effects in others? Conversely, what environmental factors would create a favorable feeding or breeding habitat for an endangered species, such as the humpback whale or whooping crane? Such questions, which involve population-regulating factors, are at the core of management programs that have helped prevent the extinction of certain endangered species.

Population Change and Population Density

The first step in understanding why a population stops growing is to study how the rates of birth, death, immigration, and emigration change as population density rises. If immigration and emigration offset each other, then a population grows when the birth rate exceeds the death rate and declines when the death rate exceeds the birth rate.

A birth rate or death rate that does *not* change with population density is said to be **density independent**. In a classic

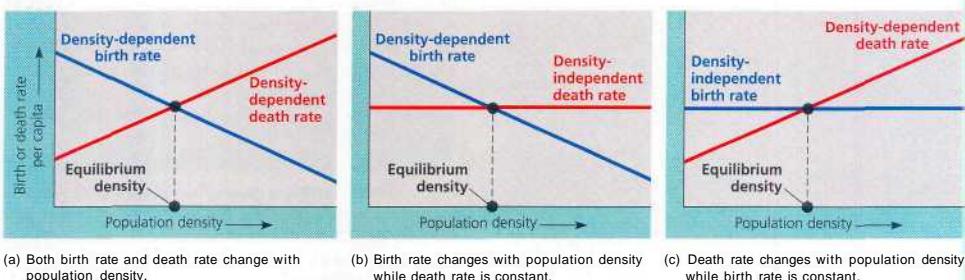

study of population regulation, Andrew Watkinson and John Harper, plant population ecologists from the University of Wales, found that the mortality of dune fescue grass is mainly due to physical factors that kill similar proportions of a local population, regardless of its density. In contrast, a death rate that rises as population density rises is said to be density dependent, as is a birth rate that falls with rising density. Watkinson and Harper found that reproduction by dune fescue declines as population density increases. Thus, in this grass population, the key factors regulating birth rate were density dependent, while death rate was largely regulated by density-independent factors. **Figure 52.14** models how a population may stop increasing and reach equilibrium due to various combinations of density-dependent and density-independent regulation.

Density-Dependent Population Regulation

Density-dependent birth and death rates are an example of negative feedback, a type of regulation described in Chapter 1. Without some type of negative feedback between population density and the vital rates of birth and death, a population would not stop growing. However, at increased densities, birth rates decline and/or death rates increase, providing the negative feedback that halts continued population growth. Once we know how birth and death rates change with population density, we need to determine the mechanisms causing these changes, which may involve many factors.

Competition for Resources

In crowded populations, increasing population density intensifies intraspecific competition for declining nutrients and other resources, resulting in a lower birth rate. For example, crowding

A Figure 52.14 Determining equilibrium for population density. This simple model considers only birth and death rates (immigration and emigration rates are assumed to be either zero or equal).

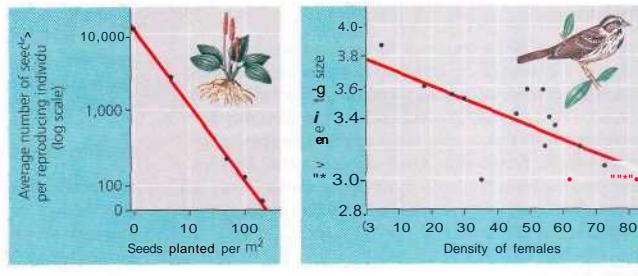

can reduce seed production by plants (**Figure 52.15a**). And available food supplies often limit the reproductive output of songbirds; as bird population density increases in a particular habitat, each female lays fewer eggs, a density-dependent response (**Figure 52.15b**). In an experiment in which female song sparrows living in high-density conditions were given extra food, they did not suffer a reduction in clutch size,

Territoriality

In many vertebrates and some invertebrates, territoriality may limit density. In this case, territory space becomes the resource for which individuals compete. Cheetahs, for example, are highly territorial, using chemical communication to warn other cheetahs of their territorial boundaries (**Figure 52.16**). Oceanic birds, such as gannets, often nest on rocky islands, where they are relatively safe from predators (**Figure 52.17**). Up to a certain population density, most birds can find a suitable nest site, but beyond that threshold, few birds breed successfully. Thus, the limiting resource that determines breeding population density for gannets is safe nesting territory. Birds that cannot obtain a nesting spot do not reproduce. The presence of surplus, or nonbreeding, individuals is a good indication that territoriality is restricting population growth, as it does in many bird populations.

Health

Population density can also influence the health and thus the survival of organisms. If the transmission rate of a disease depends on a certain level of crowding in a population, the disease's impact may be density dependent. Field experiments conducted by Charles Mitchell, David Tilman, and James Groth, of the University of Minnesota, demonstrated that the severity of infection of plants by fungal pathogens is greater where the density of the host plant population is higher. Animals, too, can experience increased infection by pathogens at high population densities. Steven Kohler and Wade Hoiland of the Illinois Natural History Survey showed that in case-building caddis flies (stream-dwelling insects) peaks in disease-related mortality followed years of high insect abundance. Their study indicated that such disease-related mortality was largely responsible for cyclic fluctuations in the density of the insect population. Human pathogens can also show density-dependent infection rates. For example, tuberculosis, which is caused by bacteria that spread through the air when an infected person sneezes or coughs, strikes a greater percentage of people living in high-density cities than those in rural areas.

.4 **Figure 52.15** Decreased reproduction at high population densities. Log scales are used on both x- and y-axes.

A Figure 52.16 Cheetah staking out a territory with a chemical marker.

& Figure 52.17 Territories. Gannets nest virtually a peck apart and defend their territories by calling and pecking at one another.

Predation

Predation may be an important cause of density-dependent mortality for some prey populations if a predator encounters and captures more food as the population density of the prey increases. As a prey population builds up, predators may feed preferentially on that species, consuming a higher percentage of individuals. For example, trout may concentrate for a few days on a particular species of insect that is emerging from its aquatic larval stage, then switch prey as another insect species becomes more abundant.

Toxic Wastes

The accumulation of toxic wastes can contribute to density-dependent regulation of population size. In laboratory cultures of small microorganisms, for example, metabolic by-products accumulate as the populations grow, poisoning the organisms within this limited, artificial environment. For example, ethanol accumulates as a by-product of yeast fermentation. The alcohol content of wine is usually less than 13% because that is the maximum concentration of ethanol that most wine-producing yeast cells can tolerate.

Intrinsic Factors

For some animal species, intrinsic (physiological) factors, rather than the extrinsic (environmental) factors we've just discussed, appear to regulate population size. White-footed mice in a small field enclosure will multiply from a few to a colony of 30 to 40 individuals, but eventually reproduction will decline until the population ceases to grow. This drop in reproduction is associated with aggressive interactions that increase with population density, and it occurs even when food and shelter are provided in abundance. Although the exact mechanisms by which aggressive behavior affects reproductive rate are not yet understood, researchers have learned that high population densities in mice induce a stress syndrome in which hormonal changes can delay sexual maturation, cause reproductive organs to shrink, and depress the immune system. In this case, high densities cause an increase in mortality and a decrease in birth rates. Similar effects of crowding occur in some other wild rodent populations.

These various examples of population regulation by negative feedback show how increased densities cause population growth rates to decline by affecting reproduction, growth, and survivorship. This helps answer our first question about populations: What causes a population to stop increasing? Now let's turn to our second question: Why do some populations fluctuate dramatically over time while others remain more stable?

Population Dynamics

While some populations appear to be more stable in size than others, over the long term, all populations for which we have data show some fluctuation in numbers. Although ecologists

can determine an average population size for many species, the average is often of less interest than the variation in numbers from year to year or place to place. The study of **population dynamics** focuses on the complex interactions between biotic and abiotic factors that cause variation in population size.

Stability and Fluctuation

Populations of large mammals, such as deer and moose, were once thought to remain relatively stable over time. But some long-term studies have challenged that hypothesis. The moose population on Isle Royale, an island in Lake Superior, is a striking example. Moose from the mainland colonized the island around 1900 by walking across the frozen lake. However, the lake has not frozen over in recent years, so the moose population has been isolated from immigration and emigration. Nevertheless, as **Figure 52.18** shows, the population has been anything but stable, with two major increases and collapses over the last 40 years. In general, the severity of winter loss in large grazers and browsers inhabiting temperate and polar regions is proportional to the harshness of the winter. Colder temperatures increase energy requirements (and therefore the need for food), while deeper snow makes it harder to find food.

Figure 52.18

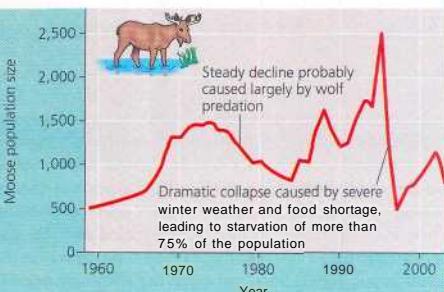

ImMiry How stable is the Isle Royale moose population?

FIELD STUDY

Researchers regularly surveyed the population of moose on Isle Royale, Michigan, from 1960 to 2003. During that time, the lake never froze over, and so the moose population was isolated from the effects of immigration and emigration.

RESULTS

Over 43 years, this population experienced two significant increases and collapses, as well as several less severe fluctuations in size.

CONCLUSION

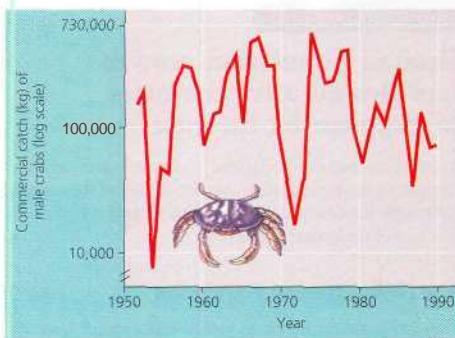

The pattern of population dynamics observed in this isolated population indicates that various biotic and abiotic factors can result in dramatic fluctuations over time in a moose population.

Although large mammal populations are more dynamic than once thought, they show much more stability than other populations. The Dungeness crab is a classic example of an erratically fluctuating population. As shown in **Figure 52.19**, the crab population at Fort Bragg on the northern California coast varied between 10,000 and hundreds of thousands over a 40-year period. By contrast, over this same period, the moose population of Isle Royale varied only between 500 and 2,500 (see Figure 52.18).

One key factor involved in the large fluctuations in the Dungeness crab population is cannibalism. Females release up to 2 million eggs each fall, and large numbers of juvenile crabs are eaten by older juveniles and by adult crabs. In addition, successful settlement of larval crabs occurs only in shallow waters and depends on ocean currents and water temperature. If winds and currents move larval crabs too far offshore, they cannot reach the ocean bottom and settle successfully. Small changes in environmental variables seem to be magnified by density-dependent cannibalism, and together these factors explain the marked fluctuations in Dungeness crab populations. These results support the hypothesis that the dynamics of many populations result from a complex interaction of biotic and abiotic factors.

Metapopulations and Immigration

To this point in our discussion of population dynamics, we have focused mainly on the contributions of births and deaths. However, as you have read, immigration and emigration can also influence populations. This is particularly true when a group of populations is linked, forming a metapopulation. For example, immigration and emigration link the Belding's ground squirrel population we discussed earlier to other populations of the species, forming a metapopulation.

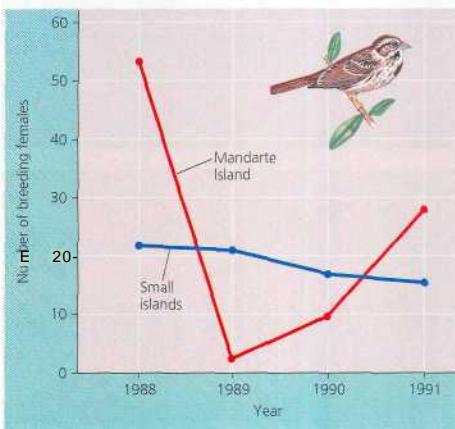

A Figure 52.19 Extreme population fluctuations. This graph shows the commercial catch of male Dungeness crabs (*Cancer magister*) at Fort Bragg, California. Note the log scale of the y-axis.

How might immigration influence population dynamics? A metapopulation of song sparrows on Mandarte Island and a cluster of smaller islands off the coast of British Columbia provides an example. On relatively isolated Mandarte Island, differences between births and deaths are the principal influences maintaining the highly dynamic population of song sparrows (see Figure 52.13c). In 1988–1991, only 1% of the breeding song sparrows were immigrants. By contrast, during the same period, immigrants made up 57% of the breeding song sparrow population on a cluster of small islands near Vancouver Island. This higher level of song sparrow immigration combined with a higher survival rate on small islands resulted in greater stability in song sparrow populations on the small islands than on Mandarte Island (**Figure 52.20**). The metapopulation concept underscores the significance of immigration and emigration in the contrasting song sparrow populations, and is important for understanding populations in patchy habitats.

Population Cycles

While many populations fluctuate at unpredictable intervals, others undergo regular boom-and-bust cycles, fluctuating in density with a remarkable regularity. For example, some small herbivorous mammals, such as voles and lemmings, tend to have 3- to 4-year cycles, and some birds, such as ruffed grouse and ptarmigans, have 9- to 11-year cycles.

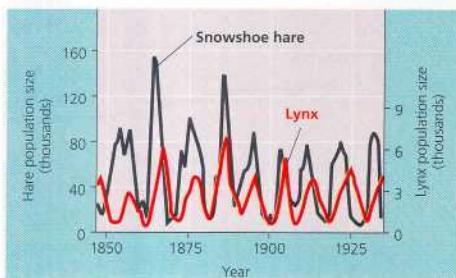

One striking example of population cycles is the 10-year cycles of snowshoe hares and lynx in the far northern forests

A Figure 52.20 Song sparrow populations and immigration. Song sparrow populations on a cluster of small islands make up a metapopulation. Immigration keeps the linked populations more stable than the isolated population on larger Mandarte Island.

of Canada and Alaska. Lynx are specialist predators of snowshoe hares, so it is not surprising that lynx numbers rise and fall with the numbers of hares (Figure 52.21). But why do hare numbers rise and fall in 10-year cycles? Three main hypotheses have been proposed. First, the cycles may be caused by food shortage during winter. Hares eat the terminal twigs of small shrubs such as willow and birch in winter and may suffer from malnutrition due to overgrazing. Second, the cycles may be due to predator-prey interactions. Many predators other than lynx eat hares, and they may overexploit their prey. Third, the cycles may be affected by a combination of food resource limitation and excessive predation.

If hare cycles are due to winter food shortage, then they should stop if extra food is added to a field population. Researchers have conducted such experiments in the Yukon for 20 years—over two hare cycles—and report two results. First, hare populations in the areas with extra food increased about threefold in density. The carrying capacity of a habitat for hares can clearly be increased by adding food. Second, the hares with extra food continued to cycle in the same way as the unfed control populations. In particular, cyclic collapses occurred in both experimental and control areas, and the decline in numbers could not be stopped by adding food. Thus, food supplies alone are not the cause of the hare cycle shown in Figure 52.21, so we can discard the first hypothesis.

A Figure 52.21 Population cycles in the snowshoe hare and lynx. Population counts are based on the number of pelts sold by trappers to the Hudson Bay Company.

By putting radio collars on hares, field ecologists can find individual hares as soon as they die and determine the immediate cause of death. Almost 90% of the hares that died were killed by predators; none appeared to have died of starvation. These data support either the second or third hypothesis. Ecologists tested these hypotheses by excluding predators from one area with electric fences and by both excluding predators and adding food to another area. The results supported the hypothesis that the hare cycle is driven largely by excessive predation but that food availability also plays an important role, particularly in the winter. Perhaps better-fed hares are more likely to escape from predators. Many different predators contribute to these losses; the cycle is not simply a hare-lynx cycle.

For the lynx, great-horned owls, weasels, and other predators that depend heavily on a single prey species, the availability of prey is the major factor influencing their population changes. When prey become scarce, predators often turn on one another. Coyotes kill foxes and lynx, and great-horned owls kill smaller birds of prey as well as weasels, accelerating the collapse of the predator populations. Long-term experimental studies will help to unravel the complex causes of such population cycles.

Concept Check 52.5

- Identify three density-dependent factors that limit population size, and explain how each exerts negative feedback.

For suggested answers, see Appendix A.

Concept 52.6

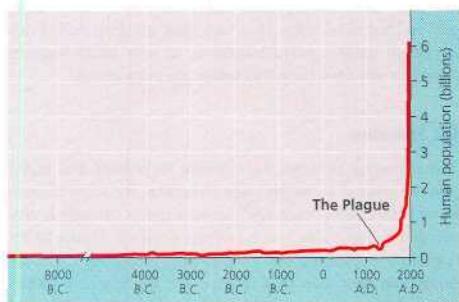

Human population growth has slowed after centuries of exponential increase

As you have read, no population can grow indefinitely, and humans are no exception. In this last section of the chapter, we'll apply the concepts of population dynamics to the specific case of the human population.

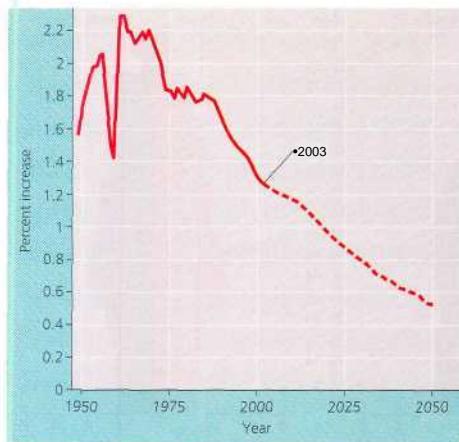

The Global Human Population

The exponential growth model in Figure 52.9 approximates the population explosion of humans since 1650. Ours is a singular case; it is unlikely that any other population of large animals has ever sustained so much growth for so long. The human

population increased relatively slowly until about 1650, at which time approximately 500 million people inhabited Earth (**Figure 52.22**). The population doubled to 1 billion within the next two centuries, doubled again to 2 billion between 1850 and 1930, and doubled still again by 1975 to more than 4 billion. The global population now numbers over 6 billion people and is increasing by about 73 million each year. The population grows by approximately 201,000 people each day, the equivalent of adding a city the size of Amarillo, Texas, or Madison,

A Figure 52.22 Human population growth (data as of 2003). The global human population has grown almost continuously throughout history, but it skyrocketed after the Industrial Revolution. Though it is not apparent at this scale, the rate of population growth has slowed in recent decades, mainly as a result of decreased birth rates throughout the world.

A Figure 52.23 Percent increase in the global human population (data as of 2003). The dashed portion of the curve indicates projected data. The sharp dip in the 1960s is due mainly to a famine in China in which about 60 million people died.

Wisconsin. Every week the population increases by the size of San Antonio, Milwaukee, or Indianapolis. It takes only four years for world population growth to add the equivalent of another United States. Population ecologists predict a population of 7.3–8.4 billion people on Earth by the year 2025.

Though the global population is still growing, the *rate* of growth began to slow during the 1960s. **Figure 52.23** presents the percentage increase in the global population from 1950 to 2003 and projected to the year 2050. The rate of increase in the global population peaked at 2.19% in 1962; by 2003 it had declined to 1.16%. Current models project a decline in the overall growth rate to just over 0.4% by 2050. This reduction in growth rate shows that the human population has departed from true exponential growth, which assumes a constant rate. These declines are the result of fundamental changes in population dynamics due to diseases, such as AIDS, and voluntary population control.

Regional Patterns of Population Change

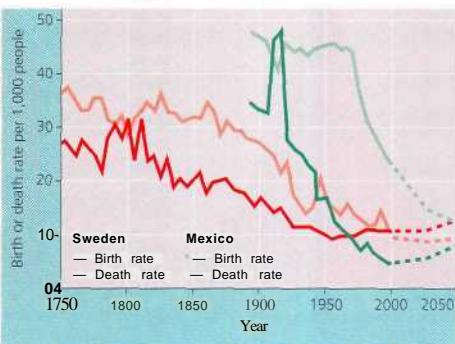

So far we have described changes in the global population. But population dynamics vary widely from region to region. To maintain population stability, a regional human population can exist in one of two configurations:

Zero population growth = High birth rates — High death rates

or

Zero population growth = Low birth rates — Low death rates

The movement from the first toward the second state is called the demographic transition. **Figure 52.24** compares the demographic transition in one of the most economically developed countries, Sweden, and in a developing country, Mexico. The demographic transition in Sweden took about 150 years,

A Figure 52.24 Demographic transition in Sweden and Mexico, 1750–2050 (data as of 2003).

from 1810 to 1960; in Mexico, the changes are projected to continue until sometime after 2050, almost the same length of time. Demographic transition is associated with an increase in the quality of health care and sanitation as well as improved access to education, especially for women.

After 1950, mortality rates declined rapidly in most developing countries, but birth rates have declined in a more variable manner. Birth rate decline has been most dramatic in China. In 1970, the Chinese birth rate predicted an average of 5.9 children per woman per lifetime (total fertility rate); by 2004, largely because of the government's strict one-child policy, the expected total fertility rate was 1.7 children. In India, birth rates have fallen more slowly. In some countries of Africa, the transition to lower birth rates has been dramatic, though birth rates remain high in most of sub-Saharan Africa.

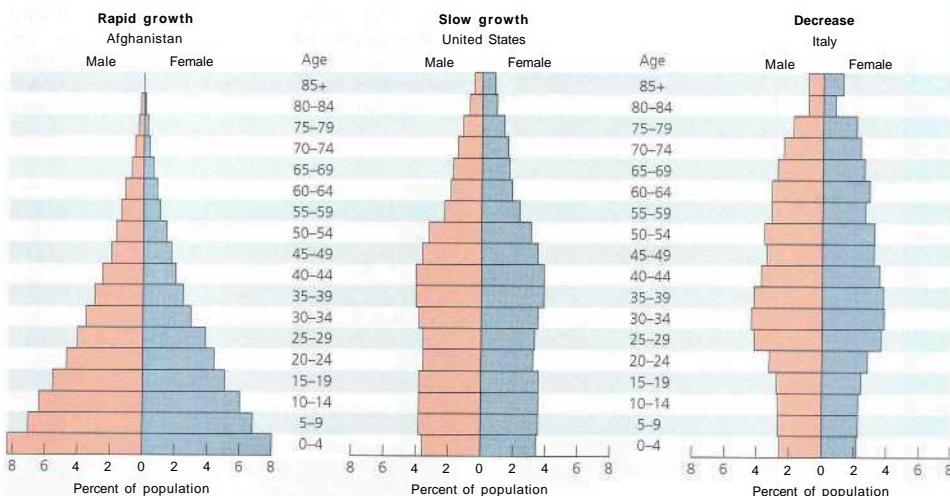

How do such variable birth rates affect the growth of the world's population? In the developed nations, populations are near equilibrium (growth rate about 0.1% per year), with reproductive rates near the replacement level (total fertility rate = 2.1 children per female). In many developed countries, including Canada, Germany, Japan, Italy, and the United Kingdom, total reproductive rates are in fact *below* replacement. These populations will eventually decline if there is no immigration and if the birth rate does not change. In fact, the population is already declining in many eastern and central European countries. Most

of the current global population growth (1.4% per year) is concentrated in developing countries, where about 80% of the world's people now live.

A unique feature of human population growth is the ability to control it with family planning and voluntary contraception. Reduced family size is the key to the demographic transition. Social change and the rising educational and career aspirations of women in many cultures encourage women to delay marriage and postpone reproduction. Delayed reproduction helps to decrease population growth rates and to move a society toward zero population growth under conditions of low birth rates and low death rates. However, there is a great deal of disagreement among world leaders as to how much support should be provided for global family planning efforts.

Age Structure

One important demographic variable in present and future growth trends is a country's **age structure**, the relative number of individuals of each age. Age structure is commonly represented in "pyramids," such as those shown in [Figure 52.21](#). For Italy, the pyramid has a small base, indicating that individuals younger than reproductive age are relatively underrepresented in the population. This situation contributes to the projection of continuing population decrease in Italy. In contrast, Afghanistan has an age structure that is bottom-

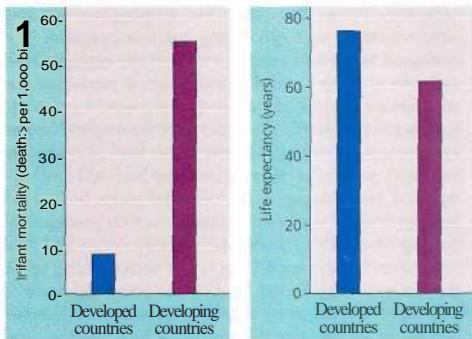

A Figure 52.25 Age-structure pyramids for the human population of three countries (data from 2000). As of 2004, Afghanistan was growing at 2.6% per year, the United States was growing at 0.6% per year, and Italy was declining at -0.1% per year.

heavy, skewed toward young individuals who will grow up and may sustain the explosive growth with their own reproduction. The age structure for the United States is relatively even (until the older, postreproductive ages) except for a bulge that corresponds to the "baby boom" that lasted for about two decades after the end of World War II. Even though couples born during those years have had an average of fewer than two children, the nation's overall birth rate still exceeds the death rate because there are still so many "boomers" and their offspring of reproductive age. Moreover, although the current total reproductive rate in the United States is 2.1 children per woman—approximately replacement rate—the population is projected to grow slowly through 2050 as a result of immigration.

Age-structure diagrams not only predict a population's growth trends, but they can also illuminate social conditions. Based on the diagrams in Figure 52.25, we can predict, for instance, that employment and education opportunities will continue to be a significant problem for Afghanistan in the foreseeable future. The large number of young entering the Afghan population could also be a source of continuing social and political unrest, particularly if their needs and aspirations are not met. In Italy and the United States, a decreasing proportion of younger working-age people will soon be supporting an increasing population of retired "boomers." In the United States, this demographic feature has made the future of Social Security and Medicare a major political issue. Understanding age structures can help us plan for the future.

Infant Mortality and Life Expectancy

[Infant mortality, the number of infant deaths per 1,000 live births, and life expectancy at birth, the predicted average length of life at birth, vary widely among different human populations. These differences reflect the quality of life faced by children at birth. Figure 52.26 contrasts average infant mortality and average life expectancy in the developed and developing countries of the world in 2000. While these averages are markedly different, they do not capture the broad range of the human condition. In 2003, for example, Afghanistan had an infant mortality rate of 143 (14.3%). By contrast, in Japan only 3 children out of every 1,000 born died in infancy. Moreover, life expectancy at birth in Afghanistan was 47 years, compared to 81 years in Japan. While global life expectancy has been increasing since about 1950, more recently it has dropped in a number of regions, including countries of the former Soviet Union and in sub-Saharan Africa. In these regions, the combination of social upheaval, decaying infrastructure, and infectious diseases such as AIDS and tuberculosis is reducing life expectancy. In the East African country of Rwanda, for instance, life expectancy in 2003 was approximately 39 years, about half that in Japan, Sweden, Italy, and Spain.

A Figure 52.26 Infant mortality and life expectancy at birth in developed and developing countries. (Data as of 2003)

Global Carrying Capacity

No ecological question is more important than the future size of the human population. The projected worldwide population size depends on assumptions about future changes in birth and death rates. For 2050, the United Nations projects a global population of approximately 7.5 to 10.3 billion people. In other words, without some catastrophe, an estimated 1.2–4.0 billion people will be added to the population in the next four decades because of the momentum of population growth. But just how many humans can the biosphere support? Will the world be overpopulated in 2050? Is it already overpopulated?

Estimates of Carrying Capacity

For more than three centuries, scientists have asked, What is the carrying capacity of Earth for humans? The first known estimate, 13.4 billion, was made by Anton van Leeuwenhoek in 1679. Since then, estimates have varied from less than 1 billion to over 1,000 billion (1 trillion) people, with an average of 10–15 billion.

Carrying capacity is difficult to estimate, and the scientists who provide these estimates use different methods to get their answers. Some researchers use curves like that produced by the logistic equation (see Figure 52.12) to predict the future maximum of the human population. Others generalize from existing "maximum" population density and multiply this by the area of habitable land. Still other estimates are based on a single limiting factor, such as food, and require many assumptions (such as the amount of available farmland, the average yield of crops, the prevalent diet—vegetarian or meat-based—and the number of calories needed per person per day).

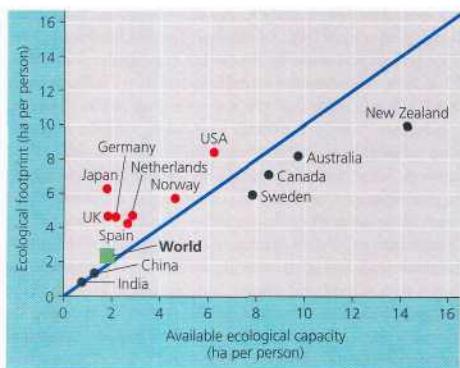

Ecological Footprint

A more comprehensive approach to estimating the carrying capacity of Earth is to recognize that humans have multiple

constraints: We need food, water, fuel, building materials, and other requisites, such as clothing and transportation. The ecological footprint concept summarizes the aggregate land and water area appropriated by each nation to produce all the resources it consumes and to absorb all the waste it generates. Six types of ecologically productive areas are distinguished in calculating the ecological footprint: arable land (land suitable for crops), pasture, forest, ocean, built-up land, and fossil energy land. (Fossil energy land is calculated on the basis of the land required for vegetation to absorb the CO₂ produced by burning fossil fuels.) All measures are converted to land area as hectares (ha) per person (1 ha = 2.47 acres). Adding up all the ecologically productive land on the planet yields about 2 ha per person. Reserving some land for parks and conservation means reducing this allotment to 1.7 ha per person—the benchmark for comparing actual ecological footprints.

Figure 52.27 graphs the ecological footprints for 13 countries and for the whole world as of 1997. We can draw two key conclusions from the graph. First, countries vary greatly in their individual footprint size and in their available ecological capacity (the actual resource base of each country). The United States has an ecological footprint of 8.4 ha per person but has only 6.2 ha per person of available ecological capacity. In other words, the U.S. population is already above carrying capacity. By contrast, New Zealand has a larger ecological footprint of 9.8 ha per person but an available capacity of 14.3 ha per person, so it is below its carrying capacity.

The second conclusion is that, in general, the world was *already* in ecological deficit when the study was conducted. The overall analysis suggests that the world is now at or slightly above its carrying capacity.

A Figure 52.27 Ecological footprint in relation to available ecological capacity. Countries indicated by red dots were in an ecological deficit in 1997 when the study was conducted. Countries indicated by black dots still had resource surpluses relative to the demands of their populations.

We can only speculate about Earth's ultimate carrying capacity for the human population or about what factors will eventually limit our growth. Perhaps food will be the main factor. Malnutrition and famines are common in some regions, but they result mainly from unequal distribution, rather than inadequate production, of food. So far, technological improvements in agriculture have allowed food supplies to keep up with global population growth. However, the principles of energy flow through ecosystems (explained in Chapter 54) tell us that environments can support a larger number of herbivores than carnivores. If everyone ate as much meat as the wealthiest people in the world, less than half of the present world population could be fed on current food harvests.

Perhaps we will eventually be limited by suitable space, like the gannets on ocean islands. Certainly, as our population grows, the conflict over how space will be utilized will intensify, and agricultural land will be developed for housing. There seem to be few limits, however, on how closely humans can be crowded together.

Humans could also run out of nonrenewable resources, such as certain metals and fossil fuels. The demands of many populations have already far exceeded the local and even regional supplies of one renewable resource—water. More than 1 billion people do not have access to sufficient water to meet their basic sanitation needs. It is also possible that the human population will eventually be limited by the capacity of the environment to absorb its wastes. In such cases, Earth's current human occupants could lower the planet's long-term carrying capacity for future generations.

Some optimists have suggested that because of our ability to develop technology, human population growth has no practical limits. Technology has undoubtedly increased Earth's carrying capacity for humans, but as we have emphasized, no population can continue to grow indefinitely. Exactly what the world's human carrying capacity is and under what circumstances we will approach it are topics of great concern and debate. Unlike other organisms, we can decide whether zero population growth will be attained through social changes based on human choices or through increased mortality due to resource limitation, plagues, war, and environmental degradation.

Concept Check 52.6

- How does a population's age structure affect its growth rate?
- What are the relationships among carrying capacity, ecological capacity, and ecological footprint for a country's population? Define each term in your answer.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

Concept 52.1

Dynamic biological processes influence population density, dispersion, and demography

- **Density and Dispersion** (pp. 1137-1139) Population density—the number of individuals per unit area or volume—results from the interplay of births, deaths, immigration, and emigration. Environmental and social factors influence the spacing of individuals into clumped, uniform, or random dispersion patterns.

Activity *Techniques for Estimating Population Density and Size*

- **Demography** (pp. 1139-1141) Populations increase from births and immigration and decrease from deaths and emigration. Life tables, survivorship curves, and reproductive tables summarize specific demographic trends.

Activity *Investigating Survivorship Curves*

Concept 52.2

Life history traits are products of natural selection

- Life history traits are evolutionary outcomes reflected in the development, physiology, and behavior of an organism. (p. 1141).
- **Life History Diversity** (pp. 1141-1142) Big-bang, or semelparous, organisms reproduce a single time and die. In contrast, iteroparous organisms produce offspring repeatedly.
- **"Trade-offs" and Life Histories (pp. 1142-1143)** Life history traits such as brood size, age at maturity, and parental care giving represent trade-offs between conflicting demands for limited time, energy, and nutrients.

Concept 52.3

The exponential model describes population growth in an idealised, unlimited environment

- **Per Capita Rate of Increase (pp. 1143-1144)** If immigration and emigration are ignored, a population's growth rate (the per capita rate of increase) equals birth rate minus death rate.
- **Exponential Growth** (pp. 1144-1145) The exponential growth equation $dN/dt = r_{max}N$ represents a population's potential growth in an unlimited environment, where r_{max} is the maximum per capita, or intrinsic, rate of increase and N is the number of individuals in the population. This model predicts that the larger a population becomes, the faster it grows. Plotting population size over time in such a population yields a J-shaped graph.

Concept 52.4

The logistic growth model includes the concept of carrying capacity

- Exponential growth cannot be sustained for long in any population. A more realistic population model limits growth by incorporating carrying capacity (K), the maximum population size the environment can support (p. 1145).

- **The Logistic Growth Model** (pp. 1145-1146) According to the logistic equation $dN/dt = r_{max}N(K - N)/K$, growth levels off as population size approaches the carrying capacity

- **The Logistic Model and Real Populations** (p. 1146) The logistic model fits few real populations, but it is useful for estimating possible growth.

- **The Logistic Model and Life Histories (p. 1147)** Two hypothetical, but controversial, life history patterns are K-selection, or density-dependent selection, and r-selection, or density-independent selection.

Concept 52.5

Populations are regulated by a complex interaction of biotic and abiotic influences

- **Population Change and Population Density** (p. 1148) In density-dependent populations, death rates rise and birth rates fall with increasing density. In density-independent populations, birth and death rates do not change with increasing density.

Density-Dependent Population Regulation

- (pp. 1148-1150) Density-dependent changes in birth and death rates curb population increase through negative feedback and can eventually stabilize a population near its carrying capacity. Density-dependent limiting factors include intraspecific competition for limited food or space, increased predation, disease, stress due to crowding, and buildup of toxins.

- **Population Dynamics** (pp. 1150-1151) Because changing environmental conditions periodically disrupt them, all populations exhibit some size fluctuations. Metapopulations are groups of populations linked by immigration and emigration.

- **Population Cycles** (pp. 1151-1152) Many populations undergo regular boom-and-bust cycles that are influenced by complex interactions between biotic and abiotic factors.

Biology Labs On-Line *Population EcohlyLab*

Concept 52.6

Human population growth has slowed after centuries of exponential increase

- **The Global Human Population** (pp. 1152-1155) Since about 1650, the global human population has grown exponentially, but within the last 40 years, the rate of growth has fallen by nearly 50%. Differences in age structure show that while some nations are growing rapidly, others are stable or declining in size. Infant mortality rates and life expectancy at birth differ markedly between developed and developing countries.

Activity *Human Population Growth*

Activity *Analyzing Age-Structure Pyramids*
Biology Labs On-line *DemographyLab*

- **Global Carrying Capacity** (pp. 1155-1156) The carrying capacity of Earth for humans is uncertain. Ecological footprint, the aggregate land and water area needed to sustain the people of a nation, is one measure of how close we are to the carrying capacity of Earth. At more than 6 billion people, the world is already in ecological deficit.

TESTING YOUR KNOWLEDGE

Evolution Connection

Write a paragraph contrasting the conditions that favor the evolution of semelparous (one-time) versus iteroparous (repeated) reproduction.

Scientific Inquiry

You are testing the hypothesis that population density of a particular plant species influences the rate at which a pathogenic fungus infects the plant. Because the fungus causes visible scars on the leaves, you can easily determine whether a plant is infected. Design an experiment to test your hypothesis. Include your experimental treatments and control, the data you will collect, and the results expected if your hypothesis is correct.

Biology Labs On-Line *DemographyLab*

Science, Technology, and Society

Many people regard the rapid population growth of developing countries as our most serious environmental problem. Others think that the population growth in developed countries, though smaller, is actually a greater environmental threat. What problems result from population growth in (a) developing countries and (b) the industrialized world? Which do you think is a greater threat, and why?

53

Community Ecology

A Figure 53.1 A savanna community in Chobe National Park, Botswana.

Key Concepts

- 53.1 A community's interactions include competition, predation, herbivory, symbiosis, and disease
- 53.2 Dominant and keystone species exert strong controls on community structure
- 53.3 Disturbance influences species diversity and composition
- 53.4 Biogeographic factors affect community biodiversity
- 53.5 Contrasting views of community structure are the subject of continuing debate

Overview

What Is a Community?

On your next walk through a field or a woodland or even across campus or a park, try to observe some of the interactions between the species present. You may see birds using trees as nesting sites, bees pollinating flowers, spiders trapping insects in their webs, ferns growing in shade provided by trees—a tiny sample of the many interactions between species that exist in any ecological theater. In addition to the physical and chemical factors discussed in Chapter 50, an organism's environment includes biotic factors: other individuals of the same species as well as individuals of other species. Such an assemblage of populations of various species living close enough for potential interaction is called a biological community.

Ecologists define the boundaries of a particular community to fit their research questions. They might study, for example, the community of decomposers and other organisms living on a rotting log, the benthic community in Lake Superior, or the

community of trees and shrubs in Shenandoah National Park. The various animals as well as the grass and trees surrounding the watering hole in Figure 53.1 are all members of a savanna community in southern Africa.

In this chapter, we will examine the factors that are most significant in structuring a community—in determining how many species there are overall, which particular species are present, and the relative abundance of these species. We begin with a fundamental factor influencing community structure: the interactions between the organisms in a community.

Concept 53.1

A community's interactions include competition, predation, herbivory, symbiosis, and disease

Some key relationships in the life of an organism, are its interactions with other species in the community. Ecologists refer to these relationships as interspecific interactions. We will start with the simplest situation: interactions between populations of just two species.

The possible interactions that can link species include competition, predation, herbivory, symbiosis (parasitism, mutualism, and commensalism), and disease. Here we will use the symbols + and — to indicate how each interspecific interaction affects survival and reproduction of the two species engaged in the interaction. For example, in mutualism, the survival and reproduction of each species is increased in the presence of the other; therefore, this is a +/+ interaction. Predation is an example of a +/— interaction, with a positive effect on the survival and reproduction of the predator population and a negative

effect on that of the prey population. A 0 indicates that a population is not affected by the interaction in any known way.

Historically, most ecological research has focused on interactions with a negative effect on at least one species, such as competition and predation. However, positive interactions are ubiquitous, and their contributions to community structure are the subject of much study.

Competition

Interspecific competition occurs when species compete for a particular resource that is in short supply. For instance, the weeds growing in a garden compete with garden plants for soil nutrients and water. Grasshoppers and bison in the Great Plains compete for the grass they both eat. Lynx and foxes in the northern forests of Alaska and Canada compete for prey such as snowshoe hares. In contrast, some resources, such as oxygen, are rarely in short supply; thus, although almost all species use this resource, they do not compete for it. When two species *do* compete for a resource, the result is detrimental to one or both species (—). Strong competition can lead to the local elimination of one of the two competing species, a process called competitive exclusion.

The Competitive Exclusion Principle

In 1934, the Russian ecologist G. F. Gause studied the effects of interspecific competition in laboratory experiments with two closely related species of protists, *Paramecium aurelia* and *Paramecium caudatum*. He cultured the protists under stable conditions with a constant amount of food added every day

When Gause grew the two species in separate cultures, each population grew rapidly and then leveled off at what was apparently the carrying capacity of the culture. But when Gause cultured the two species together, *P. caudatum* was driven to extinction in the culture. Gause inferred that *P. aurelia* had a competitive edge in obtaining food, and he concluded that two species competing for the same limiting resources cannot coexist in the same place. One species will use the resources more efficiently and thus reproduce more rapidly than the other. Even a slight reproductive advantage will eventually lead to local elimination of the inferior competitor. Ecologists call Gause's concept the *competitive exclusion principle*.

Ecological Niches

The sum total of a species' use of the biotic and abiotic resources in its environment is called the species' ecological niche. One way to grasp the concept is through an analogy made by ecologist Eugene Odum: If an organism's habitat is its "address," the niche is the organism's "profession." Put another way, an organism's niche is its ecological role—how it "fits into" an ecosystem. For example, the niche of a tropical tree lizard consists of, among many components, the temperature range it tolerates, the size of branches on which it perches, the time of day when it is active, and the sizes and kinds of insects it eats.

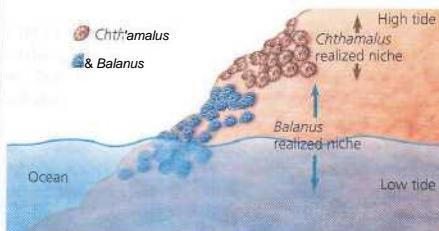

We can use the niche concept to restate the competitive exclusion principle: Two species cannot coexist in a community if their niches are identical. However, ecologically similar species *can* coexist in a community if there are one or more significant differences in their niches (Figure 53.2). As a result of competition, a species' *fundamental niche*, which is the niche potentially

Figure 53.2

Inquiry Can a species' niche be influenced by interspecific competition?

EXPERIMENT

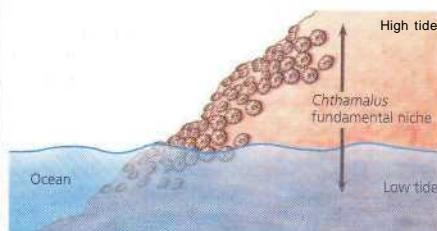

Ecologist Joseph Connell studied two barnacle species—*Balanus balanoides* and *Chthamalus stellatus*—that have a stratified distribution on rocks along the coast of Scotland.

In nature, *Balanus* fails to survive high on the rocks because it is unable to resist desiccation (drying out) during low tides. Its realized niche is therefore similar to its fundamental niche. In contrast, *Chthamalus* is usually concentrated on the upper strata of rocks. To determine the fundamental niche of *Chthamalus*, Connell removed *Balanus* from the lower strata.

RESULTS

When Connell removed *Balanus* from the lower strata, the *Chthamalus* population spread into that area.

Conclusion

The spread of *Chthamalus* when *Balanus* was removed indicates that competitive exclusion makes the realized niche of *Chthamalus* much smaller than its fundamental niche.

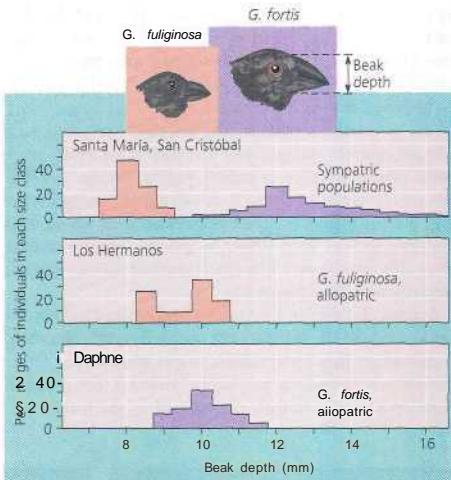

occupied by that species, may be different from its *realized niche*, the niche it actually occupies in a particular environment.

Resource Partitioning

When competition between species having identical niches does not lead to local extinction of either species, it is generally because one species' niche becomes modified. In other words, evolution by natural selection can result in one of the species using a different set of resources. The differentiation of niches that enables similar species to coexist in a community is called **resource partitioning** (Figure 53.3). You can think of resource partitioning in a community as "the ghost of competition past"—indirect evidence of earlier interspecific competition resolved by the evolution of niche differentiation.

Character Displacement

A related line of indirect evidence of the effects of competition comes from comparisons of closely related species whose populations are sometimes allopatric (geographically separate; see Chapter 24) and sometimes sympatric (geographically overlapping). In some cases, the allopatric populations of such species are morphologically similar and use similar resources. By contrast, sympatric populations, which would potentially compete for resources, show differences in body structures and in the resources they use. This tendency for characteristics to be more divergent in sympatric populations of two species than in allopatric populations of the same two species is called character displacement. An example of character displacement is the variation in beak size between different popula-

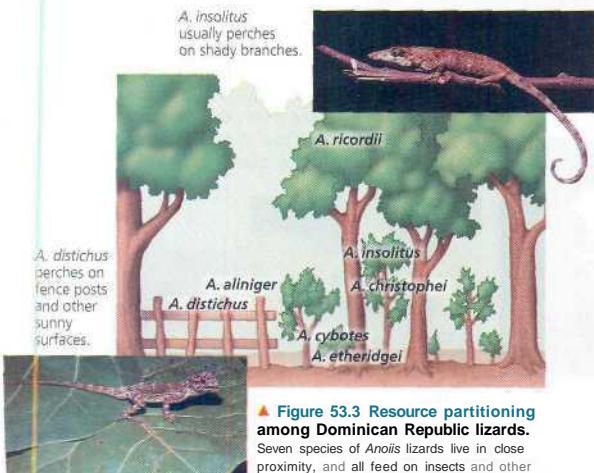

A Figure 53.4 Character displacement: indirect evidence of past competition. Allopatric populations of *Geospiza fuliginosa* and *Geospiza fortis* on Los Hermanos and Daphne Islands have similar beak morphologies (bottom two graphs) and presumably eat similarly sized seeds. However, where the two species are sympatric on Santa María and San Cristóbal, *G. fuliginosa* has a shallower, smaller beak and *G. fortis* a deeper, larger one (top graph), adaptations that favor eating different sizes of seeds.

tions of the Galapagos finches *Geospiza fuliginosa* and *Geospiza fortis* (Figure 53.4).

Predation

Predation refers to a +/— interaction between species in which one species, the predator, kills and eats the other, the prey. Though the term *predation* generally elicits such images as a lion attacking and eating an antelope, it applies to a wide range of interactions defined by the killing of prey. For instance, animals such as certain weevils that chew up or digest plant seeds, thereby killing them, are called *seed predators*. Because eating and avoiding being eaten are prerequisite to reproductive success, the adaptations of both predators and prey tend to be refined through natural selection.

Many important feeding adaptations of predators are both obvious and familiar. Most predators have acute senses that enable them to locate and identify potential prey. In addition, many predators have adaptations such as claws, teeth, fangs, stingers, or poison that help catch and subdue the organisms on which they feed. Rattlesnakes and other pit vipers, for example, locate their prey with heat-sensing

▲ Figure 53.3 Resource partitioning among Dominican Republic lizards.

Seven species of *Anolis* lizards live in close proximity, and all feed on insects and other small arthropods. However, competition for food is reduced because each lizard species has a different perch, thus occupying a distinct niche.

organs located between each eye and nostril, and they kill small birds and mammals by injecting them with toxins through their fangs. Predators that pursue their prey are generally fast and agile, whereas those that lie in ambush are often disguised in their environments.

Just as predators possess adaptations for securing prey, prey animals have adaptations that help them avoid being eaten. Behavioral defenses include hiding, fleeing, and self-defense. Active self-defense is not common, though some large grazing mammals vigorously defend their young from predators such as lions. Other behavioral defenses include alarm calls that summon many individuals of the prey species, which then mob the predator.

Animals also display a variety of morphological and physiological defensive adaptations. For example, cryptic coloration, or camouflage, makes prey difficult to spot (Figure 53.5). Other animals have mechanical or chemical defenses. For example, most predators are strongly discouraged by the familiar de-

fenses of porcupines and skunks. Some animals, such as the poison arrow frog of Costa Rica, can synthesize toxins, while others passively acquire a chemical defense by accumulating toxins from the plants they eat. Animals with effective chemical defenses often exhibit bright warning coloration, or aposematic coloration, like that of the poison arrow frog (Figure 53.6). Aposematic coloration seems to be adaptive; there is evidence that predators are particularly cautious in dealing with potential prey having bright color patterns (see Chapter 1).

Sometimes, one prey species may gain significant protection by mimicking the appearance of another. In Batesian mimicry, a palatable or harmless species mimics an unpalatable or harmful model. For example, the larva of the hawk-moth puffs up its head and thorax when disturbed, looking like the head of a small poisonous snake (Figure 53.7). In this case, the mimicry even involves behavior; the larva weaves its head back and forth and hisses like a snake, in Müllerian mimicry, two or more unpalatable species, such as the cuckoo

bee and yellow jacket, resemble each other (Figure 53.8). Presumably, each species gains an additional advantage because the greater the number of unpalatable prey the more quickly and intensely predators adapt, avoiding any prey with that particular appearance. The mimicry thus acts as a kind of aposematic coloration. In an example of convergent evolution, unpalatable animals in several different taxa have similar patterns of coloration: Black and yellow or red stripes characterize unpalatable animals as diverse as yellow jackets and coral snakes (see Figure 1.27).

Predators also use mimicry in a variety

of ways. For example, some snapping turtles have tongues that resemble a wriggling worm, thus luring small fish; any fish that tries to eat the "bait" is itself quickly consumed as the turtle's strong jaws snap closed.

A Figure 53.7 Batesian mimicry: A harmless species mimics a harmful one.

A Figure 53.8 Müllerian mimicry: Two unpalatable species mimic each other.

Erbivory

Geologists use the term herbivory to refer to a $+/-$ interaction in which an herbivore eats parts of a plant or alga. While the large mammalian herbivores such as cattle, sheep, and water buffalo may be most familiar, most herbivores are small invertebrates, such as grasshoppers and beetles. In the ocean, herbivores include snails, sea urchins, and some tropical fishes, such as the surgeon fish. Like predators, herbivores have specialized adaptations.

Because plants are so chemically diverse, it is advantageous for herbivores to be able to distinguish between toxic and nontoxic plants as well as between more nutritious and less nutritious plants. Many herbivorous insects have chemical sensors on their feet that recognize appropriate food plants. Some mammalian herbivores, such as goats, use their sense of smell to examine plants, rejecting some and eating others. In some cases, they eat just a specific part of a plant, such as the flowers. Many herbivores also have specialized teeth or digestive systems adapted for processing vegetation (see Chapter 41).

Unlike prey animals, of course, plants cannot run away to avoid being eaten. Instead, a plant's main arsenal against herbivores includes chemical toxins, often in combination with spines and thorns. Among the plant compounds that serve as chemical weapons are the poison strychnine, produced by the tropical vine *Strychnos toxifera*; nicotine, from the tobacco plant; and tannins, from a variety of plant species. Compounds that are not toxic to humans but may be distasteful to many herbivores are responsible for the familiar flavors of cinnamon, cloves, and peppermint. Certain plants produce chemicals that cause abnormal development in some insects that eat them.

Parasitism

Parasitism is a $+/-$ symbiotic interaction in which one organism, the parasite, derives its nourishment from another organism, its host, which is harmed in the process. (This text adopts the most general definition of *symbiosis* as an interaction in which two organisms of different species live together in direct contact, including parasitism, mutualism, and commensalism. However, some biologists use *symbiosis* more specifically as a synonym for mutualism.) Parasites that live within the body of their host, such as tapeworms and malarial parasites, are called endoparasites; parasites that feed on the external surface of a host, such as ticks and lice, are called ectoparasites. In a particular type of parasitism called parasitoidism, insects—usually small wasps—lay eggs on or in living hosts. The larvae then feed on the body of the host, eventually killing it.

Many parasites have a complex life cycle involving a number of hosts. For instance, the life cycle of the blood fluke, which currently infects approximately 200 million people

around the world, involves two hosts: humans and freshwater snails (see Figure 33.11). Some parasites change the behavior of their hosts in a way that increases the probability of the parasite being transferred from one host to another. For instance, the presence of parasitic acanthocephalan (spiny-headed) worms leads their crustacean hosts to engage in a variety of atypical behaviors, including leaving the protection of cover and moving into the open. As a result of their modified behavior, the crustaceans have a greater chance of being eaten by the birds that are the second host in the parasitic worm's life cycle.

Parasites can have a significant effect on the survival, reproduction, and density of their host population, either directly or indirectly. For example, ticks that live as ectoparasites on moose weaken their hosts by withdrawing blood and causing hair breakage and loss, increasing the chance that the moose will die from cold stress or predation by wolves. Some of the declines of the moose population on Isle Royale, Michigan, have been attributed to tick outbreaks (see Figure 52.18).

Disease

In terms of their effect on host organisms, pathogens, or disease-causing agents, are similar to parasites ($+/-$). Pathogens are typically bacteria, viruses, or protists, but fungi and prions (protein bodies; see Chapter 18) may also be pathogenic. In contrast to many parasites, which are relatively large, multicellular organisms, most pathogens are microscopic. Further, while most parasites cause nonlethal damage to their hosts—by pilfering nutrients, for example—many pathogens inflict lethal harm.

Despite the potential of pathogenic organisms to limit populations, pathogens have been the subject of relatively few ecological studies. This imbalance is now being addressed as dramatic events highlight the ecological importance of disease. One such event was the appearance of sudden oak death, a tree disease caused by a fungus-like protistan pathogen called *Phytophthora ramorum*. By 2004, sudden oak death had spread 650 km from where it was first discovered in Marin County, California, in 1994. In one decade, the disease killed tens of thousands of oaks of several species from the central California coast to southern Oregon and in the process changed the structure of the affected forest communities.

Animal populations also tend to decline in the face of disease epidemics. From 1999 to 2004, the mosquito-transmitted West Nile virus spread from New York to 46 other states, killing hundreds of thousands of birds as it moved across the United States. Crows appear to be particularly susceptible to this disease. Meanwhile, the number of human cases in the United States rose from 62 in 1999 to 9,862 in 2003, resulting in 7 and 264 deaths, respectively. These statistics indicate a fraction of the total exposure, since most people exposed to the virus show no symptoms.

A. Figure 53.9 Mutualism between acacia trees and ants. Certain species of acacia trees have hollow thorns that house stinging ants of the genus *Pseudomyrmex*. The ants feed on sugar produced by nectaries on the tree and on protein-rich swellings (orange in the photograph) at the tips of leaflets. The acacia benefits because the pugnacious ants, which attack anything that touches the tree, remove fungal spores and other debris and clip vegetation that grows close to the acacia.

Mutualism

Mutualistic symbiosis, or mutualism, is an interspecific interaction that benefits both species (+/+). **Figure 53.9** illustrates mutualism between ants and acacia trees in Central and South America. We have described many other examples of mutualism in previous chapters: nitrogen fixation by bacteria in the root nodules of legumes; the digestion of cellulose by microorganisms in the digestive systems of termites and ruminant mammals; photosynthesis by unicellular algae in the tissues of corals; and the exchange of nutrients in mycorrhizae, the association of fungi and the roots of plants.

Mutualistic relationships sometimes involve the evolution of related adaptations in both species, with changes in either species likely to affect the survival and reproduction of the other. For example, most flowering plants have adaptations such as fruit or nectar that attract animals that function in pollination or seed dispersal. The hypothesis is that natural selection might favor evolution of such adaptations because by sacrificing organic materials such as nectar rather than pollen or seeds to a consumer, the plant loses fewer gametes and thereby increases its relative reproductive success. In turn, many animals have adaptations that help them find and consume nectar.

Commensalism

Commensalism is defined as an interaction between species that benefits one of the species but neither harms nor helps the other (+/0). Commensal interactions have been difficult to document in nature because any close association between species likely affects both species, if only slightly. For instance,

A. Figure 53.10 A possible example of commensalism between cattle egrets and water buffalo.

"hitchhiking" species, such as algae that grow on the shells of aquatic turtles or barnacles that attach to whales, are sometimes considered commensal. The hitchhikers gain access to a substrate while seeming to have little effect on their ride. However, the hitchhikers may in fact slightly decrease the reproductive success of their hosts by reducing the hosts' efficiency of movement in searching for food or escaping from predators. Conversely, the hitchhikers may provide a benefit in the form of camouflage.

Some putative commensal associations involve one species obtaining food that is inadvertently exposed by another. For instance, cowbirds and cattle egrets feed on insects flushed out of the grass by grazing bison, cattle, horses, and other herbivores (**Figure 53.10**). Because the birds increase their feeding rates when following the herbivores, they clearly benefit from the association. Much of the time, the herbivores may be unaffected by the relationship. However, they, too, may sometimes derive some benefit; the birds tend to be opportunistic feeders that occasionally remove and eat ticks and other ectoparasites from the herbivores. They may also give warning to the herbivores of a predator's approach.

Interspecific Interactions and Adaptation

Earlier in this book, we discussed the concept of coevolution, reciprocal evolutionary adaptations of two interacting species. A change in one species acts as a selective force on another species, whose adaptation in turn acts as a selective force on the first species. This linkage of adaptations requires that genetic change in one of the interacting populations of the two species be tied to genetic change in the other population. An example of such dual adaptation that probably qualifies as

coevolution is the gene-for-gene recognition between a plant species and a species of avirulent pathogen (see Figure 39.31). In contrast, the aposematic coloration of various tree frogs and the corresponding aversion reactions of various predators do *not* qualify as coevolution because these are adaptations to multiple species in the community rather than coupled genetic changes in just two interacting species.

In fact, the term *coevolution* may often be used too loosely in describing the adaptations of certain organisms to the presence of other organisms in a community. There is little evidence for true coevolution in most cases of interspecific interactions. Nevertheless, the more generalized adaptation of organisms to other organisms in their environment is a fundamental characteristic of life. At present, much evidence seems to indicate that competition and predation are the key processes driving community dynamics. But this conclusion is based mainly on research in temperate communities. Far fewer data exist for interspecific interactions in tropical communities. In addition, the hypothesis that competition and predation control community structure is being challenged by ecologists exploring the influences of parasitism, disease, mutualism, and commensalism on communities.

Concept Check 53.1

- Explain how interspecific competition, predation, and mutualism differ in their effects on the interacting populations of two species.
- According to the competitive exclusion principle, what outcome is expected when two species compete for a resource? Why?
- Is the evolution of Batesian mimicry an example of coevolution? Explain your answer.

For suggested answers, see Appendix A.

Concept 53.2

Dominant and keystone species exert strong controls on community structure

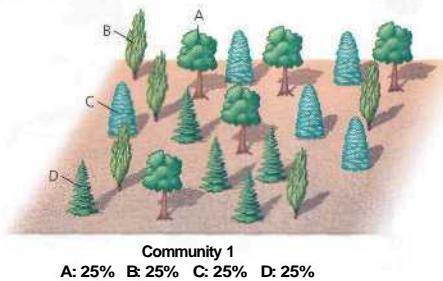

In general, a small number of the species in a community exert strong control on that community's structure, particularly on the composition, relative abundance, and diversity of its species. Before examining the effects of these particularly influential species, we first need to consider two fundamental features of community structure: species diversity and feeding relationships.

Species Diversity

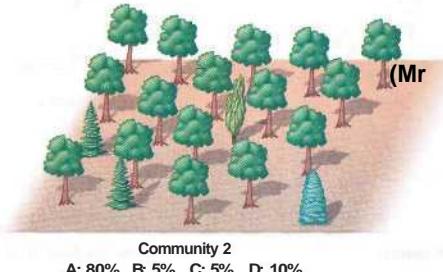

The species diversity of a community—the variety of different kinds of organisms that make up the community—has two components. One is species richness, the total number of different species in the community. The other is the **relative abundance** of the different species, the proportion each species represents of the total individuals in the community. For example, imagine two small forest communities, each with 100 individuals distributed among four different tree species (A, B, C, and D) as follows:

Community 1: 25A, 25B, 25C, 25D
Community 2: 80A, 5B, 5C, 10D

The species richness is the same for both communities because they both contain four species, but the relative abundance is very different (Figure 53.11). You would easily notice the four different types of trees in community 1, but without looking carefully, you might see only the abundant species A in the second forest. Most observers would intuitively describe community 1 as the more diverse of the two communities. Indeed, for an ecologist, the species diversity of the community is dependent on *both* species richness and relative abundance.

Community 1
A: 25% B: 25% C: 25% D: 25%

Community 2
A: 80% B: 5% C: 5% D: 10%

A Figure 53.11 Which forest is more diverse? Ecologists would say that community 1 has greater species diversity, a measure that includes both species richness and relative abundance.

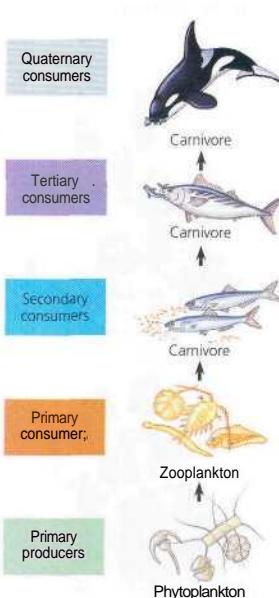

Determining the number of species in a community is easier said than done. Various sampling techniques can be employed, but since most species in a community are relatively rare, it may be hard to come up with a sample size large enough to be representative. It is particularly difficult to accurately census the highly mobile or less visible members of communities, such as mites and nematodes. Nevertheless, measuring species diversity is essential not only for understanding community structure, but for conserving biodiversity, as you will read in Chapter 55.

Trophic Structure

The structure and dynamics of a community depend to a large extent on the feeding relationships between organisms—the **trophic structure** of the community. The transfer of food energy up the trophic levels from its source in plants and other photosynthetic organisms (primary producers) through herbivores (primary consumers) to carnivores (secondary and tertiary consumers) and eventually to decomposers is referred to as a **food chain** (Figure 53.12).

A terrestrial food chain

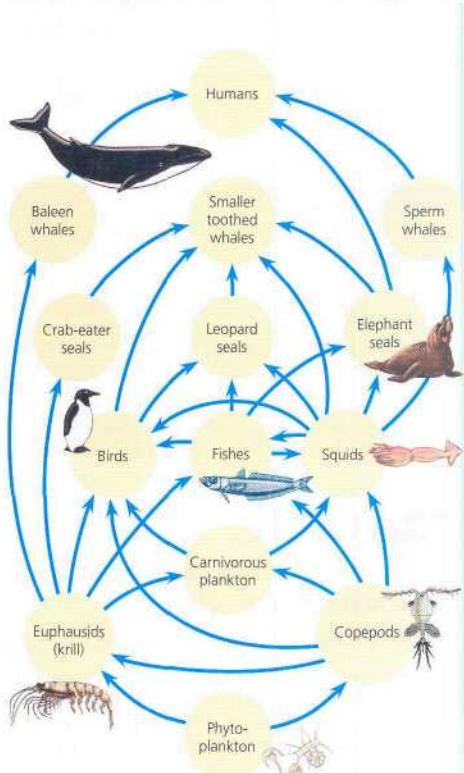

A marine food chain

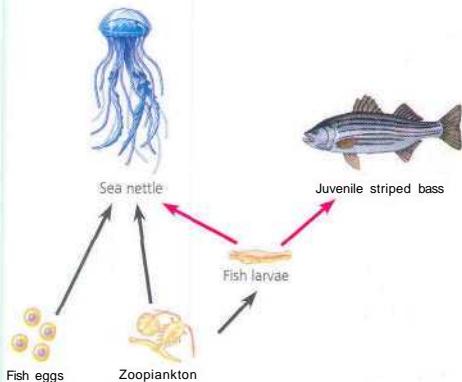

A Figure 53.12 Examples of terrestrial and marine food chains. The arrows trace energy and nutrients that pass through the trophic levels of a community when organisms feed on one another. Decomposers, which "feed" on organisms from all trophic levels, are not shown here.

Food Webs

In the 1920s, Oxford University biologist Charles Elton recognized that food chains are not isolated units but are linked together in **food webs**. An ecologist can summarize the trophic relationships of a community by diagramming a food web with arrows linking species according to who eats whom. For example, Figure 53.13 is a simplified food web for an antarctic pelagic community. The primary producers in the community are phytoplankton, which serve as food for the dominant grazing zooplankton, especially euphausiids (krill) and copepods, both of which are crustaceans. These zooplankton species are in turn eaten by various carnivores, including other plankton, penguins, seals, fishes, and baleen whales. Squids, which are carnivores that feed on fishes as well as zooplankton, are another important link in these food webs, as they are in turn eaten by seals and toothed whales. During the time

A Figure 53.13 An antarctic marine food web. Arrows follow the transfer of food from the producers (phytoplankton) up through the trophic levels. For simplicity, this diagram omits decomposers.

A Figure 53.14 Partial food web for the Chesapeake Bay estuary on the U.S. Atlantic coast. The sea nettle (*Chrysaora quinquecirrha*) and juvenile striped bass (*Morone saxatilis*) are the main predators of fish larvae (bay anchovy and several other species). Note that sea nettles are secondary consumers (black arrows) when they eat zooplankton and tertiary consumers (red arrows) when they eat fish larvae, which are themselves secondary consumers of zooplankton.

when whales were commonly hunted for food, humans became the top predator in this food web. Having hunted many whale species to low numbers, humans are now harvesting at lower trophic levels, catching krill as well as fishes.

How are food chains linked into food webs? First, a given species may weave into the web at more than one trophic level. For example, in the antarctic food web, euphausiids feed on phytoplankton as well as on other grazing zooplankton, such as copepods. Such "nonexclusive" consumers are also found in terrestrial communities. For example, foxes are omnivores with diets that include berries and other plant materials, herbivores such as mice, and other predators, such as weasels. Humans are among the most versatile of omnivores.

Food webs can be very complicated, but we can simplify them for easier study in two ways. First, we can group species with similar trophic relationships in a given community into broad functional groups. For example, in Figure 53.13, more than 100 phytoplankton species are grouped as the primary producers in the food web. A second way to simplify a food web for closer study is to isolate a portion of the web that interacts very little with the rest of the community. **Figure 53.14** illustrates a partial food web for sea nettles (jellies) and juvenile striped bass in Chesapeake Bay.

Limits on Food Chain Length

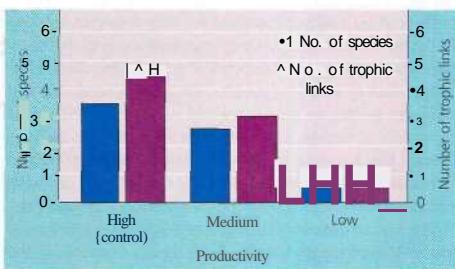

Each food chain within a food web is usually only a few links long. In the antarctic web of Figure 53.13, there are rarely more than seven links from the producers to any top-level

predator, and there are even fewer links in most chains. In fact, most food webs studied to date consist of five or fewer links, as Charles Elton first pointed out in the 1920s.

Why are food chains relatively short? There are two main hypotheses. One, the energetic hypothesis, suggests that the length of a food chain is limited by the inefficiency of energy transfer along the chain. As you will read in Chapter 54, only about 10% of the energy stored in the organic matter of each trophic level is converted to organic matter at the next trophic level. Thus, a producer level consisting of 100 kg of plant material can support about 10 kg of herbivore biomass and 1 kg of carnivore biomass. The energetic hypothesis predicts that food chains should be relatively longer in habitats of higher photo-synthetic productivity, since the starting amount of energy is greater.

A second hypothesis, the dynamic stability hypothesis, proposes that long food chains are less stable than short chains. Population fluctuations at lower trophic levels are magnified at higher levels, potentially causing the local extinction of top predators. In a variable environment, top predators must be able to recover from environmental shocks (such as extreme winters) that can reduce the food supply all the way up the food chain. The longer the food chain, the slower the recovery from environmental setbacks for top predators. This hypothesis predicts that food chains should be shorter in unpredictable environments.

Most of the data available support the energetic hypothesis. For example, ecologists have used tree-hole communities in tropical forests as experimental models to test the energetic hypothesis. Many trees have small branch scars that rot, forming small holes in the tree trunk. The tree holes hold water and provide a habitat for tiny communities consisting of decomposer microorganisms and insects that feed on leaf litter, as well as predatory insects. **Figure 53.15** shows the results of

K Figure 53.15 Test of the energetic hypothesis for the restriction of food chain length. Researchers manipulated the productivity of tree-hole communities in Queensland, Australia, by providing leaf litter input at three levels: high litter input = natural (control) rate of litter fall; medium = 1/e times natural rate; and low = 1/e/e times natural rate. Reducing energy input reduced food chain length, a result consistent with the energetic hypothesis.

a set of experiments in which researchers manipulated productivity (leaf litter falling into the tree holes). As predicted by the energetic hypothesis, holes with the most leaf litter, and hence the greatest total food supply at the producer level, supported the longest food chains.

Another factor that may limit food chain length is that animals in a food chain tend to be larger at successive trophic levels (except for parasites). The size of an animal and its feeding mechanism put some upper limit on the size of food it can take into its mouth. And except in a few cases, large carnivores cannot live on very small food items because they cannot procure enough food in a given time to meet their metabolic needs. Among the exceptions are baleen whales, huge suspension feeders with adaptations that enable them to consume enormous quantities of krill and other small organisms (see Figure 41.2).

Species with a Large Impact

Certain species have an especially large impact on the structure of entire communities either because they are highly abundant or because they play a pivotal role in community dynamics. The impact of these species can occur either through their trophic interactions or through their influences on the physical environment.

Dominant Species

Dominant species are those species in a community that are the most abundant or that collectively have the highest biomass (the total mass of all individuals in a population). As a result, dominant species exert a powerful control over the occurrence and distribution of other species. For example, the abundance of sugar maples, the dominant plant species in many eastern North American forest communities, has a major impact on abiotic factors such as shading and soil, which in turn affect which other species live there.

There is no single explanation for why a species becomes dominant in a community. One hypothesis suggests that dominant species are most competitive in exploiting limited resources such as water or nutrients. Another explanation is that dominant species are most successful at avoiding predation or the impact of disease. This latter idea could explain the high biomass that invasive species (species, generally introduced by humans, that take hold outside their native range) can attain in environments lacking their natural predators and pathogens.

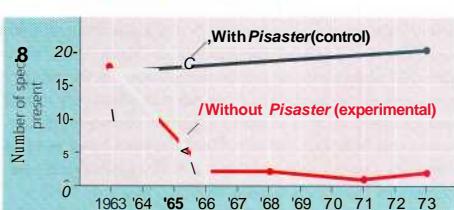

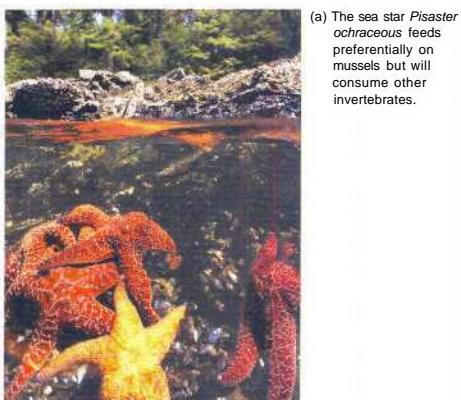

One way to discover the impact of a dominant species is to remove it from the community. Humans have carried out this type of experiment many times by accident. For example, the American chestnut was a dominant tree in eastern North American deciduous forests before 1910, making up more than 40% of the canopy (top-story) trees. Then humans accidentally introduced the fungal disease called chestnut blight to New York City via nursery stock imported from Asia. Between 1910 and 1950, this fungus, which attacks only chestnuts,

killed all the chestnut trees in eastern North America. The once-dominant tree of many of these forests was eliminated.

In this case, removing the dominant species apparently had a relatively small impact on most of the other species. Species of oak, hickory, beech, and red maple that were already present in the forest increased in abundance and replaced the chestnut. No mammals or birds seemed to be seriously affected by the loss of this dominant species. Some insect species, however, were significantly affected. Fifty-six species of moths and butterflies fed on the American chestnut. Of these, 7 species became extinct, though the other 49 species, which did not feed exclusively on the chestnut, still survive. This is only one example of a community response to the loss of a dominant species. More research is needed before we can generalize about the overall effects of such losses.

Keystone Species

In contrast to dominant species, keystone species are not necessarily abundant in a community (Figure 53.16a). They

(b) When *Pisaster* was removed from an intertidal zone, mussels eventually took over the rock face and eliminated most other invertebrates and algae. In a control area from which *Pisaster* was not removed, there was little change in species diversity.

A Figure 53.16 Testing a keystone predator hypothesis.

exert strong control on community structure not by numerical might but by their pivotal ecological roles, or niches. A good way to identify keystone species is by removal experiments, which is how ecologist Robert Paine of the University of Washington first developed the concept of keystone species. The sea star *Pisaster ochraceus* is a predator of mussels such as *Mytilus californianus* in rocky intertidal communities of western North America. *M. californianus* is a dominant species, a superior competitor for space. Predation by *Pisaster* offsets this competitive edge and allows other species to use the space vacated by *Mytilus*. After Paine removed *Pisaster* from rocky intertidal areas, the abundant mussels were able to monopolize space and exclude other invertebrates and algae from attachment sites (Figure 53.16b). When sea stars were present, 15 to 20 species of invertebrates and algae occurred in the intertidal zone. But after experimental removal of *Pisaster*, species diversity quickly declined to fewer than 5 species. *Pisaster* thus acts as a keystone species, exerting an influence on the whole community that is not reflected in its abundance.

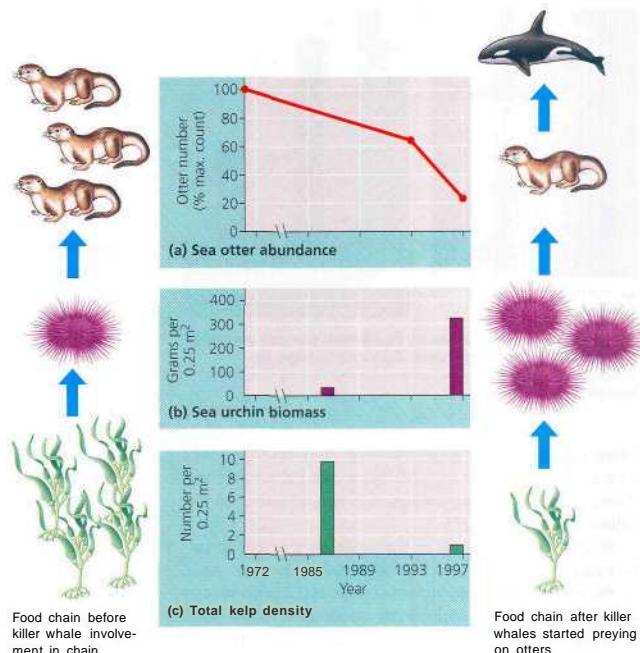

The sea otter, *Enhydra lutris*, a keystone predator in the North Pacific, offers another example. Sea otters feed on sea

urchins, and sea urchins feed mainly on kelp. In areas where sea otters are abundant, sea urchins are rare and kelp forests are well developed. Where sea otters are rare, sea urchins are common and kelp is almost absent. Over the last 20 years, killer whales have been preying on sea otters as the whales' usual prey has declined. As a result, sea otter populations have declined precipitously in large areas off the coast of western Alaska (Figure 53.17), sometimes at rates as high as 25% per year. The loss of this keystone species has allowed sea urchin populations to increase, resulting in the destruction of kelp forests.

Ecosystem "Engineers" (Foundation Species)

Some organisms exert their influence not through their trophic interactions but by causing physical changes in the environment that affect the structure of the community. Such organisms may alter the environment through their behavior or by virtue of their large collective biomass.

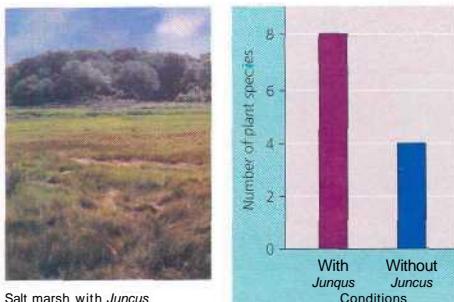

An example of a species that dramatically alters its physical environment is the beaver (Figure 53.18), which, through tree

* **Figure 53.17** Sea otters as keystone predators in the North Pacific. The graphs correlate changes over time in sea otter abundance (a) with changes in sea urchin biomass (b) and changes in kelp density (c) in kelp forests at Adak Island (part of the Aleutian Island chain). The food chains alongside the graphs symbolically indicate the relative abundance of species before and after killer whales entered the chain.

A Figure 53.18 Beavers as ecosystem "engineers" in temperate and boreal forests. By felling trees, building dams, and creating ponds, beavers can transform large areas of forest into flooded wetlands.

Salt marsh with *Juncus* (foreground)

A Figure 53.19 Facilitation by black rush (*Juncus gerardi*) in New England salt marshes. Black rush facilitates the occupation of the middle upper zone of the marsh, which increases local plant species richness.

felling and dam building, can transform landscapes on a very large scale. Species with such effects are called ecosystem "engineers" or, to avoid implications of conscious intent, "lounation species."

By altering the structure or dynamics of the environment, foundation species act as facilitators that have positive effects on the survival and reproduction of some of the other species in the community. For example, by modifying soils, the black rush *Juncus gerardi* increases the species richness in some zones of New England salt marshes. *Juncus* helps prevent salt buildup in the soil by shading the soil surface, which reduces evaporation. *Juncus* also prevents the salt marsh soils from becoming anoxic as it transports oxygen to its below-ground tissues. Sally Hacker and Mark Bertness, of Brown University, uncovered some of Junais's facilitation effects through removal experiments (Figure 53.19). When they removed *Juncus* from study plots in a New England salt marsh, three other plant species died out. Hacker and Bertness suggest that without *Juncus*, the upper middle intertidal zone would support approximately 50% fewer plant species.

Bottom-Up and Top-Down Controls

Simplified models based on relationships between adjacent trophic levels are useful for discussing how biological communities might be organized. For example, let's consider the three possible relationships between plants (V for vegetation) and herbivores (H):

$$V \rightarrow H \quad V \leftarrow H \quad V \leftrightarrow H$$

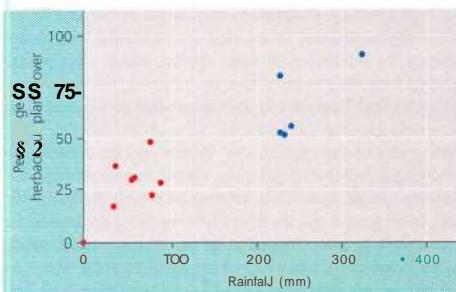

The arrows indicate that a change in the biomass (total mass) of one trophic level causes a change in the other trophic level. $V \rightarrow H$ means that an increase in vegetation will impact (increase) the numbers or biomass of herbivores, but not vice

versa. In this situation, herbivores are limited by vegetation, but vegetation is not limited by herbivory. In contrast, $V \leftarrow H$ means that an increase in herbivore biomass will have an impact on vegetation (decreasing it), but not vice versa. A double-headed arrow indicates that feedback flows in both directions, with each trophic level sensitive to changes in the biomass of the other.

Based on the possible interactions in our example, we can define two models of community organization: the bottom-up model and the top-down model. The $V \rightarrow H$ linkage suggests a bottom-up model, which postulates a unidirectional influence from lower to higher trophic levels. In this case, the presence or absence of mineral nutrients (N) controls plant (V) numbers, which control herbivore (H) numbers, which in turn control predator (P) numbers. The simplified bottom-up model is thus $N \wedge V \rightarrow H \rightarrow P$. To change the community structure of a bottom-up community, you need to alter biomass at the lower trophic levels. For example, if you add mineral nutrients to stimulate growth of vegetation, then the higher trophic levels should also increase in biomass. If you add predators to or remove predators from a bottom-up community, however, the effect will not extend down to the lower trophic levels.

In contrast, the top-down model postulates that the influence moves in the opposite direction: It is mainly predation that controls community organization because predators limit herbivores, which in turn limit plants, which in turn limit nutrient levels through their uptake of nutrients during growth and reproduction. The simplified top-down model is thus $TV \leftarrow V \leftarrow H \leftarrow P$ and is also called the *trophic cascade model*. For example, in a lake community with four trophic levels, the top-down model predicts that removing the top carnivores will increase the abundance of primary carnivores, in turn decreasing herbivores, increasing phytoplankton, and eventually decreasing concentrations of mineral nutrients. If there were only three trophic levels in a lake, removing the primary carnivores would increase the herbivores and decrease the phytoplankton, causing nutrient levels to rise. The effects of any manipulation thus moves down the trophic structure as a series of +/- effects.

Many intermediate models between the bottom-up and top-down extremes are possible. For example, all the interactions between trophic levels may be reciprocal (*). Or, the direction of interaction may alternate over time. For instance, one long-term experimental study of a desert shrub community in Chile showed that controls on primary producer biomass shift periodically from bottom-up to top-down, depending on the amount of rainfall (Figure 53.20). During wet years triggered by the El Niño Southern Oscillation, top-down controls by predators and herbivores prevail. In contrast, during dry years, bottom-up control by moisture limitation of plant growth is most important. Despite the discovery of complex scenarios such as this shifting direction of

k Figure 53.20 Relationship between rainfall and herbaceous plant cover in a desert shrub community in Chile. Moisture limitation on plant growth during dry non-El Niño years (red points) creates strong bottom-up control on this community, whereas abundant moisture during El Niño years (blue points) stimulates increased plant and animal abundance, inducing strong top-down control.

control, the simplified models discussed in this section remain valuable as a starting point for the analysis of communities. Let's look at one example where ecologists have applied these simple models to counter complex pollution problems in lakes.

Pollution has degraded the freshwater lakes in many countries. Because many freshwater lake communities seem to be structured according to the top-down model, ecologists have a potential means of improving water quality. We can summarize this strategy, called **biomanipulation**, with a diagram:

In lakes with three trophic levels, for example, removing fish should improve water quality by increasing zooplankton and thereby decreasing algal populations. In lakes with four trophic levels, adding top predators should have the same effect.

Ecologists applied biomanipulation on a large scale in Lake Vesijärvi in southern Finland. Lake Vesijärvi is a large (110 km^2), shallow lake that was heavily polluted with city sewage and industrial wastewater until 1976. Pollution controls then stopped these inputs, and the water quality of the lake began to recover. But by 1986, massive blooms of cyanobacteria began to occur in the lake. These blooms coincided with a very dense population of roach, a fish that had

accumulated during the years of mineral nutrient (pollution) input. Roach eat zooplankton, and by reducing zooplankton, they also reduced feeding on cyanobacteria and algae, which then increased in abundance. To reverse these changes, ecologists removed 1,018 tons of fish from Lake Vesijärvi between 1989 and 1993, reducing roach to about 20% of their former abundance. At the same time, the ecologists stocked the lake with pike perch, a predatory fish that eats roach. This added a fourth trophic level to the lake, which kept down the population of roach (the main carnivore in the lake). Biomanipulation was a success in Lake Vesijärvi. The water became clear, and cyanobacterial blooms ended in 1989. The lake remains clear even though the roach removal ended in 1993.

As these examples show, communities vary in their relative degree of bottom-up and top-down control. To manage agricultural landscapes, national parks, reservoirs, and marine fisheries, scientists need to understand the dynamics of each particular community.

Concept Check 53.2

- Describe the two components of species diversity. Explain how two communities that contain the same number of species can differ in species diversity.
- Describe two hypotheses that explain why food chains are usually short, and a key prediction of each hypothesis.
- How does a dominant species' effect on community structure differ from a **keystone species' effect**?
- How do top-down and bottom-up controls on community organization differ?

For suggested answers, see Appendix A.

Concept 53.3

Disturbance influences species diversity and composition

Decades ago, most ecologists favored the traditional view that biological communities are in a state of equilibrium, a more or less stable balance, unless seriously disturbed by human activities. This "balance of nature" view focused on interspecific competition as a key factor determining community composition and maintaining stability in communities. Stability in this context refers to the tendency of a community to reach and maintain a relatively constant composition of species in the face of disturbances. But in many communities, at least on a local scale, change seems to be more common than stability. This

recent emphasis on change has led to a **nonequilibrium model**, which describes communities as constantly changing after being buffeted by disturbances. We will now take a look at the influence of disturbances on community structure and composition.

What Is Disturbance?

A **disturbance** is an event, such as a storm, fire, flood, drought, overgrazing, or human activity, that changes a community, removes organisms from it, and alters resource availability. The types of disturbances and their frequency and severity vary from community to community. A high level of disturbance is generally the result of a high intensity and high frequency of disturbance, while low disturbance levels can result from either a low intensity or low frequency of disturbance. Storms disturb almost all communities, even those in deep oceans. Fire is a significant disturbance in most terrestrial communities; in fact, grasslands and chaparral biomes are dependent on regular burning (Figure 53.21). Freezing is a frequent occurrence in many rivers, lakes, and ponds, and many streams and ponds are disturbed by spring flooding and seasonal drying. By gathering data from specific communities over many years, ecologists are beginning to appreciate the impact of disturbances.

Although the term *disturbance* implies a negative impact on communities, this is not always the case. For example, disturbances often create opportunities for species that have not previously occupied habitats in the community. Small-scale disturbances sometimes enhance environmental patchiness, which can be a key to maintaining species diversity in a community. The **intermediate disturbance hypothesis**, which is supported by a broad range of studies of terrestrial and aquatic communities, suggests that moderate levels of disturbance can create conditions that foster greater species diversity than low

or high levels of disturbance. High levels of disturbance reduce species diversity by creating environmental stresses that exceed the tolerances of many species, which are then excluded from the community, or by subjecting the community to such a high frequency of disturbance that slowly colonizing or slowly growing species are excluded. At the other extreme, low levels of disturbance can reduce species diversity by allowing competitively dominant species to exclude less competitive species. Meanwhile, intermediate levels of disturbance can foster greater species diversity by opening up habitats for occupation by less competitive species yet not creating conditions so severe that they exceed the environmental tolerances or rate of recover^y by potential community members. Frequent small-scale disturbances can also prevent large-scale disturbances. The major fires in Yellowstone National Park during the summer of 1988 are an example of what can happen in the absence of smaller disturbances. Much of this park was dominated by lodgepole pine, a tree that requires the rejuvenating influence of periodic fires. Lodgepole cones remain closed until exposed to intense heat. When a forest fire destroys the parent trees, the cones open and the seeds are released. The new generation of lodgepole pines can then thrive on nutrients released from the burned trees and on the direct sunlight that was blocked by the old forest.

For decades, fire suppression by humans had extinguished small lightning-induced fires in Yellowstone Park. The result was that the old trees continued to live, and no patches of young trees grew. By 1988, about one-third of the Yellowstone trees were 250 to 300 years old. Lodgepole pines that are over 100 years old become increasingly flammable. The drought conditions of 1988, combined with the fuel that had accumulated in the mature trees, resulted in a large-scale fire that destroyed much of the park. But by the following year, burned areas in Yellowstone were largely covered with new vegetation,

(a) Before a controlled burn.
A prairie that has not burned for several years has a high proportion of detritus (dead grass).

(b) During the burn. The detritus serves as fuel for fires.

(c) After the burn. Approximately one month after the controlled burn, virtually all of the biomass in this prairie is living.

A Figure 53.21 Long-term effects of fire on a tallgrass prairie community in Kansas.
The trees in the photographs were growing along a stream and were not burned during the study.

(a) **Soon after fire.** As this photo taken soon after the fire shows, the burn left a patchy landscape. Note the unburned trees in the distance.

(b) **One year after fire.** This photo of the same general area taken the following year indicates how rapidly the community began to recover. A variety of herbaceous plants, different from those in the former forest, cover the ground.

A **Figure 53.22** Patchiness and recovery following a large-scale disturbance. The 1988 Yellowstone National Park fire destroyed large areas of forests dominated by balsam pines.

demonstrating that communities can often respond very rapidly to even such massive disturbance (**Figure 53.22**).

Studies of the Yellowstone forest community and many others indicate that they are nonequilibrium communities, changing continually because of natural disturbances and the internal processes of growth and reproduction. And there is mounting evidence that some amount of nonequilibrium resulting from disturbance is the norm for most communities.

Human Disturbance

Of all animals, humans have the greatest impact on biological communities worldwide. Agricultural development has disrupted what were once the vast grasslands of the North American prairie. Logging and clearing for urban development, mining, and farming have reduced large tracts of forests to small patches of disconnected woodlots in many parts of the United States and throughout Europe. After forests are clear-cut and left alone, weedy and shrubby vegetation often colonizes the area and dominates it for many years. This type of vegetation is also found in agricultural fields that are no longer under cultivation and in vacant lots and construction sites that are periodically cleared.

Human disturbance of communities is by no means limited to the United States and Europe; nor is it a recent problem. Tropical rain forests are quickly disappearing as a result of clear-cutting for lumber and pastureland. And centuries of overgrazing and agricultural disturbance have contributed to the current famine in parts of Africa by turning seasonal grasslands into great barren areas.

Because human disturbance is often severe, it usually reduces species diversity in communities. In Chapter 55, we will take a closer look at how community disturbance by human activities is affecting the diversity of life.

Ecological Succession

Changes in community composition and structure are most apparent after some disturbance, such as a glacier or a volcanic eruption, strips away all the existing vegetation. The disturbed area may be colonized by a variety of species, which are gradually replaced by other species, which are in turn replaced by still other species—a process called **ecological succession**.

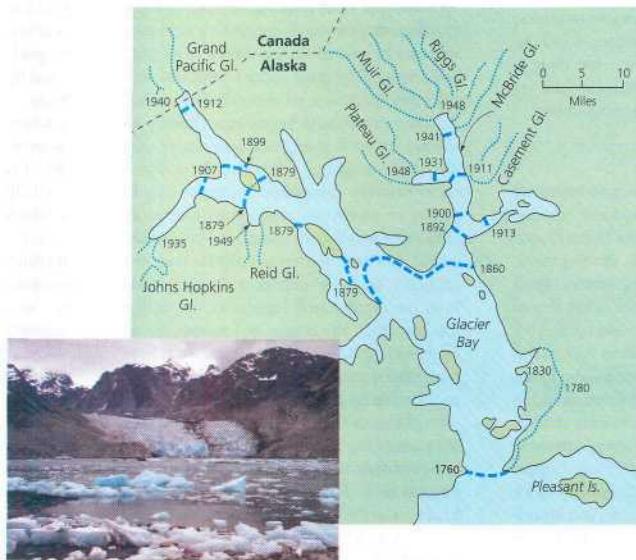

When this process begins in a virtually lifeless area where soil has not yet formed, such as on a new volcanic island or on the rubble (moraine) left behind by a retreating glacier, it is called **primary succession**. Often the only life-forms initially present are autotrophic prokaryotes. Lichens and mosses, which grow from windblown spores, are commonly the first macroscopic photosynthesizers to colonize such areas. Soil develops gradually, as rocks weather and organic matter accumulates from the decomposed remains of the early colonizers. Once soil is present, the lichens and mosses are usually overgrown by grasses, shrubs, and trees that sprout from seeds blown in from nearby areas or carried in by animals. Eventually, an area is colonized by plants that become the community's prevalent form of vegetation. Producing such a community through primary succession may take hundreds or thousands of years.

Secondary succession occurs when an existing community has been cleared by some disturbance that leaves the soil intact, as in Yellowstone following the 1988 fires (see **Figure 53.22**). Often the area begins to return to something like its original state. For instance, in a forested area that has been cleared for farming and later abandoned, the earliest plants to recolonize are often herbaceous species that grow from wind-blown or animal-borne seeds. If the area has not been burned or heavily grazed, woody shrubs may in time replace most

of the herbaceous species, and forest trees may eventually replace most of the shrubs.

Early arrivals and later-arriving species may be linked in one of three key processes. The early arrivals may *facilitate* the appearance of the later species by making the environment more favorable—for example, by increasing the fertility of the soil. Alternatively, the early species may *inhibit* establishment of the later species, so that successful colonization by later species occurs in spite of, rather than because of, the activities of the early species. Finally, the early species may be completely independent of the later species, so that they *tolerate* the later species but neither help nor hinder their colonization. Let's look at how these various processes contribute to primary succession in one specific example.

During the past 300 years, there has been a gradual retreat of glaciers in the Northern Hemisphere. As the glaciers retreat, they leave moraines. Researchers can determine the age of these post-glaciation areas of moraine from the age of the new trees growing on the moraine or, in the last 80 years, by direct observation. Ecologists have conducted the most extensive research on moraine succession at Glacier Bay in southeastern Alaska. Since about 1760, the glaciers there have retreated about 98 km, an extraordinary retreat rate of almost 400 m per year (Figure 53.23).

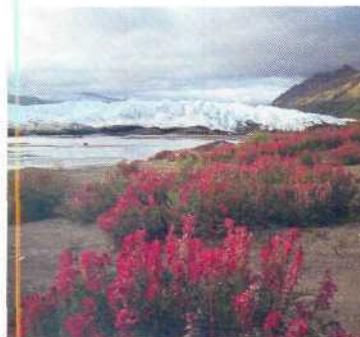

McBride glacier retreating

A Figure 53.23 A glacial retreat in southeastern Alaska. The dated locations chronicle recession of the glacier since 1760, based on historical description. As the ice retreats (inset), it leaves moraines along the edge of the bay, on which primary succession occurs.

Rocky moraines form a nearly pristine but harsh environment that plants can colonize.

Succession on the moraines in Glacier Bay follows a predictable pattern of change in vegetation and soil characteristics. The exposed moraine is colonized first by pioneering plant species, including liverworts, mosses, fireweed, and scattered *Dryas* (a mat-forming shrub), willows, and cottonwood (Figure 53.24a). After about three decades, *Dryas* dominates the plant community (Figure 53.24b). A few decades later, the area is invaded by alder (*Alnus*), which eventually forms dense, pure thickets up to 9 m tall. These alder stands are overgrown by Sitka spruce, which, after another century, forms a dense forest (Figure 53.24c). Western hemlock and mountain hemlock invade the spruce stands, and after another century, the community is a spruce-hemlock forest. This forest, however, endures only on well-drained slopes. In areas of poor drainage, the forest floor of this spruce-hemlock forest is invaded by sphagnum mosses, which hold large amounts of water and acidify the soil. The trees in such an area die because the soil is waterlogged and too oxygen-deficient to sustain their roots, and the area becomes a sphagnum bog. Thus, by about 300 years after glacial retreat, the vegetation consists of sphagnum bogs on the poorly drained flat areas and spruce-hemlock forest on the well-drained slopes.

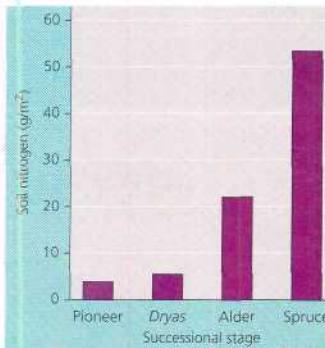

How is succession on glacial moraines related to the environmental changes caused by transitions in the vegetation? The bare soil exposed as the glacier retreats is quite basic, with a pH of 8.0–8.4 due to the carbonate compounds in the parent rocks. The soil pH falls rapidly as vegetation arrives, with the rate of change depending on the vegetation type. The most striking change is caused by spruce: Decomposition of acidic spruce needles reduces the pH of the soil from 7.0 to approximately 4.0. The soil concentrations of mineral nutrients also show marked changes with time. One of the characteristic features of the bare soil after glacial retreat is its low nitrogen content. Almost all the pioneer species begin the succession with very poor growth and yellow leaves due to inadequate nitrogen supply. The exceptions are *Dryas* and, particularly, alder; these species have symbiotic bacteria that fix atmospheric nitrogen (see Chapter 37). Soil nitrogen increases rapidly during the alder stage of succession (Figure 53.24d). The spruce forest develops by spending the capital of soil nitrogen accumulated

(a) Pioneer stage, with fireweed dominant

(b) Dryas stage

(d) Nitrogen fixation by *Dryas* and alder increases the soil nitrogen content.

A Figure 53.24 Changes in plant community structure and soil nitrogen during succession at Glacier Bay, Alaska. Plant species composition changes dramatically during succession at Glacier Bay.

by the alder. By altering soil properties, pioneer plant species permit new plant species to grow, and the new plants in turn alter the environment in different ways, contributing to succession.

Concept Check 53.3

1. Why do high and low levels of disturbance usually reduce species diversity? Why does an intermediate level of disturbance promote species diversity?
2. How do primary and secondary succession differ?
3. During succession, how might the early species facilitate the arrival of other species?

For suggested answers, see Appendix A.

(c) Spruce stage

Concept 53.4

Biogeographic factors affect community biodiversity

Communities vary greatly in the number of species they contain. Two key factors correlated with a community's species diversity are its geographic location and its size. In the 1850s, both Charles Darwin and Alfred Wallace pointed out that plant and animal life was generally more abundant and varied in the tropics than in other parts of the globe. Darwin and Wallace also noted that small or remote islands have fewer species than large islands or those nearer continents. Such observations imply that biogeographic patterns in biodiversity conform to a set of basic principles rather than being

historical coincidences. One way to understand such large-scale patterns in the diversity of life is to examine variation along environmental gradients.

Equatorial-Polar Gradients

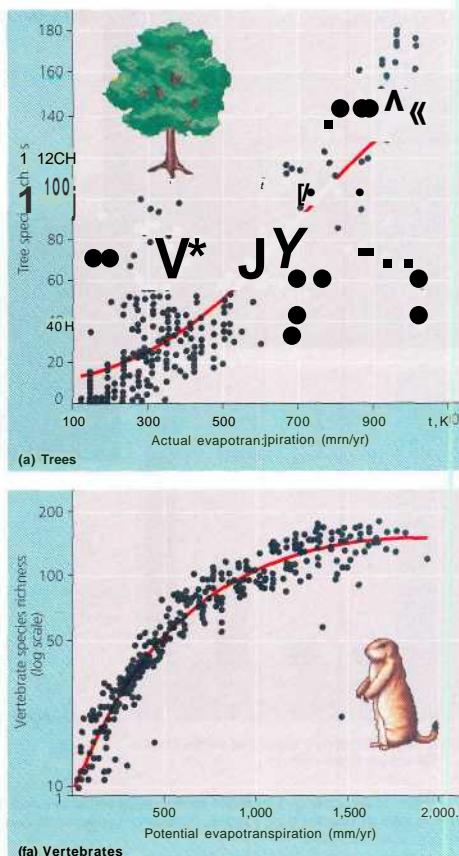

As Darwin and Wallace noted, tropical habitats support many more species than do temperate and polar regions. For example, one study found that a 6.6-hectare [1 hectare (ha) = 10,000 m²] area in Sarawak (part of Malaysia) contained 711 tree species, while a 2-ha plot of deciduous forest in Michigan contained just 10 to 15 tree species. And the whole of Western Europe north of the Alps, an area of more than 2 million km², has only 50 tree species. Similarly, there are more than 200 species of ants in Brazil, 73 in Iowa, and only 7 in Alaska.

The two key factors in equatorial-polar gradients of species richness are probably evolutionary history and climate. Over the course of evolutionary time, species diversity may increase in a community as more speciation events occur. And tropical communities are generally older than temperate or polar communities. This age difference stems partly from the fact that the growing season in tropical forests is about five times longer than the growing season in the tundra communities of high latitudes. In effect, biological time, and hence time for speciation, runs about five times faster in the tropics than near the poles. And many polar and temperate communities have repeatedly "started over" as a result of major disturbances in the form of glaciations.

Climate is likely the primary cause of the latitudinal gradient in biodiversity. The two main climatic factors correlated with biodiversity are solar energy input and water availability. These factors can be considered together by measuring a community's rate of **evapotranspiration**, the evaporation of water from soil plus the transpiration of water from plants. *Actual evapotranspiration*, which is determined by the amount of solar radiation, temperature, and water availability, is much higher in hot areas with abundant rainfall than in areas with low temperatures or low precipitation. *Potential evapotranspiration*, a measure of energy availability but not water availability, is determined by the amount of solar radiation and temperature and is highest in regions of high solar radiation and temperature. The species richness of plants and animals correlates with measures of evapotranspiration (Figure 53.25).

Area Effects

In 1807, Alexander von Humboldt described one of the first patterns of biodiversity to be recognized, the species-area curve, which quantifies what probably seems obvious: All other factors being equal, the larger the geographic area of a community, the greater the number of species. The likely explanation for this pattern is that larger areas offer a greater diversity of habitats and microhabitats than smaller areas. In conservation biology, developing species-area curves for the

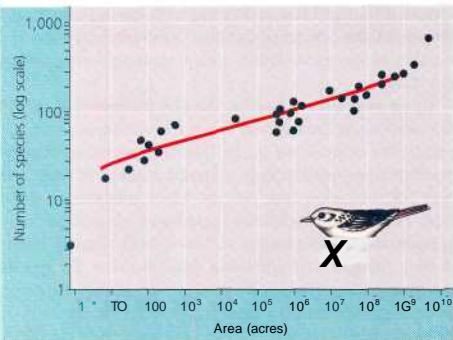

A Figure 53.25 Energy, water, and species richness.

(a) Species richness of North American trees increases most predictably with actual evapotranspiration, while (b) vertebrate species richness in North America increases most predictably with potential evapotranspiration. Evapotranspiration values are expressed as rainfall equivalents in millimeters per year.

key taxa in a community helps ecologists to predict how the potential loss of a certain area of habitat is likely to affect the community's biodiversity.

Figure 53.26 is a species-area curve for North American breeding birds (birds with breeding populations in the mapped area, as opposed to migrant populations). The slope indicates the extent to which species richness increases with community area. The slopes of different species-area curves vary, depending on the taxon being sampled and the type of

A Figure 53.26 Species-area curve for North American breeding birds. Both area and number of species are plotted on a logarithmic scale. The data points range from a 0.5-acre plot with 3 species in Pennsylvania to the whole United States and Canada (4.6 billion acres) with 625 species.

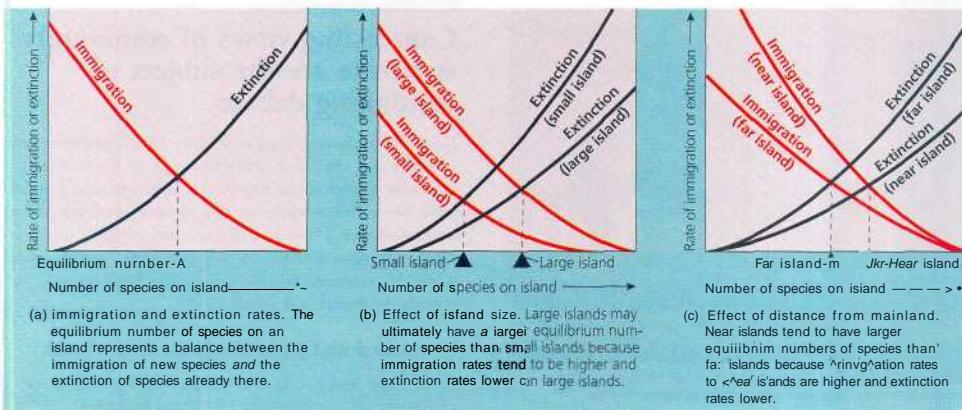

community. But the basic concept of diversity increasing with increasing area applies in a variety of situations, from surveys of ant diversity in New Guinea to the number of plant species on islands of different sizes. In fact, island biogeography provides some of the best examples of species-area curves, as we see next.

Island Equilibrium Model

Because of their isolation and limited size, islands provide excellent opportunities for studying the biogeographic fao

tors that affect the species diversity of communities. By "islands," we mean not only oceanic islands, but also habitat islands on land, such as lakes, mountain peaks separated by lowlands, or natural woodland fragments surrounded by areas disturbed by humans—in other words, any patch surrounded by an environment not suitable for the "island" species. In the 1960s, American ecologists Robert MacArthur and E. O. Wilson developed a general model of island biogeography identifying the key determinants of species diversity on an island with a given set of physical characteristics (Figure 53.27).

Consider a newly formed oceanic island that receives colonizing species from a distant mainland. Two factors determine the number of species that will eventually inhabit the island: the rate at which new species immigrate to the island and the rate at which species become extinct on the island. And two physical features of the island affect immigration and extinction rates: its size and its distance from the mainland. Small islands generally have lower immigration rates because potential colonizers are less likely to reach a small island. For instance, birds blown out to sea by a storm are more likely to land by chance on a larger island than on a small one. Small islands also have higher extinction rates, as they generally contain fewer resources and less diverse habitats for colonizing species to partition. Distance from the mainland is also important; for two islands of equal size, a closer island generally has a higher immigration rate than one farther away. And because of their higher immigration rates, closer islands also have lower extinction rates, as arriving colonists help sustain the presence of a species on a near island and prevent its extinction.

A Figure 53.27 The equilibrium model of island biogeography. Black triangles represent equilibrium numbers of species.

At any given time, an island's immigration and extinction rates are also affected by the number of species already present. As the number of species on the island increases, the immigration rate of new species decreases, because any individual reaching the island is less likely to represent a species that is not already present. At the same time, as more species inhabit an island, extinction rates on the island increase because of the greater likelihood of competitive exclusion.

These relationships make up MacArthur and Wilson's model of island biogeography (see Figure 53.27). Immigration and extinction rates are plotted as a function of the number of species present on the island. This mathematical model is called the island equilibrium model because an equilibrium will eventually be reached where the rate of species immigration equals the rate of species extinction. The number of species at this equilibrium point is correlated with the island's size and distance from the mainland. Like any ecological equilibrium, this species equilibrium is dynamic; immigration and extinction continue, and the exact species composition may change over time.

MacArthur and Wilson's studies of the diversity of plants and animals on many island chains, including the Galápagos Islands, support the prediction that species richness in-

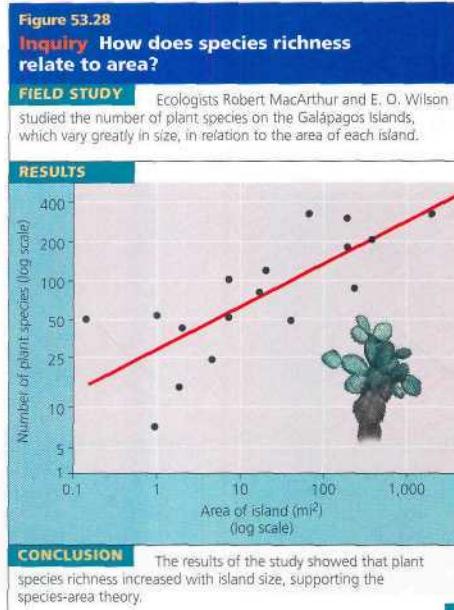

creases with island size, in keeping with species-area theory (Figure 53.28). Species counts also fit the prediction that the number of species decreases with increasing remoteness of the island.

In the past several decades, the island equilibrium model has come under considerable fire as an oversimplification. Its predictions of equilibria in the species composition of communities may apply in only a limited number of cases and over relatively short time periods, where colonization is the main process affecting species composition. Over longer time periods, abiotic disturbances such as storms, adaptive evolutionary changes, and speciation generally alter the species composition and community structure on islands. However, more important than the model's widespread applicability is its impact in stimulating discussion and research on the effects of habitat size on species diversity, a topic of vital importance for conservation biology.

Concept Check 53.4

- Summarize the general relationship between area and species richness.
- Describe two hypotheses that explain why species diversity is greater in tropical regions than in temperate and polar regions.
- Describe how an island's size and distance from the mainland affect the island's species richness.

For suggested answers, see Appendix A.

Concept 53.5

Contrasting views of community structure are the subject of continuing debate

Now that we have looked at various aspects of community structure and species diversity, how can we account for the particular species found together as members of a community? Two different views on this question emerged among ecologists in the 1920s and 1930s, based primarily on observations of plant distribution. We will briefly describe these historical arguments because they are the forerunners of two community models still debated today.

Integrated and Individualistic Hypotheses

In the early 1900s, E. E. Clements, of the Carnegie Institute of Washington, proposed the integrated hypothesis of community structure. This hypothesis describes a community as

an assemblage of closely linked species, locked into association by mandatory biotic interactions that cause the community to function as an integrated unit—in effect, as a superorganism. Evidence for the integrated view includes the observation that certain species of plants are consistently found together as a group. For example, deciduous forests in the northeastern United States usually include particular species of oak, maple, birch, and beech, along with a specific assemblage of shrubs and vines.

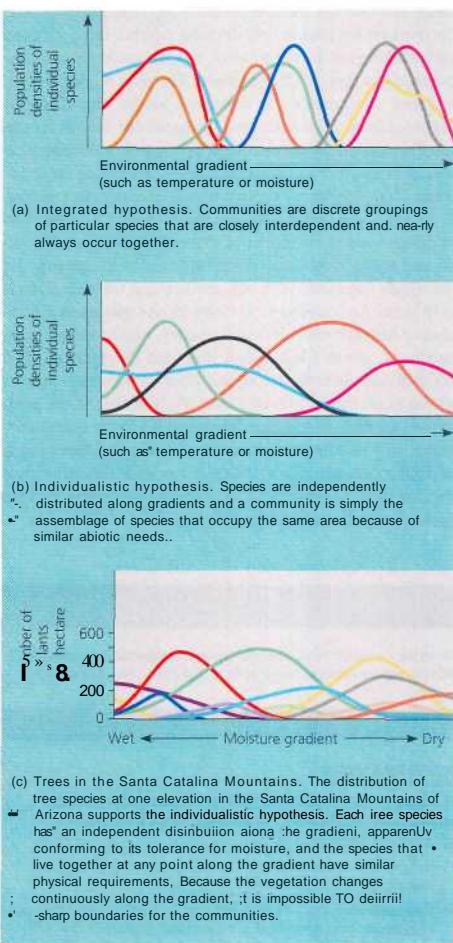

Shortly after the integrated hypothesis was proposed, H. A. Gleason, of the University of Chicago, enunciated a different view of community structure. His individualistic hypothesis depicts a plant community as a chance assemblage of species found in the same area simply because they happen to have similar abiotic requirements—for example, for temperature, rainfall, and soil type.

These two very different ways of thinking about community structure—integrated versus individualistic—suggest different priorities in studying biological communities. The integrated hypothesis emphasizes entire assemblages of species as the essential units for understanding the interrelationships and distributions of organisms, whereas the individualistic hypothesis emphasizes studying single species.

Both the integrated and the individualistic hypotheses see communities as involving interspecific interactions. However, they offer different perspectives on how species are assembled into a community. The two hypotheses also make contrasting predictions about how plant species should be distributed along an environmental gradient, such as a gradual change in moisture or temperature over some distance. The integrated hypothesis predicts that species should be clustered into discrete communities with noticeable boundaries, because the presence or absence of a particular species is largely governed by the presence or absence of other species with which it interacts in its group (Figure 53.29a). In contrast, the individualistic hypothesis predicts that communities should generally lack discrete geographic boundaries because each species has an independent (that is, individualistic) distribution along the environmental gradient. In other words, each species is distributed according to its tolerance ranges for abiotic factors that vary along a gradient, and communities should change continuously along the gradient, with the addition or loss of particular species (Figure 53.29b).

In most actual cases, especially where there are broad regions characterized by gradients of environmental variation, the composition of plant communities does seem to change continuously, with each species more or less independently distributed (Figure 53.29c). Such distributions generally support the view of plant communities as relatively loose associations without discrete boundaries. However, where some key factor in the physical environment, such as soil type, changes abruptly adjacent communities are delineated by correspond-

ingly sharp boundaries. Although such sharp boundaries between plant communities occur rarely in nature, humans have produced many artificial sharp boundaries by altering the landscape through agriculture and forestry, as you will read in Chapter 55.

A Figure 53.29 Testing the integrated and individualistic hypotheses of communities. Ecologist Robert Whittaker tested these two hypotheses by graphing the abundance of different plant species (*y*-axis) along environmental gradients of abiotic factors such as temperature or moisture (*x*-axis). Each colored curve represents the abundance of one species.

Rivet and Redundancy Models

The individualistic hypothesis is generally accepted by plant ecologists today, but further debate arises in the application of these ideas to the animals in a community. In 1981, American ecologists Paul and Anne Ehrlich proposed that species in a community are like the rivets in the wings of airplanes: Not all the rivets are required to hold the wing together but if someone started taking out the rivets one by one, we would become concerned about flying in that airplane. The rivet model of communities reincarnates the integrated model that Clements suggested for plant communities. It suggests that most of the species in a community are associated tightly with particular other species in a web of life. Thus, reducing or increasing the abundance of one species in a community affects many other species.

In 1992, Australian ecologist Brian Walker suggested an opposing view of communities, the redundancy model. According to this model, most of the species in a community are not tightly associated with one another, and the web of life is very loose. An increase or decrease in one species in a community has little effect on other species, which operate independently, just as Gleason had suggested 80 years before in his individualistic model of the plant community. Species within a community are redundant. For example, if one predator disappears, another predatory species in the community will usually take its place as a consumer of specific prey. If one pollinator ceases to visit a particular species of flowering plant because the pollinator has disappeared from the area, another pollinator species will do the job.

It is important to keep in mind that the rivet and redundancy models, like the integrated and individualistic models, represent extremes; most communities probably lie somewhere in the middle. So why is the debate that began early in the 20th century continuing? The main reason is that we still do not have enough information to answer the fundamental questions raised by Clements and Gleason: Are communities loose associations of species or highly integrated units? To fully assess the contrasting models, we need to study how species interact in communities and how tight these associations are. For example, how would the impacts on a community differ if the one species lost from it were a keystone species compared to a rare species with relatively little influence on community structure?

Such questions about community structure are important because they underlie many current environmental problems, such as how the extinction of particular species may affect the functioning of ecosystems. We will return to these models and the questions they stimulate in Chapter 55. But first, we will take a look at ecosystem ecology in Chapter 54.

Concept Check 53.5

- Describe the individualistic and integrated hypotheses of community structure and how these hypotheses are related to the rivet and redundancy models.

SUMMARY OF KEY CONCEPTS

Concept 53.1

A community's interactions include competition, predation, herbivory, symbiosis, and disease

- Populations are linked by interspecific interactions that affect the survival and reproduction of the species engaged in the interaction (pp. 1159–1160).
- Competition** (pp. 1160–1161) Interspecific competition occurs when species compete for a particular resource that is in short supply. The ecological niche is the total of the organism's use of the biotic and abiotic resources in its environment. The competitive exclusion principle states that two species cannot coexist in the same community if their niches are identical.
- Predation** (pp. 1161–1162) Predation refers to an interaction in which one species, the predator, kills and eats the other, the prey. Predation has led to diverse adaptations, including mimicry.

Table 53.1 Interspecific Interactions

| Interaction | Effects on Interacting Species |
|--------------------|---|
| Competition (—/—) | The interaction can be detrimental to both species. |
| Predation (+/—) | The interaction is beneficial to one species and detrimental to the other. |
| Herbivory (+/—) | The interaction is beneficial to both species. |
| Parasitism (+/-) | |
| Disease (+/-) | One species benefits from the interaction, and the other species is unaffected by it. |
| Mutualism (+/+) | |
| Commensalism (+/Q) | |

- **Herbivory** (p. 1163) Herbivory—an interaction in which an herbivore eats parts of a plant or an alga, has led to the evolution of various chemical and mechanical defenses in plant species as well as consequent adaptations by herbivorous species.

- Parasitism** (p. 1163) In parasitism, one organism, the parasite, derives its nourishment from another organism, its host, which is harmed in the process. Parasitism exerts substantial influence on populations and the structure of communities.
- Disease** (p. 1163) The effects of disease on populations and communities is similar to that of parasites. Most pathogens are microscopic.
- Mutualism** (p. 1164) Both species benefit in a mutualistic interaction.
- Commensalism** (p. 1164) In commensalism, one species benefits and the other is not affected. There are few if any cases of pure commensalism.
- Interspecific Interactions and Adaptation** (pp. 1164-1165) Evidence for coevolution, involving reciprocal genetic change by interacting populations, is scarce. However, generalized adaptation of organisms to other organisms in their environment is a fundamental feature of life.
*Activity Interspecific Interactions
Biology Labs On-Line PopulationEcologyLab*

Concept 53.3

Disturbance influences species diversity and composition

- What Is Disturbance?** (pp. 1172-1173) Increasingly, evidence suggests that disturbance and nonequilibrium rather than stability and equilibrium are the norm for most communities. According to the intermediate disturbance hypothesis, moderate levels of disturbance can foster higher species diversity than can low or high levels of disturbance.
- Human Disturbance** (p. 1173) Humans are the most widespread agents of disturbance, and their disturbance to communities usually reduces species diversity. Humans also prevent some naturally occurring disturbances, such as fire, which can be important to community structure.
- Ecological Succession** (pp. 1173-1175) Ecological succession is the sequence of community and ecosystem changes after a disturbance. Primary succession occurs where no soil exists when succession begins; secondary succession begins in an area where soil remains after a disturbance. Mechanisms producing community change during succession include facilitation and inhibition.
Activity Primary Succession

Concept 53.4

Biogeographic factors affect community biodiversity

- Equatorial-Polar Gradients** (p. 1176) Species richness generally declines along an equatorial-polar gradient and is especially great in the tropics. The greater age of tropical environments may account for the greater species richness of the tropics. Climate also influences the biodiversity gradient through energy (heat and light) and water.
- Area Effects** (pp. 1176-1177) Species richness is directly related to a community's geographic size, a principle formalized in the species-area curve.
- Island Equilibrium Model** (pp. 1177-1178) Species richness on islands depends on island size and distance from the mainland. The equilibrium model of island biogeography maintains that species richness on an ecological island levels off at some dynamic equilibrium point, where new immigrations are balanced by extinctions. The island equilibrium model has been questioned in recent years.
Activity Exploring Island Biogeography

Concept 53.5

Contrasting views of community structure are the subject of continuing debate

- Integrated and Individualistic Hypotheses** (pp. 1178-1179) The integrated hypothesis states that the species within a community are locked into particular biotic interactions. The individualistic hypothesis proposes that communities are loosely organized associations of independently distributed species with the same abiotic requirements.
- Rivet and Redundancy Models** (p. 1180) The rivet model suggests that all the species in a community are linked together in a tight web of interactions, so that the loss of even a single species has strong repercussions for the community. The redundancy model proposes that if a species is lost from a community, other species will fill the gap.

TESTING YOUR KNOWLEDGE

Evolution Connection

Explain why adaptations of particular organisms to interspecific competition may not necessarily represent instances of character displacement. What would a researcher have to demonstrate about two competing species to make a convincing case for character displacement?

Scientific Inquiry

An ecologist studying plants in the desert performed the following experiment. She staked out two identical plots, each of which included a few sagebrush plants and numerous small annual wildflowers. She found the same five wildflower species in roughly equal numbers on both plots. She then enclosed one of the plots with a fence to keep out kangaroo rats, the most common grain-eaters of the area. After two years, four of the wildflower species were no longer present in the fenced plot, but one species had increased drastically. The control plot had not changed in species diversity. Using the principles of community ecology, propose a hypothesis to explain her results. What additional evidence would support your hypothesis?

Measured?

Science, Technology, and Society

By 1935, hunting and trapping had eliminated wolves from the United States except for Alaska. Because wolves have since been protected as an endangered species, they have moved south from Canada and have become reestablished in the Rocky Mountains and northern Great Lakes region. Conservationists who would like to speed up wolf recovery have reintroduced wolves into Yellowstone National Park. Local ranchers are opposed to bringing back the wolves because they fear predation on their cattle and sheep. What are some reasons for reestablishing wolves in Yellowstone National Park? What effects might the reintroduction of wolves have on the ecological communities in the region? What might be done to mitigate the conflicts between ranchers and wolves?

self-harmers will be at increased risk for future self-harm. This study found that those who had self-harm in the past were more likely to self-harm again. This finding is consistent with previous research showing that self-harm is associated with an increased risk of future self-harm (Kilpatrick et al., 2003). Self-harm is a complex phenomenon and it is important to consider the individual's history of self-harm when assessing the risk of future self-harm. This study found that those who had self-harm in the past were more likely to self-harm again. This finding is consistent with previous research showing that self-harm is associated with an increased risk of future self-harm (Kilpatrick et al., 2003). This finding is consistent with previous research showing that self-harm is associated with an increased risk of future self-harm (Kilpatrick et al., 2003). Self-harm is a complex phenomenon and it is important to consider the individual's history of self-harm when assessing the risk of future self-harm.

Conclusion

Limitations

This study found that those who had self-harm in the past were more likely to self-harm again. This finding is consistent with previous research showing that self-harm is associated with an increased risk of future self-harm (Kilpatrick et al., 2003). Self-harm is a complex phenomenon and it is important to consider the individual's history of self-harm when assessing the risk of future self-harm.

The limitations of this study include the cross-sectional design, which does not allow for causal inference. Future research should aim to explore the mechanisms underlying self-harm and to identify risk factors for future self-harm. In addition, further research is needed to examine the long-term outcomes of self-harm and to develop effective interventions for self-harm.

Self-harm is a complex phenomenon and it is important to consider the individual's history of self-harm when assessing the risk of future self-harm. This study found that those who had self-harm in the past were more likely to self-harm again. This finding is consistent with previous research showing that self-harm is associated with an increased risk of future self-harm (Kilpatrick et al., 2003). Self-harm is a complex phenomenon and it is important to consider the individual's history of self-harm when assessing the risk of future self-harm.

Author biography

Dr. Jane Smith is a clinical psychologist and researcher. She has conducted numerous studies on self-harm and mental health. Her current research interests include the development of interventions for self-harm and the identification of risk factors for self-harm. She has published numerous articles in peer-reviewed journals and has presented her research at international conferences. She is currently working on a new study investigating the effectiveness of cognitive-behavioral therapy for self-harm.

Overview

Ecosystems, Energy, and Matter

An ecosystem consists of all the organisms living in a community as well as all the abiotic factors with which they interact. Ecosystems can range from a microcosm, such as the aquarium in **Figure 54.1**, to a large area such as a lake or forest. As with populations and communities, the boundaries of ecosystems are usually not discrete. Cities and farms are examples of human-dominated ecosystems. Many ecologists regard the entire biosphere as a global ecosystem, a composite of all the local ecosystems on Earth.

Regardless of an ecosystem's size, its dynamics involve two processes that cannot be fully described by population or community processes and phenomena: energy flow and chemical cycling. Energy enters most ecosystems in the form of sunlight. It is then converted to chemical energy by autotrophic organisms, passed to heterotrophs in the organic compounds of food, and dissipated in the form of heat. Chemical elements, such as carbon and nitrogen, are cycled

among abiotic and biotic components of the ecosystem. Photosynthetic organisms assimilate these elements in inorganic form from the air, soil, and water and incorporate them into organic molecules, some of which are consumed by animals. The elements are returned in inorganic form to the air, soil, and water by the metabolism of plants and animals and by other organisms, such as bacteria and fungi, that break down organic wastes and dead organisms.

Both energy and matter move through ecosystems via the transfer of substances during photosynthesis and feeding relationships. However, because energy, unlike matter, cannot be recycled, an ecosystem must be powered by a continuous influx of energy from an external source—in most cases, the sun. Energy flows through ecosystems, while matter cycles within them.

Resources critical to human survival and welfare, ranging from the food we eat to the oxygen we breathe, are products of ecosystem processes. In this chapter, we will explore the dynamics of energy flow and chemical cycling in ecosystems and consider some of the impacts of human activities on these processes.

Concept 54.1

Ecosystem ecology emphasizes energy flow and chemical cycling

Ecosystem ecologists view ecosystems as transformers of energy and processors of matter. By grouping the species in a community into trophic levels of feeding relationships (see Chapter 53), we can follow the transformation of energy in the ecosystem and map the movements of chemical elements through the biotic community.

Ecosystems and Physical Laws

Because ecosystem ecologists work at the interface between organisms and the physical environment, much of their analysis of ecosystem dynamics derives from well-established laws of physics and chemistry. The principle of conservation of energy, which you studied in Chapter 8, states that energy cannot be created or destroyed but only transformed. Thus, we can potentially account for the transfer of energy through an ecosystem from its input as solar radiation to its release as heat from organisms. Plants and other photosynthetic organisms convert solar energy to chemical energy, but the total amount of energy does not change. The total amount of energy stored in organic molecules plus the amounts reflected and dissipated as heat must equal the total solar energy intercepted by the plant. One area of ecosystem ecology involves computing such energy budgets and tracing energy flow through ecosystems in order to understand the factors controlling these energy transfers.

One implication of the second law of thermodynamics is that energy conversions cannot be completely efficient; some energy is always lost as heat in any conversion process (see Chapter 8). This idea suggests that we can measure the efficiency of ecological energy conversions in the same way we measure the efficiency of lightbulbs and car engines.

Energy flowing through ecosystems is ultimately dissipated into space as heat, so if the sun were not continuously providing energy to Earth, ecosystems would vanish. In contrast, chemical elements are continually recycled. A carbon or nitrogen atom moves from trophic level to trophic level and eventually to the decomposers and then back again in an endless cycle. Elements are not lost on a global scale, although they may move from one ecosystem to another. The measurement and

analysis of chemical cycling in ecosystems and in the entire biosphere represent another area of study in ecosystem ecology.

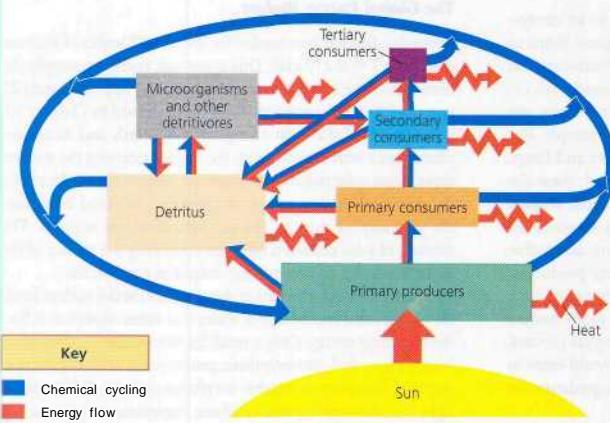

Trophic Relationships

As you read in Chapter 53, ecologists assign species to trophic levels on the basis of their main source of nutrition and energy. Figure 54.2 summarizes the trophic relationships in an ecosystem. The trophic level that ultimately supports all others consists of autotrophs, also called the **primary producers** of the ecosystem. Most autotrophs are photosynthetic organisms that use light energy to synthesize sugars and other organic compounds, which they then use as fuel for cellular respiration and as building material for growth. Plants, algae, and photosynthetic prokaryotes are the biosphere's main autotrophs, although chemosynthetic prokaryotes are the primary producers in certain ecosystems, such as deep-sea hydrothermal vents (see Figure 50.17).

Organisms in trophic levels above the primary producers are heterotrophs, which directly or indirectly depend on the photosynthetic output of primary producers. Herbivores, which eat plants and other primary producers, are **primary consumers**. Carnivores that eat herbivores are **secondary consumers**, and carnivores that eat other carnivores are **tertiary consumers**. Another important group of heterotrophs consists of the detritivores. **Detritivores**, or **decomposers**, are consumers that get their energy from **detritus**, which is nonliving organic material, such as the remains of dead organisms, feces, fallen leaves, and wood.

Decomposition

The prokaryotes, fungi, and animals that feed as detritivores form a major link between the primary producers and the

M Figure 54.2 An overview of energy and nutrient dynamics in an ecosystem. Energy enters, flows through, and exits an ecosystem, whereas chemical nutrients cycle within it. In this generalized scheme, energy (orange arrows) enters from the sun as radiation, moves as chemical energy transfers through the food web, and exits as heat radiated into space. Most transfers of nutrients (blue arrows) through the trophic levels lead eventually to detritus; the nutrients then cycle back to the primary producers.

A **Figure 54.3** Fungi decomposing a dead tree.

consumers in an ecosystem. In a forest, for example, birds might feed on earthworms that have been feeding on leaf litter and its associated prokaryotes and fungi. But even more important than this channeling of resources from producers to consumers is the role that detritivores play in making vital chemical elements available to producers.

Detritivores decompose the organic material in an ecosystem and transfer the chemical elements in inorganic forms to abiotic reservoirs such as soil, water, and air. Producers can then recycle these elements into organic compounds. All organisms perform some decomposition, breaking down organic molecules during cellular respiration, for example. But an ecosystem's main decomposers are prokaryotes and fungi, which secrete enzymes that digest organic material; these decomposers then absorb the breakdown products (**Figure 54.3**). Decomposition by prokaryotes and fungi accounts for most of the conversion of organic materials from all trophic levels to inorganic compounds usable by primary producers, thereby closing the loop of an ecosystem's chemical cycling. Because most detritivores are not readily visible to the human eye, decomposition is an underappreciated ecological process. Yet if decomposition stopped, all life on Earth would cease as detritus piled up and the supply of chemical ingredients for new organic matter was exhausted.

Concept Check 54.1

1. Why is the transfer of energy in an ecosystem referred to as energy flow, not energy cycling?
2. HOW does the second law of thermodynamics explain why an ecosystem's energy supply must be continually replenished?
3. How are detritivores essential to sustaining ecosystems?

For suggested answers, see Appendix A.

Concept 54.2

Physical and chemical factors limit primary production in ecosystems

The amount of light energy converted to chemical energy (organic compounds) by autotrophs during a given time period is an ecosystem's primary production. This photosynthetic product is the starting point for studies of ecosystem metabolism and energy flow.

Ecosystem Energy Budgets

Most primary producers use light energy to synthesize energy-rich organic molecules, which can subsequently be broken down to generate ATP (see Chapter 10). Consumers acquire their organic fuels secondhand (or even third- or fourthhand) through food webs such as that in Figure 53.13. Therefore, the extent of photosynthetic production sets the spending limit for the energy budget of the entire ecosystem.

The Global Energy Budget

Every day, Earth is bombarded by about 10^{22} joules of solar radiation ($1\text{J} = 0.239\text{ cal}$). This is enough energy to supply the demands of the entire human population for approximately 25 years at 2004 consumption levels. As described in Chapter 50, the intensity of the solar energy striking Earth and its atmosphere varies with latitude, with the tropics receiving the greatest input. Most solar radiation is absorbed, scattered, or reflected by the atmosphere, depending on variations in cloud cover and the quantity of dust in the air over different regions. The amount of solar radiation ultimately reaching the surface of the globe limits the photosynthetic output of ecosystems.

Much of the solar radiation that reaches Earth's surface lands on bare ground and bodies of water that either absorb or reflect the incoming energy. Only a small fraction actually strikes plant leaves, algae, and photosynthetic prokaryotes, and only some of this is of wavelengths suitable for photosynthesis. Of the visible light that does reach photosynthetic organisms, only about 1%

is converted to chemical energy by photosynthesis, though this yield varies with the type of organism, light level, and other factors. Although the fraction of the total incoming solar radiation that is ultimately trapped by photosynthesis is very small, primary producers on Earth collectively create about 170 billion tons of organic material per year.

Gross and Net Primary Production

Total primary production in an ecosystem is known as that ecosystem's gross primary production (GPP)—the amount of light energy that is converted to chemical energy by photosynthesis per unit time. Not all of this production is stored as organic material in the growing plants, because the plants use some of the molecules as fuel in their own cellular respiration. Net primary production (NPP) is equal to gross primary production minus the energy used by the primary producers for respiration (R):

$$\text{NPP} = \text{GPP} - \text{R}$$

To ecologists, net primary production is the key measurement because it represents the storage of chemical energy that will be available to consumers in the ecosystem. For example, in forests, net primary production may be as little as one-

fourth of gross primary production. Trees must support large masses of trunks, branches, and roots through respiration; thus, more energy is spent in respiration in forests than in herbaceous and crop communities.

Net primary production can be expressed as energy per unit area per unit time ($\text{J/m}^2/\text{yr}$) or as biomass (weight) of vegetation added to the ecosystem per unit area per unit time ($\text{g/m}^2/\text{yr}$). (Note that biomass is usually expressed in terms of the dry weight of organic material because water molecules contain no usable energy and because the water content of plants varies over short periods of time.) An ecosystem's net primary production should not be confused with the *total* biomass of photosynthetic autotrophs present at a given time, a measure called the standing *crop*. Net primary production is the amount of *new* biomass added in a given period of time. Although a forest has a very large standing crop biomass, its net primary production may actually be less than that of some grasslands, which do not accumulate vegetation because animals consume the plants rapidly and because some of the plants are annuals.

Different ecosystems vary considerably in their net primary production as well as in their contribution to the total net primary production on Earth (Figure 54.4). Tropical rain forests are among the most productive terrestrial ecosystems and contribute a large portion of the planet's overall net primary

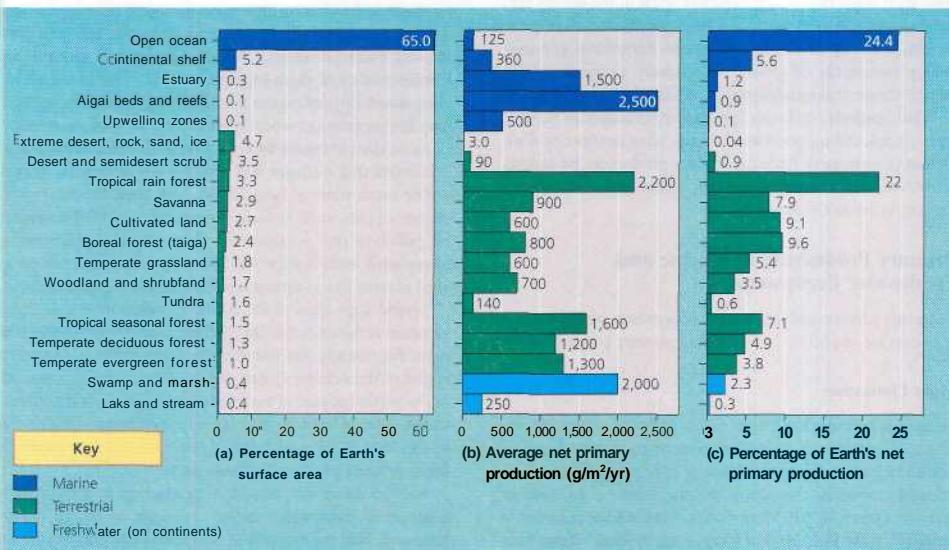

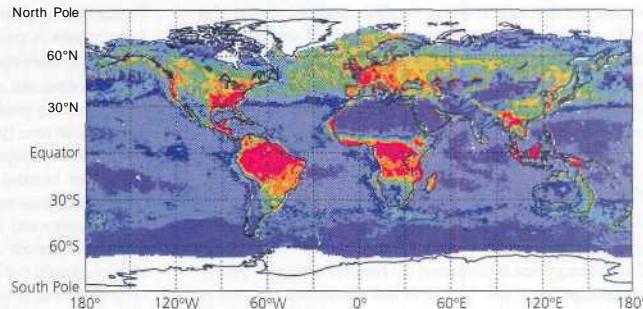

Figure 54.4 Net primary production of different ecosystems. The geographic extent (a) and the net primary production per unit area (b) of different ecosystems determine their total contribution to worldwide net primary production (c).

> Figure 54.5 Regional annual net primary production for Earth. The image is based on data, such as chlorophyll density, collected by satellites. Lighter violet indicates regions of lowest net primary production, with increasing net primary production indicated by darker violet, light blue, dark green, light green, yellow, orange, and red in that order. Ocean data are averages from 1978 to 1983. Land data are averages from 1982 to 1990.

production. Estuaries and coral reefs also have very high net primary production, but their total contribution to global net primary production is relatively small because these ecosystems cover only about one-tenth the area covered by tropical rain forests. The open ocean contributes more net primary production than any other single ecosystem, but this is because of its very large size; net primary production per unit area is relatively low;

Satellite images now provide a means of studying global patterns of primary production. The most striking impression from such maps is how unproductive most of the oceans are, per unit area, in contrast to the high production of tropical forests. Overall, terrestrial ecosystems contribute approximately two-thirds of global net primary production and marine ecosystems approximately one-third (**Figure 54.5**).

What controls, or limits, primary production in ecosystems? To ask this question another way, what factors could we change to increase or decrease primary production for a given ecosystem? We look next at the factors that limit primary production in aquatic ecosystems.

Primary Production in Marine and Freshwater Ecosystems

In aquatic (marine and freshwater) ecosystems, both light and nutrients are important in controlling primary production.

Light Limitation

Because solar radiation drives photosynthesis, you might expect that light is a key variable in controlling primary production in oceans. Indeed, the depth of light penetration affects primary production throughout the photic zone of an ocean or lake (see Figure 50.16). More than half of the solar radiation is absorbed in the first meter of water. Even in "clear" water, only 5–10% of the radiation may reach a depth of 20 m.

If light is the main variable limiting primary production in the ocean, we would expect production to increase along a

gradient from the poles toward the equator, which receives the greatest intensity of light. However, you can see in Figure 54.5 that there is no such gradient. Some parts of the tropics and subtropics are very unproductive, while some high-latitude ocean regions are relatively productive. Another factor must influence primary production in the ocean.

Nutrient Limitation

More than light, nutrients limit primary production both in different geographic regions of the ocean and in lakes. A limiting nutrient is the element that must be added in order for production to increase in a particular area. The nutrient most often limiting marine production is either nitrogen or phosphorus. Concentrations of these nutrients are very low in the photic zone, where phytoplankton live; ironically, they are more abundant in deeper water, where it is too dark for photosynthesis.

As detailed in **Figure 54.6**, nutrient enrichment experiments confirmed that nitrogen was limiting phytoplankton growth off the south shore of Long Island, New York. Practical applications of this work include preventing algal blooms caused by pollution that fertilizes the phytoplankton: Eliminating phosphates from sewage will not help solve the problem of algal blooms unless nitrogen pollution is also controlled.

Several large areas of the ocean, however, have low phytoplankton densities in spite of relatively high nitrogen concentrations. For example, the waters of the Sargasso Sea, a subtropical region of the Atlantic Ocean, are among the most transparent in the world because of their very low density of phytoplankton. A series of nutrient enrichment experiments revealed that in this case, it is availability of the micronutrient iron that limits primary production (**Table 54.1**).

Such evidence that iron limits production in some oceanic ecosystems encouraged marine ecologists to mount several large-scale field experiments in the Pacific Ocean during the last two decades. For example, in one study researchers spread low concentrations of dissolved iron over 72 km² of ocean and then measured the change in phytoplankton density over a seven-day

Figure 54.6

Which nutrient limits phytoplankton production along the coast of Long Island?

EXPERIMENT

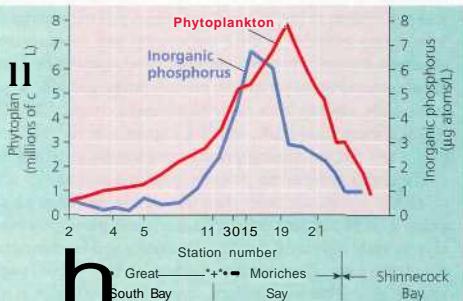

Moriches Bay adds both nitrogen and phosphorus to the coastal water off Long Island. Researchers cultured the phytoplankton *Nannochloris atomus* with water collected from several bays.

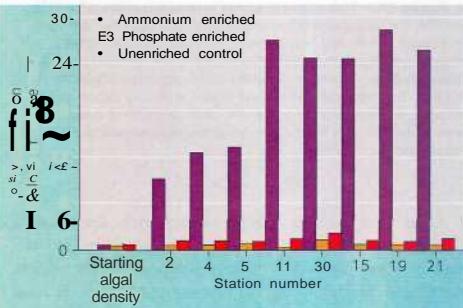

Coast of Long Island, New York.
The numbers on the map indicate the data collection stations.

RESULTS

Phytoplankton abundance parallels the abundance of phosphorus in the water (a). Nitrogen, however, is immediately taken up by algae, and no free nitrogen is measured in the coastal waters. The addition of ammonium (NH_4^+) caused heavy phytoplankton growth in bay water, but the addition of phosphate (PO_4^{3-}) did not induce algal growth (b).

(a) Phytoplankton biomass and phosphorus concentration

(b) Phytoplankton response to nutrient enrichment

CONCLUSION

Since adding phosphorus, which was already in rich supply, had no effect on *Nannochloris* growth, whereas adding nitrogen increased algal density dramatically, researchers concluded that nitrogen was the nutrient limiting phytoplankton growth in this ecosystem.

Table 54.1 Nutrient Enrichment Experiment for Sargasso Sea Samples

| Nutrients Added to Experimental Culture | Relative Uptake of ^{14}C by Cultures* |
|---|---|
| None (controls) | 1.00 |
| Nitrogen (N) + phosphorus (P) only | 1.10 |
| N + P + metals (excluding iron) | 1.08 |
| N + P + metals (including iron) | 12.90 |
| N + P + iron | 12.00 |

* ^{14}C uptake by cultures measures primary production.

period. A massive phytoplankton bloom occurred, as indicated by a 27-fold increase in chlorophyll concentration in water samples from the test sites.

Why are iron concentrations naturally low in certain oceanic regions? Windblown dust from the land is the main process delivering iron to the ocean, and relatively little dust reaches the central Pacific and central Atlantic Oceans.

The iron factor in marine ecosystems is actually related to the nitrogen factor. Where iron is limiting, adding iron stimulates growth of cyanobacteria that fix nitrogen, converting atmospheric N_2 to nitrogenous compounds (see Chapter 27). These nitrogenous nutrients in turn stimulate proliferation of eukaryotic phytoplankton. This relationship can be summarized as:

$$\text{Iron} \xrightarrow{*} \text{Cyanobacteria} \wedge \text{Nitrogen fixation} \xrightarrow{*} \text{Phytoplankton production}$$

A Figure 54.7 The experimental eutrophication of a lake. In 1974, the far basin of this lake was separated from the near basin by a plastic curtain and fertilized with inorganic sources of carbon, nitrogen, and phosphorus. Within two months, the fertilized basin was covered with a cyanobacterial bloom, which appears white in the photograph. The near basin, which was treated with only carbon and nitrogen, remained unchanged. In this case, phosphorus was the key limiting nutrient, and its addition stimulated the explosive growth of cyanobacteria.

Areas of upwelling, where nutrient-rich deep waters circulate to the ocean surface, have exceptionally high primary production, which supports the hypothesis that nutrient availability determines marine primary production. Because the steady supply of nutrients stimulates growth of the phytoplankton populations that form the base of marine food webs, upwelling areas are prime fishing locations. The largest areas of upwelling occur in the Southern Ocean (Antarctic Ocean) and in the coastal waters off Peru, California, and parts of western Africa.

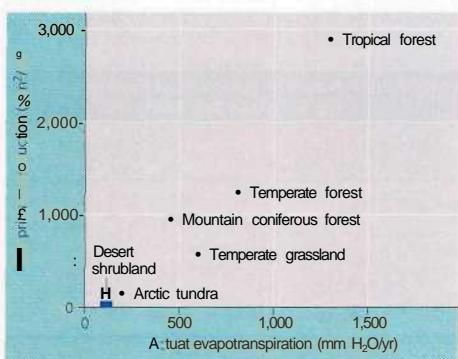

Nutrient limitation is also common in freshwater lakes. During the 1970s, scientists, including David Schindler from the University of Alberta, Canada, noted that sewage and fertilizer runoff from farms and yards added large amounts of nutrients to lakes. In many lakes, phytoplankton communities that had been dominated by diatoms or green algae became dominated by cyanobacteria. This process, known as eutrophication (from the Greek *eutrophos*, well nourished), has a wide range of ecological impacts, including the eventual loss of all but the most tolerant fish species from the lakes (see Figure 50.17). Controlling eutrophication requires knowing which polluting nutrient enables the cyanobacteria to bloom; nitrogen is rarely the limiting factor for primary production in lakes. Schindler conducted a series of whole-lake experiments that pointed to phosphorus as the nutrient that limited cyanobacterial growth (Figure 54.7). His research led to the use of phosphate-free detergents and other water quality reforms.

Primary Production in Terrestrial and Wetland Ecosystems

On a large geographic scale, temperature and moisture are the key factors controlling primary production in terrestrial and wetland ecosystems. Note again in Figure 54.3b that tropical rain forests, with their warm, wet conditions that promote plant growth, are the most productive of all terrestrial ecosystems. In contrast, low-productivity terrestrial ecosystems are generally dry—for example, deserts, which receive little precipitation—or cold and dry—for instance, arctic tundra. Between these extremes lie the temperate forest and grassland ecosystems, which have moderate climates and intermediate productivity levels. These contrasts in climate can be represented by a measure called actual evapotranspiration, which is the annual amount of water transpired by plants and evaporated from a landscape, usually measured in millimeters. Actual evapotranspiration increases with the amount of precipitation in a region and the amount of solar energy available to drive evaporation and transpiration.

Figure 54.8 shows the significant positive relationship between actual evapotranspiration and net primary production in selected ecosystems, ranging from desert shrubland to tropical forest.

On a more local scale, mineral nutrients in the soil can play a key role in limiting primary production in terrestrial and wetland ecosystems. Primary production removes soil nutrients, sometimes faster than they are replaced. At some point, a single nutrient deficiency may cause plant growth to slow or cease. It is unlikely that all nutrients will be exhausted simultaneously. If a certain nutrient limits production, adding a nonlimiting nutrient, even if that nutrient is in short supply, will not stimulate production. For example, if nitrogen is limiting, adding phosphorus will not stimulate production, whereas additional nitrogen will act as a stimulant until some other nutrient—say, phosphorus—becomes

A Figure 54.8 Actual evapotranspiration (temperature and moisture) related to terrestrial net primary production in selected ecosystems.

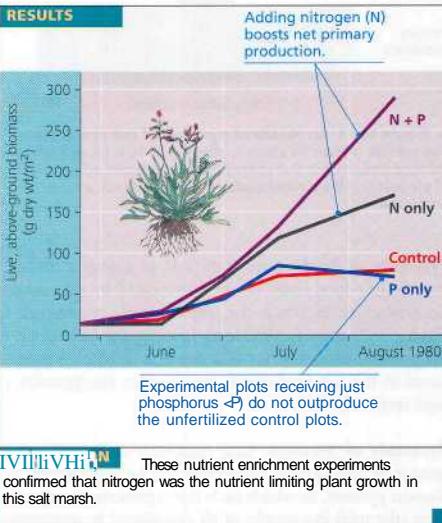

Figure 54.9

Inquiry Is phosphorus or nitrogen the limiting nutrient in a Hudson Bay salt marsh?

EXPERIMENT

Over the summer of 1980, researchers added phosphorus to some experimental plots in the salt marsh, nitrogen to other plots, and both phosphorus and nitrogen to others. Some plots were left unfertilized as controls.

RESULTS

limiting (Figure 54.9). In fact, nitrogen and phosphorus are most often the nutrients limiting terrestrial and wetland production.

Studies relating nutrients to terrestrial primary production have practical applications in agriculture. Farmers maximize their crop yields by using fertilizers with the right balance of nutrients for the local soil and the type of crop.

Concept Check 54.2

- Why is only a small portion of the solar energy that strikes Earth's atmosphere stored by primary producers?
- How can ecologists experimentally determine the factor limiting primary production in an ecosystem?
- Why does the open ocean account for almost 25% of Earth's primary production despite its relatively low rate of primary production?
- Why is an ecosystem's net primary production lower than its gross primary production?

For suggested answers, see Appendix A.

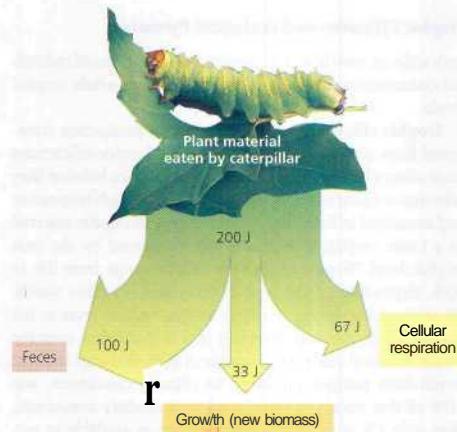

Concept 54.3

Energy transfer between trophic levels is usually less than 20% efficient

The amount of chemical energy in consumers' food that is converted to their own new biomass during a given time period is called the secondary production of the ecosystem. Consider the transfer of organic matter from primary producers to herbivores, the primary consumers. In most ecosystems, herbivores eat only a small fraction of plant material produced. And they cannot digest all the plant material that they *do* eat, as anyone who has walked through a dairy farm will attest. Thus, much of primary production is not used by consumers. Let's analyze this process of energy transfer more closely.

Production Efficiency

First let's examine secondary production in an individual organism—a caterpillar. When a caterpillar feeds on a plant leaf, only about 33 J out of 200 J (48 cal), or one-sixth of the energy in the leaf, is used for secondary production, or growth (Figure 54.10). The caterpillar uses some of the remaining energy for cellular respiration and passes the rest in its feces. The energy contained in the feces remains in the ecosystem, as it will be consumed by detritivores. The energy used for the caterpillar's respiration, however, is lost

A Figure 54.10 Energy partitioning within a link of the food chain. Less than 17% of the caterpillar's food is actually used for secondary production (growth).

Primary Production in Terrestrial and Wetland Ecosystems

from the ecosystem as heat. This is why energy is said to flow through, not cycle within, ecosystems. Only the chemical energy stored by herbivores as biomass (through growth or the production of offspring) is available as food to secondary consumers.

Our caterpillar example is based on the leaf tissue that is actually consumed but says nothing about the available plant material not eaten. The greenness of most terrestrial landscapes is visible evidence that most net primary production is in fact *not* consumed by herbivores and converted to secondary production.

"We can measure the efficiency of animals as energy transformers using the following equation:

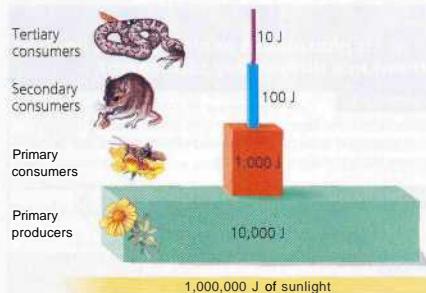

$$\text{Production efficiency} = \frac{\text{Net secondary production}}{\text{Assimilation of primary production}}$$

Net secondary production is the energy stored in biomass represented by growth and reproduction. Assimilation consists of the total energy taken in and used for growth, reproduction, and respiration. Production efficiency, therefore, is the fraction of energy stored in food that is *not* used for respiration. For the caterpillar in Figure 54.10, production efficiency is 33%; 67 J of the 100 J of assimilated energy is used for respiration. (Note that the energy lost as undigestible material in feces does not count toward assimilation.) Birds and mammals typically have low production efficiencies, in the range of 1–3%, because they use so much energy in maintaining a constant, warm body temperature. Fishes, which are ectotherms (see Chapter 40), have production efficiencies around 10%. Insects are even more efficient, with production efficiencies averaging 40%.

Trophic Efficiency and Ecological Pyramids

Let's scale up now from the production efficiencies of individual consumers to the flow of energy through whole trophic levels.

Trophic efficiency is the percentage of production transferred from one trophic level to the next. Trophic efficiencies must always be less than production efficiencies because they take into account not only the energy lost through respiration and contained in feces, but also the energy in organic material in a lower trophic level that is not consumed by the next trophic level. Trophic efficiencies usually range from 5% to 20%, depending on the type of ecosystem. In other words, 80–95% of the energy available at one trophic level is not transferred to the next. And this loss is multiplied over the length of a food chain. For example, if 10% of energy is transferred from primary producers to primary consumers, and 10% of that energy is transferred to secondary consumers, then only 1% of net primary production is available to secondary consumers (10% of 10%).

A Figure 54.11 An idealized pyramid of net production.

This example is based on a trophic efficiency of 10% for each link in the food chain. Notice that primary producers convert only about 1% of the energy in the sunlight available to them into net primary production.

Pyramids of Production. This loss of energy with each transfer in a food chain can be represented by a *pyramid of net production*, in which the trophic levels are stacked in blocks, with primary producers forming the foundation of the pyramid (Figure 54.11). The size of each block is proportional to the net production, expressed in energy units, of each trophic level.

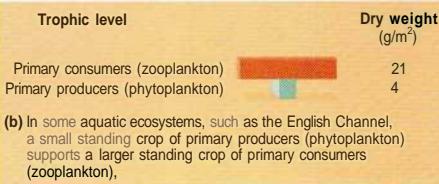

Pyramids of Biomass. One important ecological consequence of low trophic efficiencies can be represented in a *biomass pyramid*, in which each tier represents the standing crop (the total dry weight of all organisms) in one trophic level. Most biomass pyramids narrow sharply from primary producers at the base to top-level carnivores at the apex because energy transfers between trophic levels are so inefficient (Figure 54.12a). Certain aquatic ecosystems, however, have inverted biomass pyramids: Primary consumers outweigh the producers (Figure 54.12b). Such inverted biomass pyramids occur because the producers—phytoplankton—so quickly grow, reproduce, and are consumed by the zooplankton that they never develop a large population size, or standing crop. In other words, phytoplankton have a short turnover time, which means they have a small standing crop biomass compared to their production:

$$\text{Turnover time} = \frac{\text{Standing crop biomass (mg/m}^3\text{)}}{\text{Production (mg/m}^3\text{/day)}}$$

Because the phytoplankton continue to replace their biomass at such a rapid rate, they can support a biomass of zooplankton bigger than their own biomass. Nevertheless, because phytoplankton have much higher production than zooplankton, the pyramid of production for this ecosystem is bottom-heavy, like the one in Figure 54.11.

(a) Most biomass pyramids show a sharp decrease in biomass at successively higher trophic levels, as illustrated by data from a bog at Silver Springs, Florida.

A Figure 54.12 Pyramids of biomass (standing crop).
Numbers denote the dry weight (g/m^2) for all organisms at a trophic level.

Pyramids of Numbers. The progressive loss of energy along a food chain severely limits the overall biomass of top-level carnivores that any ecosystem can support. Only about 0.1% of the chemical energy fixed by photosynthesis can flow all the way through a food web to a tertiary consumer, such as a snake, hawk, or shark (see Figure 54.11). This explains why most food webs include only about four or five trophic levels (see Chapter 53).

Although there are situations in which many small consumers feed on a few larger primary producers, such as insects feeding on trees, predators are usually larger than the prey they eat. Thus, top-level predators tend to be fairly large animals. As a result, the limited biomass at the top of an ecological pyramid is concentrated in a relatively small number of large individuals. This phenomenon is reflected in a *pyramid of numbers*, in which the size of each block is proportional to

Trophic level

Secondary consumers

Primary consumers

Primary producers

< Figure 54.14 Relative food energy available to the human population at different trophic levels. Most humans have a diet between these two extremes.

Number of individual organisms

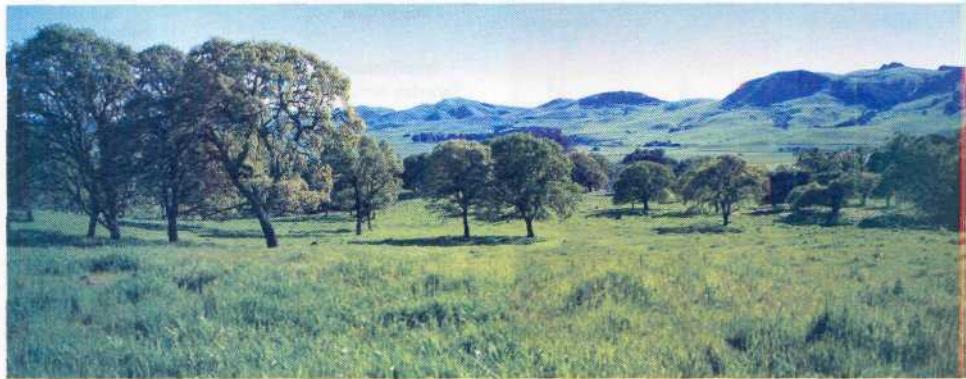

A Figure 54.13 A pyramid of numbers. In a bluegrass field in Michigan, only three top carnivores are supported in an ecosystem based on production by nearly 6 million plants.

the number of individual organisms present in that trophic level (Figure 54.13). Because populations of top predators are typically small, and the animals may be widely spaced within their habitats, many predators are highly susceptible to extinction (as well as to the evolutionary consequences of small population size discussed in Chapter 23).

The dynamics of energy flow through ecosystems have important implications for the human population. Eating meat is a relatively inefficient way of tapping photosynthetic production. A human obtains far more calories by eating a certain amount of grain directly as a primary consumer than by processing that same amount of grain through another trophic level and eating meat from grain-fed animals (beef, poultry, pork, lamb, farmed fish). Worldwide agriculture could, in fact, successfully feed many more people than it does today and require less cultivated land to support those people if humans all fed more efficiently—as primary consumers, eating only plant material (Figure 54.14).

The Green World Hypothesis

With so many primary consumers (herbivores) feeding on plants, how can we explain why most terrestrial ecosystems are actually quite green, boasting large standing crops of vegetation? According to the green world hypothesis, terrestrial herbivores consume relatively little plant biomass because they are held in check by a variety of factors, including predators, parasites, and disease.

A. **Figure 54.15 A green ecosystem.** Most terrestrial ecosystems have large standing crops of vegetation despite the large number of resident herbivores. The green world hypothesis offers possible explanations for this observation.

just how green is our green world? A total of approximately 83×10^{10} metric tons of carbon are stored in the plant biomass of terrestrial ecosystems. And the global rate of terrestrial primary production is about 5×10^{10} metric tons of plant biomass per year. On a global scale, herbivores annually consume less than 17% of the total net primary production by plants; (most of the rest is eventually consumed by detritivores). Thus, overall, herbivores represent only a minor nuisance to plants. Of course, some herbivores have the potential to completely strip local vegetation over the short term; an example is the ability of exploding gypsy moth populations to occasionally defoliate areas of forest in the northeastern United States. Such exceptions only heighten our curiosity about why Earth is so green (**Figure 54.15**).

The green world hypothesis proposes several factors that keep herbivores in check:

- Plants have defenses against herbivores. These defenses include spines and noxious chemicals, such as those described in Chapter 39.
- Nutrients, not energy supply, usually limit herbivores. Animals need certain nutrients, such as organic nitrogen (protein), that plants tend to supply in relatively small amounts. Even in a world of plentiful green energy, the growth and reproduction of many herbivores are limited by availability of essential nutrients.
- Abiotic factors limit herbivores. Unfavorable seasonal changes in temperature and moisture are examples of abiotic factors that can set a carrying capacity for herbivores in a particular environment far below the number that would strip vegetation there.

- Intraspecific competition can limit herbivore numbers. Territorial behavior and other consequences of competition may maintain herbivores' population densities below what the vegetation could feed.
- Interspecific interactions keep herbivore densities in check. The green world hypothesis postulates that predators, parasites, and disease are the most important factors limiting the growth of herbivore populations. This applies the top-down model of community structure, which we discussed in Chapter 53.

In the next section, we will look at how the transfer of chemical nutrients along with energy through food webs is part of a larger picture of nutrient recycling in ecosystems.

Concept Check 54.3

1. If an insect that eats plant seeds containing 100 J of energy uses 30 J of that energy for respiration and excretes 50 J in its feces, what is the insect's net secondary production? What is its production efficiency?
2. On a global scale, herbivores consume only about 17% of net primary production by terrestrial plants, yet most plant biomass is eventually consumed. Explain.
3. Why does the production pyramid have the same general shape as the biomass pyramid in most ecosystems? Under what circumstances might the shapes of the two pyramids differ?

For suggested answers, see Appendix A.

Concept 54.4

Biological and geochemical processes move nutrients between organic and inorganic parts of the ecosystem

Although most ecosystems receive an essentially inexhaustible influx of solar energy; chemical elements are available only in limited amounts. (The meteorites that occasionally strike Earth are the only extraterrestrial source of new matter.) Life on Earth therefore depends on the recycling of essential chemical elements. While an individual organism is alive, much of its chemical stock is rotated continuously as nutrients are assimilated, and waste products released. Atoms present in the complex molecules of an organism when it dies are returned as simpler compounds to the atmosphere, water, or soil by the action of decomposers. This decomposition replenishes the pools of inorganic nutrients that plants and other autotrophs use to build new organic matter. Because nutrient circuits involve both biotic and abiotic components, they are also called biogeochemical cycles.

A General Model of Chemical Cycling

A chemicals specific route through a biogeochemical cycle varies with the particular element and the trophic structure of the ecosystem. We can, however, recognize two general categories of biogeochemical cycles: global and local. Gaseous forms of carbon, oxygen, sulfur, and nitrogen occur in the atmosphere, and cycles of these elements are essentially global. For example, some of the carbon and oxygen atoms a plant acquires from the air as CO_2 may have been released into the atmosphere by the respiration of an organism in a distant locale. Other, less mobile elements, including phosphorus, potassium, and calcium, generally cycle on a more localized scale, at least over the short term. Soil is the main abiotic reservoir of these elements, which are absorbed by plant roots and eventually returned to the soil by decomposers, usually in the same vicinity.

Before examining the details of individual cycles, let's look at a general model of nutrient cycling that includes the main reservoirs of elements and the processes that transfer elements between reservoirs (Figure 54.16). Each reservoir is defined by two characteristics: whether it contains organic or inorganic materials and whether or not the materials are directly available for use by organisms.

The nutrients in living organisms themselves and in detritus (reservoir a in Figure 54.16) are available to other organisms when consumers feed and when detritivores consume nonliving organic matter. Some material moved from the living organic reservoir to the fossilized organic reservoir (reservoir b) long ago, when dead organisms were buried by sedimentation

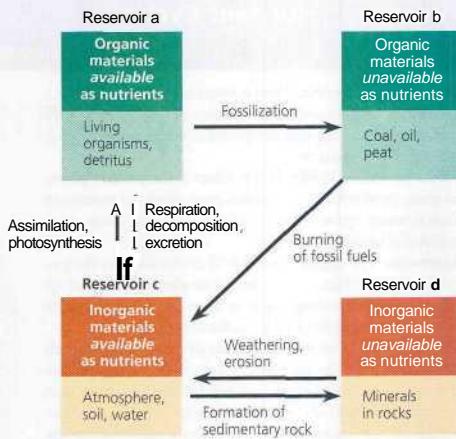

Figure 54.16 A general model of nutrient cycling. Arrows indicate the processes that move nutrients between reservoirs.

over millions of years, becoming coal, oil, or peat (fossil fuels). Nutrients in these deposits cannot be assimilated directly.

Inorganic materials (elements and compounds) that are dissolved in water or present in soil or air (reservoir c) are available for use. Organisms assimilate materials from this reservoir directly and return chemicals to it through the relatively rapid processes of cellular respiration, excretion, and decomposition. Although organisms cannot directly tap into the inorganic elements tied up in rocks (reservoir d), these nutrients may slowly become available through weathering and erosion. Similarly unavailable organic materials move into the available reservoir of inorganic nutrients when fossil fuels are burned, releasing exhaust into the atmosphere.

Tracing elements through particular biogeochemical cycles is much more complex, especially since ecosystems exchange elements with other ecosystems. Even in a pond, which has discrete boundaries, dust or leaves blowing into the pond and the emergence of aquatic insects can add or remove key nutrients. Keeping track of inflow and outflow is even more challenging in less clearly delineated terrestrial ecosystems. Nevertheless, ecologists have worked out the schemes for chemical cycling in several ecosystems. Ecologists study chemical cycling by adding tiny amounts of radioactive isotopes of the elements they want to track or by following the movement of naturally occurring stable, nonradioactive isotopes through the various biotic and abiotic components of an ecosystem.

Biogeochemical Cycles

Figure 54.17, on the next two pages, provides a detailed look at the cycling of water, carbon, nitrogen, and phosphorus. The

Figure 54.17
Exploring Nutrient Cycles

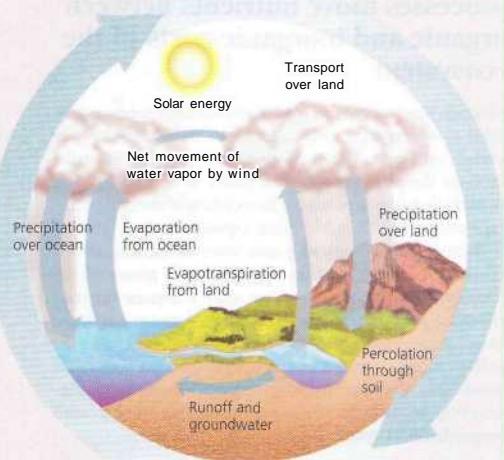

THE WATER CYCLE

Biological importance: Water is essential to all organisms (see Chapter 3), and its availability influences rates of ecosystem processes, particularly primary production and decomposition in terrestrial ecosystems.

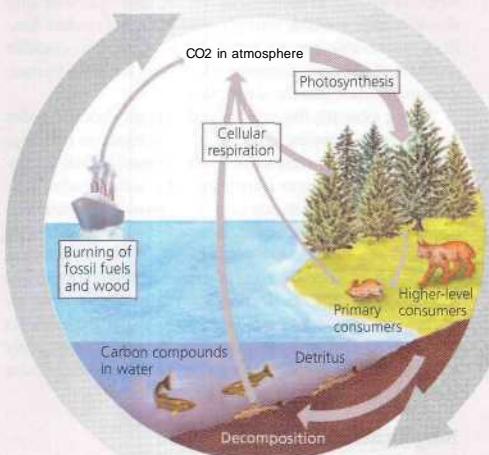

Forms available to life: Liquid water is the primary physical phase in which water is used, though some organisms can harvest water vapor. Freezing of soil water can limit water availability to terrestrial plants.

Reservoirs: The oceans contain 97% of the water in the biosphere. Approximately 2% is bound in glaciers and polar ice caps, and the remaining 1% is in lakes, rivers, and groundwater, with a negligible amount in the atmosphere.

Key processes: The main processes driving the water cycle are evaporation of liquid water by solar energy, condensation of water vapor into clouds, and precipitation. Transpiration by terrestrial plants also moves significant volumes of water. Surface and groundwater flow can return water to the oceans, completing the water cycle. The widths of the arrows in the diagram reflect the relative contribution of each process to the movement of water in the biosphere.

THE CARBON CYCLE

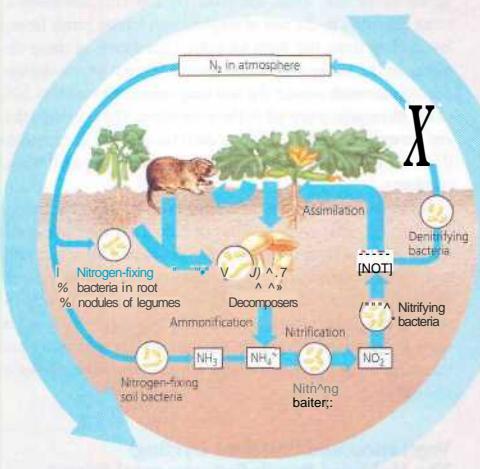

Biological importance: Carbon forms the framework for the organic molecules essential to all organisms.

Forms available to life: Photosynthetic organisms utilize CO₂ during photosynthesis and convert the carbon to organic forms that are used by consumers, including heterotrophic prokaryotes (see Chapter 27).

Reservoirs: The major reservoirs of carbon include fossil fuels, soils, the sediments of aquatic ecosystems, the oceans (dissolved carbon compounds), plant and animal biomass, and the atmosphere (CO₂). The largest reservoir is sedimentary rocks such as limestone; however, this pool turns over very slowly. **Key processes:** Photosynthesis by plants and phytoplankton removes substantial amounts of atmospheric CO₂ each year. This quantity is approximately equaled by CO₂ added to the atmosphere through cellular respiration by producers and consumers. Over geologic time, volcanoes are a substantial source of CO₂. The burning of fossil fuels is adding significant amounts of additional CO₂ to the atmosphere. The widths of the arrows reflect the relative contribution of each process.

THE NITROGEN CYCLE

Biological importance: Nitrogen is a component of amino acids, proteins, and nucleic acids and is a crucial and often limiting plant nutrient.

Forms available to life: Plants and algae can use two inorganic forms of nitrogen: ammonium (NH_4^+) or nitrate (NO_3^-). Various bacteria can also use NH_4^+ and NO_3^- , as well as nitrite (NO_2^-). Animals can utilize only organic forms of nitrogen (such as amino acids or proteins).

Reservoirs: The main reservoir of nitrogen is the atmosphere, which is 80% nitrogen gas (N_2). The other reservoirs are bound nitrogen in soils; in the sediments of lakes, rivers, and oceans; dissolved in surface water and groundwater systems; and in the biomass of living organisms.

Key processes: The major pathway for nitrogen to enter an ecosystem is via *nitrogen fixation*, the conversion of N_2 by bacteria to forms that can be used to synthesize nitrogenous organic compounds (see Chapter 37). Some nitrogen is also fixed by lightning. Nitrogen fertilizer, precipitation, and blowing dust can also provide substantial inputs of NH_4^+ and NO_3^- to ecosystems. *Ammonification* decomposes organic nitrogen to NH_4^+ . In *nitrification*, NH_4^+ is converted to NO_3^- by nitrifying bacteria. Under anaerobic conditions, denitrifying bacteria use NO_3^- in their metabolism instead of O_2 , releasing N_2 in a process known as *denitrification*. The widths of the arrows reflect the relative contribution of each process.

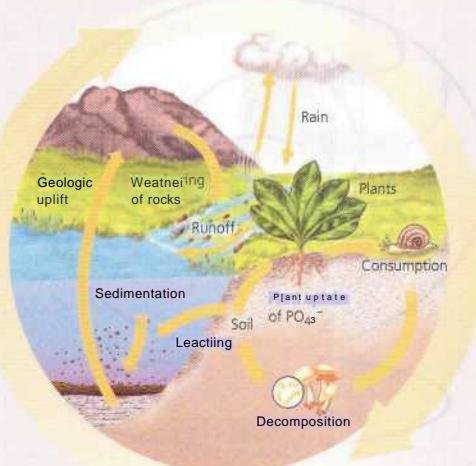

THE PHOSPHORUS CYCLE

Biological importance: Organisms require phosphorus as a major constituent of nucleic acids, phospholipids, and ATP and other energy-storing molecules, and as a mineral constituent of bones and teeth.

Forms available to life: The only biologically important inorganic form of phosphorus is phosphate (PO_4^{3-}), which plants absorb and use to synthesize organic compounds.

Reservoirs: The largest accumulations of phosphorus are in sedimentary rocks of marine origin. There are also large quantities of phosphorus in soils, in the oceans (in dissolved form), and in organisms. Because humus and soil particles bind phosphate, the recycling of phosphorus tends to be quite localized in ecosystems.

Key processes: Weathering of rocks gradually adds phosphate to soil; some leaches into groundwater and surface water and may eventually find its way into the sea. Phosphate taken up by producers and incorporated into biological molecules may be eaten by consumers and distributed through the food web. Phosphate is returned to soil or water through either decomposition of biomass or excretion by consumers. Because there are no significant phosphorus-containing gases, only relatively small amounts of phosphorus move through the atmosphere, usually in the form of dust and sea spray. The widths of the arrows reflect the relative contribution of each process.

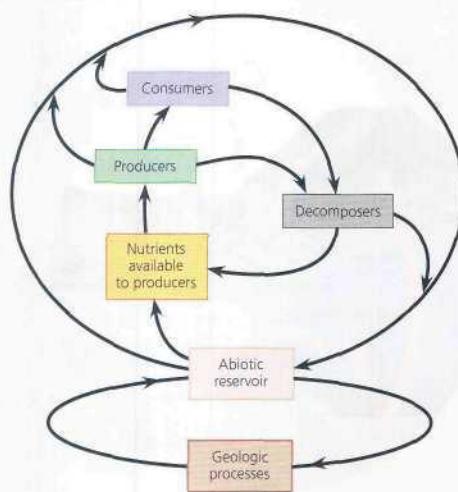

diagrams focus on four important factors that ecologists consider as they research biogeochemical cycles:

1. The biological importance of each chemical
2. The forms in which each chemical is available or used by organisms
3. The major repositories or reservoirs for each chemical
4. The key processes that drive the movement of each chemical through its biogeochemical cycle

Decomposition and Nutrient Cycling Rates

Now that we have examined several individual biogeochemical cycles, we can review the general pattern of chemical cycling as illustrated in **Figure 54.18**. Note again the key role of decomposers (detritivores). The rates at which nutrients cycle in different ecosystems are extremely variable, mostly as a result of differences in rates of decomposition. In tropical rain forests, for instance, most organic material decomposes in a few months to a few years, while in temperate forests, decomposition takes four to six years, on average. The difference is largely the result of the warmer temperatures and more abundant precipitation in the tropical forests. Temperature and the availability of water affect rates of decomposition and thus nutrient cycling times. Like net primary production, the rate of decomposition in terrestrial ecosystems increases with actual evapotranspiration. (Other factors that can also influence nutrient cycling are the local soil chemistry and the frequency of fires.)

A **Figure 54.18** Review: Generalized scheme for biogeochemical cycles.

When decomposition occurs in a tropical rain forest, relatively little organic material accumulates as leaf litter on the forest floor; about 75% of the nutrients in the ecosystem are present in the woody trunks of trees, and about 10% are contained in the soil. Thus, the relatively low concentrations of some nutrients in the soil of tropical rain forests result from a fast cycling time, not from an overall scantiness of these elements in the ecosystem. In temperate forests, where decomposition is much slower, the soil may contain as much as 50% of all the organic material in the ecosystem. The nutrients that are present in temperate forest detritus and soil may remain there for fairly long periods of time before being assimilated by plants.

In aquatic ecosystems decomposition in anaerobic muds can take 50 years or more. Bottom sediments are comparable to the detritus layer in terrestrial ecosystems; however, algae and aquatic plants usually assimilate nutrients directly from the water. Thus, the sediments often constitute a nutrient sink, and aquatic ecosystems are very productive only when there is interchange between the bottom layers of water and the surface (as in the upwelling regions described earlier in this chapter).

Vegetation and Nutrient Cycling: The Hubbard Brook Experimental Forest

In one of the longest-running examples of long-term ecological research (LTER) in North America, a team of scientists led by Herbert Bormann and Gene Likens (see interview on pages 1078-1079) has been studying nutrient cycling in a forest ecosystem since 1963. The study site, the Hubbard Brook Experimental Forest in the White Mountains of New Hampshire, is a deciduous forest with several valleys, each drained by a small creek that is a tributary of Hubbard Brook. Bedrock impenetrable to water is close to the surface of the soil, and each valley constitutes a watershed that can drain only through its creek.

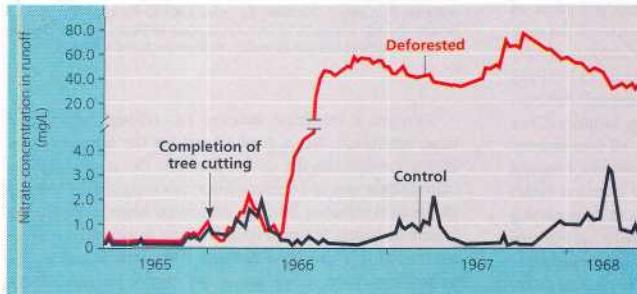

The research team first determined the mineral budget for each of six valleys by measuring the input and outflow of several key nutrients. They collected rainfall at several sites to measure the amount of water and dissolved minerals added to the ecosystem. To monitor the loss of water and minerals, they constructed a small concrete dam with a V-shaped spillway across the creek at the bottom of each valley (**Figure 54.19a**). About 60% of the water added to the ecosystem as rainfall and snow exits through the stream, and thus the remaining 40% is lost by transpiration from plants and evaporation from other organisms and the soil.

Preliminary studies confirmed that internal cycling within a terrestrial ecosystem conserves most of the mineral nutrients. For example, only about 0.3% more calcium (Ca^{2+}) left a valley via its creek than was added by rainwater, and this small net loss was probably replaced by chemical

(a) Concrete dams and weirs built across streams at the bottom of watersheds enabled researchers to monitor the outflow of water and nutrients from the ecosystem.

(b) One watershed was clear cut to study the effects of the loss of vegetation on drainage and nutrient cycling.

(c) The concentration of nitrate in runoff from the deforested watershed was 60 times greater than in a control (unlogged) watershed.

A Figure 54.19 Nutrient cycling in the Hubbard Brook Experimental Forest: an example of long-term ecological research.

decomposition of the bedrock. During most years, the forest actually registered small net gains of a few mineral nutrients, including nitrogen.

In one experiment, the trees in one valley were cut down and then the valley was sprayed with herbicides for three years to prevent regrowth of plants (Figure 54.19b). All the original plant material was left in place to decompose. The inflow and outflow of water and minerals in this experimentally altered watershed were compared with the inflow and outflow in a control watershed. Over the three years, water runoff from the altered watershed increased by 30–40%, apparently because there were no plants to absorb and transpire water from the soil. Net losses of minerals from the altered watershed were huge. The concentration of Ca^{2+} in the creek increased fourfold, for example, and the concentration of K^+ increased by a factor of 15. Most remark-

able was the loss of nitrate, which increased in concentration in the creek 60-fold (Figure 54.19c). Not only was this vital mineral nutrient drained from the ecosystem, but nitrate in the creek reached a level considered unsafe for drinking water.

This study demonstrated that the amount of nutrients leaving an intact forest ecosystem is controlled mainly by the plants. These effects of removing the trees are almost immediate, occurring within a few months, and continue as long as living plants are absent.

The 40 years of data from Hubbard Brook reveal some other trends. For instance, since the 1950s, acid rain and snow have dissolved most of the Ca^{2+} from the forest soil, and the streams have carried it away. By the 1990s, the forest biomass at Hubbard Brook had stopped growing, apparently because of a lack of Ca^{2+} . To test the possibility of growth limitation by inadequate supplies of calcium, ecologists at Hubbard Brook began a massive experiment in 1998. They first established a control and an experimental watershed, which they monitored over two years before using a helicopter to add Ca^{2+} to the experimental watershed. As Gene Likens indicated in the interview on pages 1078–1079, the Ca^{2+} -enriched soil is already showing signs of increased growth.

Results of the Hubbard Brook studies, as well as 25 other LTER projects in the United States, not only assess natural ecosystem dynamics but also provide important insight into the mechanisms by which human activities affect these processes.

Concept Check 54.4

- For each of the four biogeochemical cycles detailed in Figure 54.17, draw a simple diagram that shows one possible path for an atom or molecule of that chemical from abiotic to biotic reservoirs and back.
- Why does deforestation of a watershed increase the concentration of nitrates in streams draining the watershed?

For suggested answers, see Appendix A.

Concept 54.5

The human population is disrupting chemical cycles throughout the biosphere

As the human population has grown in size, our activities and technological capabilities have disrupted the trophic structure, energy flow, and chemical cycling of ecosystems in most areas of the world. As you will read in this section, the effects are sometimes local or regional, but the ecological impact of humans can even be global.

Nutrient Enrichment

Human activity often intrudes in nutrient cycles by removing nutrients from one part of the biosphere and adding them to another. On the simplest level, someone eating a piece of broccoli in Washington, DC, is consuming nutrients that only days before might have been in the soil in California; and a short time later, some of these nutrients will be in the Potomac River on their way to the sea, having passed through the individual's digestive system and the local sewage facilities. On a larger scale, nutrients in farm soil may run off into streams and lakes, resulting in nutrient depletion in one area, excesses in another, and the disruption of the natural chemical cycles in both locations. Furthermore, in addition to transporting nutrients from one location to another, humans have added entirely new materials—many of them toxic—to ecosystems.

Humans have intruded on nutrient cycles to such an extent that it is no longer possible to understand any cycle without taking these effects into account. Let's examine a few specific examples of how humans are impacting the biosphere's chemical dynamics.

Agriculture and Nitrogen Cycling

After natural vegetation is cleared from an area, the existing reserve of nutrients in the soil is sufficient to grow crops for some time without nutrient supplementation. However, in agricultural ecosystems, a substantial fraction of these nutrients is not recycled but is exported from the area in the form of crop biomass (**Figure 54.20**). The "free" period for crop production—when there is no need to add nutrients to the soil—varies greatly. When some of the early North American prairie lands were first tilled, for example, good crops could be produced for many years because the large store of organic materials in the soil continued to decompose and provide nutrients. By contrast, some cleared land in the tropics can be farmed for only one or two years because so little of the ecosystems' nutrient load is contained in the soil. Despite such variations, in any area under intensive agriculture, the natural store of nutrients eventually becomes exhausted.

4 Figure 54.20 Agricultural impact on soil nutrients.

Removal of harvested plant biomass for market removes mineral nutrients that would otherwise be cycled back to the local soil. To replace the lost nutrients, farmers must apply fertilizers—either organic fertilizers, such as manure or mulch, or manufactured fertilizers.

Nitrogen is the main nutrient lost through agriculture; thus, agriculture has a great impact on the nitrogen cycle. Plowing and mixing the soil are processes that increase the decomposition rate of organic matter, releasing usable nitrogen that is then removed from the ecosystem when crops are harvested. Industrially synthesized fertilizer is then used to make up for the loss of usable nitrogen from agricultural ecosystems. In addition, as we saw in the case of Hubbard Brook, without plants to take up nitrates from the soil, the nitrates are likely to be leached from the ecosystem.

Recent studies indicate that human activities have approximately doubled Earth's supply of fixed nitrogen available to primary producers. The main cause is industrial nitrogen fixation for fertilizers, but increased cultivation of legumes, with their nitrogen-fixing symbionts, is also important. In addition, the deliberate burning of fields after harvest, as well as burning to clear tropical forest for agriculture, releases nitrogen compounds stored in soil and vegetation, thereby enhancing nitrogen cycling. Excessive supplements of fixed nitrogen are also associated with a greater release of N_2 and nitrogen oxides into the air by denitrifying bacteria (see Figure 54.17). (Nitrogen oxides can contribute to atmospheric warming, to the depletion of atmospheric ozone, and in some ecosystems to acid precipitation.)

Contamination of Aquatic Ecosystems

The key problem with excess nitrogen seems to be critical load, the amount of added nutrient, usually nitrogen or phosphorus, that can be absorbed by plants without damaging ecosystem integrity. Nitrogenous minerals in the soil that exceed the critical load eventually leach into groundwater or run off

directly into freshwater and marine ecosystems, contaminating water supplies, choking waterways, and killing fish. Many rivers contaminated with nitrates and ammonium from agricultural runoff and sewage drain into the North Atlantic Ocean, with the highest nitrogen inputs coming from northern Europe. Groundwater concentrations of nitrate are also increasing in agricultural areas, sometimes exceeding the maximum level considered safe for drinking water (10 mg of nitrate per liter).

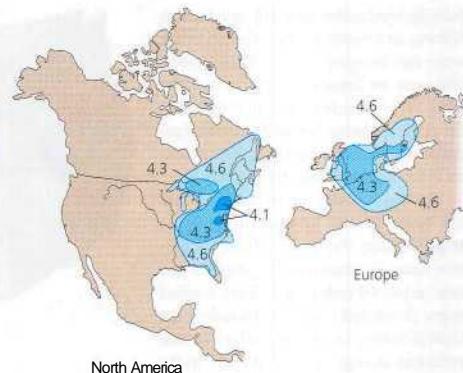

As we discussed in Chapter 50, lakes are classified by nutrient availability as oligotrophic or eutrophic (see Figure 50.17). In an oligotrophic lake, primary productivity is relatively low because the mineral nutrients required by phytoplankton are scarce. In other lakes, basin and watershed characteristics result in the addition of more nutrients. These nutrients are captured by the primary producers and then continuously recycled through the lake's food webs. Thus, the overall productivity is higher in lakes that are eutrophic.

Human intrusion has disrupted freshwater ecosystems by what is termed *cultural eutrophication*. Sewage and factory wastes; runoff of animal waste from pastures and stockyards; and the leaching of fertilizer from agricultural, recreational, and urban areas have all overloaded many streams, rivers, and lakes with inorganic nutrients. This enrichment often results in an explosive increase in the density of photosynthetic organisms, whose population growth, as described earlier in this chapter, is generally limited by either nitrogen or phosphorus. As a consequence, shallower areas become choked with weeds, making boating and fishing impossible. Large "blooms" of algae and cyanobacteria become common (see Figure 54.7). A eutrophic lake may be supersaturated with oxygen produced during the day while photosynthesis is taking place, but anoxic (oxygen-poor) at night when respiration occurs in the absence of photosynthesis. As the photosynthetic organisms die and organic material accumulates at the lake bottom, detritivores use all the oxygen in the deeper waters.

All these conditions threaten the survival of some organisms. For example, cultural eutrophication of Lake Erie wiped out commercially important fishes such as blue pike, whitefish, and lake trout by the 1960s. Since then, tighter regulations on waste dumping into the lake have enabled some fish populations to rebound, but many of the native species of fishes and invertebrates have not recovered.

Acid Precipitation

The burning of wood and of coal and other fossil fuels releases oxides of sulfur and nitrogen that react with water in the atmosphere, forming sulfuric and nitric acid, respectively. The acids eventually fall to Earth's surface as acid precipitation—rain, snow, sleet, or fog that has a pH less than 5.6. Acid precipitation lowers the pH of aquatic ecosystems and affects the soil chemistry of terrestrial ecosystems. Although acid precipitation due to fuel combustion has been occurring ever since the Industrial Revolution, emissions have increased during

A Figure 54.21 Distribution of acid precipitation in North America and Europe, 1980. The numbers identify the average pH of precipitation in the shaded areas.

the past hundred years, mainly as a result of ore smelters and electrical generating plants.

Acid precipitation is a regional and even global problem rather than a local one. To avoid local pollution problems, smelters and generating plants are built with very tall exhaust stacks (more than 300 m high). This reduces pollution at ground level, but exports the problem far downwind. The sulfurous and nitrogenous pollutants from fuel combustion may drift hundreds of kilometers before falling as acid precipitation.

Gene Likens and other ecologists first documented damage to forests and lakes in eastern North America and Europe in the 1960s. Lake-dwelling organisms in eastern Canada were dying because of air pollution from factories in the midwestern United States. Lakes and forests in southern Norway and Sweden were losing fish because of acid rain from pollutants generated in Great Britain and central and eastern Europe. By 1980, precipitation in large areas of North America and Europe averaged pH 4.0–4.5, with "record" storms occasionally dropping rain as acidic as pH 3.0 (**Figure 54.21**).

In terrestrial ecosystems, such as the deciduous forests of New England, the change in soil pH due to acid precipitation causes calcium and other nutrients to leach from the soil (as we saw earlier in the chapter from the Hubbard Brook studies). The nutrient deficiencies affect the health of plants and limit their growth. Acid precipitation can also damage plants directly, mainly by leaching nutrients from leaves.

Freshwater ecosystems are particularly sensitive to acid precipitation. The lakes in North America and northern Europe that are most readily damaged by acid precipitation are those underlain by granite bedrock. Such lakes generally have relatively poor buffering capacity because the concentration of bicarbonate, an important buffer, is low. Fish populations

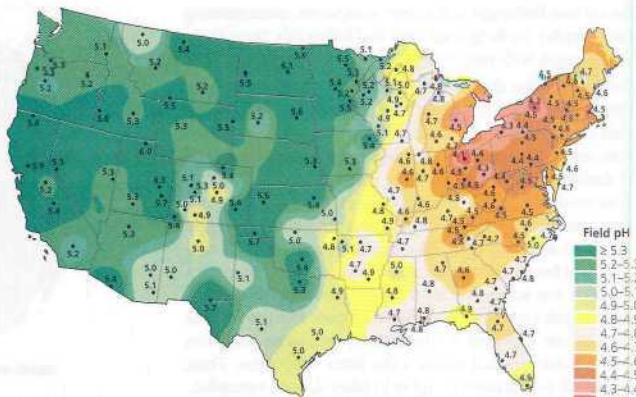

have declined in thousands of such lakes in Norway and Sweden, where the pH of the water has dropped below 5.0. In Canada, lake trout are keystone predators in many lakes. Newly hatched lake trout die when the pH drops below 5.4, and when they are replaced by acid-tolerant fish, the dynamics of food webs change dramatically.

The entire contiguous United States has been affected by acid precipitation (Figure 54.22). But there is also some positive news. Environmental regulations and new industrial technologies have enabled many developed countries, including the United States, to reduce sulfur dioxide emissions during the past 30 years. In the United States, for example, sulfur dioxide emissions were reduced 31% between 1993 and 2002. The water chemistry in the streams and freshwater lakes of New England is slowly improving after decades of severe acid precipitation. However, ecologists estimate that it will take another 10 to 20 years for these ecosystems to recover, even if sulfur dioxide emissions continue to decrease. Meanwhile, massive emissions of sulfur dioxide and acid precipitation continue in parts of central and eastern Europe, contributing to forest destruction over vast areas.

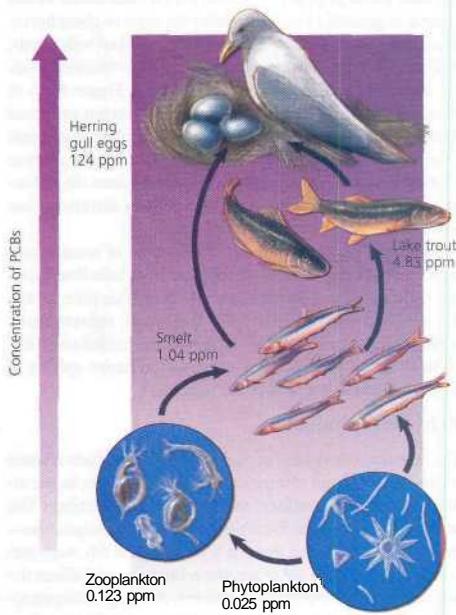

Toxins in the Environment

Humans release an immense variety of toxic chemicals, including thousands of synthetics previously unknown in nature, with little regard for the ecological consequences. Organisms acquire toxic substances from the environment along with nutrients and water. Some of the poisons are metabolized and excreted, but others accumulate in specific tissues, especially fat. One of the reasons such toxins are particularly harmful is that they become more concentrated in successive trophic levels of a food web, a process called biological magnification. Magnification occurs because the biomass at any given trophic level is produced from a much larger biomass ingested from the level below. Thus, top-level carnivores tend to be the organisms most severely affected by toxic compounds in the environment.

One class of industrially synthesized compounds that have demonstrated biological magnification are the chlorinated hydrocarbons, which include many pesticides, such as DDT, and the industrial chemicals called PCBs (polychlorinated biphenyls). Current research implicates many of these compounds in endocrine system disruption in a large number of animal species, including humans. Biological magnification of PCBs has been found in the food web of the Great Lakes, where the concentration of PCBs in herring gull eggs at the top of the food web is nearly 5,000 times greater than in phytoplankton at the base of the food web (Figure 54.23).

A Figure 54.22 Average pH for precipitation in the contiguous United States in 2002.

A Figure 54.23 Biological magnification of PCBs in a Great Lakes food web.

An infamous case of biological magnification that harmed top-level carnivores involved DDT, a chemical used to control insects such as mosquitoes and agricultural pests. In the decade after World War II, the pesticide industry promoted the benefits of DDT before anybody really understood the ecological consequences. By the 1950s, scientists were learning that DDT persists in the environment and is transported by water to areas far from where it is applied. But by then, the poison had already become a global problem. One of the first signs that DDT was a serious environmental problem was a decline in the populations of pelicans, ospreys, and eagles, birds that feed at the top of food webs. The accumulation of DDT (and DDE, a product of its partial breakdown) in the tissues of these birds interfered with the deposition of calcium in their eggshells, a trend that may have already begun because of other environmental contaminants. When these birds tried to incubate their eggs, the weight of the parents broke the shells of affected eggs, resulting in catastrophic declines in their reproduction rates. Rachel Carson's *Silent Spring* helped bring the problem to public attention in the 1960s (see Chapter 50), and DDT was banned in the United States in 1971. A dramatic recovery in populations of the affected bird species followed. The pesticide is still used in many other parts of the world, however.

Many toxins cannot be degraded by microorganisms and consequently persist in the environment for years or even decades. In other cases, chemicals released into the environment may be relatively harmless but are converted to more toxic products by reaction with other substances or by the metabolism of microorganisms. For example, mercury, a by-product of plastic production and coal-fired power generation, has been routinely expelled into rivers and the sea in an insoluble form. Bacteria in the bottom mud convert the waste to methyl mercury, an extremely toxic soluble compound that accumulates in the tissues of organisms, including humans who consume fish from the contaminated waters.

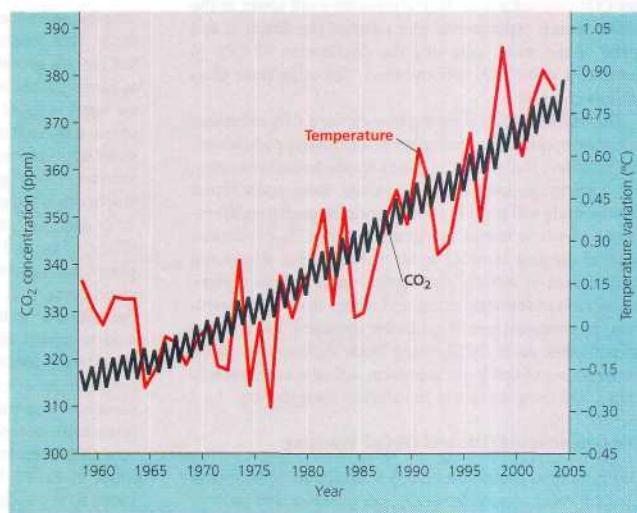

Atmospheric Carbon Dioxide

Many human activities release a variety of gaseous waste products. People once thought that the vastness of the atmosphere could absorb these materials without significant consequences, but we now know that such additions can cause fundamental changes in the composition of the atmosphere and in its interactions with the rest of the biosphere. One pressing problem is the rising level of atmospheric carbon dioxide.

Rising Atmospheric CO₂

Since the Industrial Revolution, the concentration of CO₂ in the atmosphere has been increasing as a result of the combustion of fossil fuels and the burning of enormous quantities of wood removed by deforestation. Scientists estimate that the average CO₂ concentration in the atmosphere before 1850 was about 274 ppm. In 1958, a monitoring station began taking very accurate measurements on Hawaii's Mauna Loa peak, where the air is free from the variable short-term effects that occur near large urban areas. At that time, the CO₂ concentration was 316 ppm (Figure 54.24). Today, the concentration of CO₂ in the atmosphere exceeds 370 ppm, an increase of about 17%. If CO₂ emissions continue to increase at the present rate, by the year 2075, the atmospheric concentration of this gas will be double what it was at the start of the Industrial Revolution.

Increased productivity by vegetation is one predictable consequence of increasing CO₂ levels. In fact, when CO₂ concentrations are raised in experimental chambers such as greenhouses, most plants respond with increased growth. However, because C₃ plants are more limited than C₄ plants by CO₂ availability (see Chapter 10), one effect of increasing global CO₂ concentration may be the spread of C₃ species into terrestrial habitats previously favoring C₄ plants. This may

& Figure 54.24 The increase in atmospheric carbon dioxide at Mauna Loa, Hawaii, and average global temperatures over land from 1958 to 2004. Aside from normal seasonal fluctuations, the total amount of CO₂ has increased steadily (black). Though average global land temperatures over the same period fluctuate a great deal (red), there is a warming trend.

have important agricultural implications. For example, corn (maize), a C₄ plant and the most important grain crop in the United States, may be replaced by wheat and soybeans, C₃ crops that outproduce corn in a CO₂-enriched environment. To predict the gradual and complex effects of rising CO₂ levels on species composition in nonagricultural communities, scientists are turning to long-term field experiments.

How Elevated CO₂ Affects Forest Ecology: The FACTS-I Experiment

To assess how increasing atmospheric concentration of CO₂ might affect temperate forests, scientists at Duke University began the Forest-Atmosphere Carbon Transfer and Storage (FACTS-I) experiment in 1995. The researchers are manipulating a single environmental factor, the concentration of CO₂, to which tracts of forest are exposed. All other factors, such as temperature, precipitation, and wind speed and direction vary normally for both experimental plots and adjacent control plots exposed to only atmospheric CO₂.

The FACTS-I experiment includes six plots in a 200-acre (80-hectare) tract of loblolly pine within Duke University's experimental forest. Each plot consists of a circular area, approximately 30 m in diameter, ringed by 16 towers (Figure 54.25). Within three of the plots (the experimental plots), the towers produce air containing about 11/2 times present-day CO₂ concentrations. Instruments on a tall tower in the center of each experimental plot measure the direction and speed of the wind, adjusting the distribution of CO₂ to maintain a stable CO₂ concentration. The other three plots serve as controls.

The FACTS-I study is testing how elevated CO₂ influences tree growth, carbon concentration in soils, insect populations, soil moisture, the growth of plants in the forest understory, and other factors over a ten-year period. Researchers expect that the study will provide a sound basis for predicting the response of whole forests to elevated future CO₂ conditions. Some of the data recorded so far include higher weight and lipid content of loblolly pine seeds, higher soil respiration, higher rates of soil weathering, and higher rates of photosynthesis by sweetgum trees (*Liquidambar styraciflua*) in the experimental plots. As in the Hubbard Brook experimental forest, the responses of this forest ecosystem will take many years to unfold, and there are sure to be surprises along the way.

The Greenhouse Effect and Global Warming

One factor that complicates predictions about the long-term effects of rising atmospheric CO₂ concentration is its possible influence on Earth's heat budget. Much of the solar radiation that strikes the planet is reflected back into space. Although CO₂ and water vapor in the atmosphere are transparent to visible light, they intercept and absorb much of the reflected

A Figure 54.25 Large-scale experiment on the effects of elevated CO₂. Rings of towers in the Duke University Experimental Forest emit enough carbon dioxide to raise and maintain CO₂ levels 200 ppm above present-day concentrations.

infrared radiation, re-reflecting some of it back toward Earth. This process retains some of the solar heat. If it were not for this **greenhouse effect**, the average air temperature at Earth's surface would be -18°C (-2.4°F), and most life as we know it could not exist. The marked increase in atmospheric CO₂ concentrations over the last 150 years concerns many scientists because of its potential to increase global temperature. (See Figure 54.24 for circumstantial evidence of a link between increasing CO₂ and global warming.)

To date, no models are sophisticated enough to include all the biotic and abiotic factors that can influence atmospheric gas concentrations and temperature (for example, cloud cover, CO₂ uptake by photosynthetic organisms, and the effects of particles in the air). However, a number of studies predict that by the end of the 21st century, atmospheric CO₂ concentration will double, and average global temperature will increase by about 2°C . Supporting these models is a correlation between CO₂ levels and temperatures in prehistoric times. Climatologists can actually measure CO₂ levels in bubbles trapped in glacial ice at different times in Earth's history. Prehistoric temperatures are inferred by several methods, including analysis of past vegetation based on fossils.

An increase of only 1.3°C would make the world warmer than at any time in the past 100,000 years. A worst-case scenario suggests that the warming would be greatest near the

poles. The resultant melting of polar ice might raise sea level by an estimated 100 m gradually flooding areas 150 km (or more) inland from the current coastline; New York, Miami, Los Angeles, and many other cities would then be under water. Recent collapses in the Antarctic ice shelf, which in 2002 released an iceberg four times the area of Manhattan, may be an early sign of global warming.

A warming trend would also alter the geographic distribution of precipitation, making major agricultural areas of the central United States much drier, for example. However, the various mathematical models disagree about the details of how climate in each region will be affected. By studying how *past* periods of global warming and cooling affected plant communities, ecologists are trying to predict the consequences of *future* temperature changes. Analysis of fossilized pollen provides evidence that plant communities change dramatically with changes in temperature. However, past climate changes occurred gradually and plant and animal populations could migrate into areas where abiotic conditions allowed them to survive. Many organisms, especially plants that cannot disperse rapidly over long distances, will probably not be able to survive the high rates of climate change projected to result from global warming.

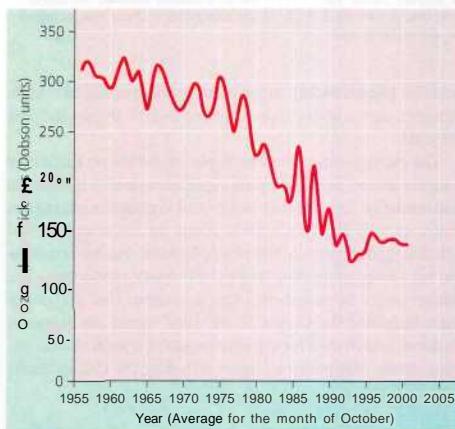

The global warming that apparently is now under way as a result of the addition of CO_2 to the atmosphere is a problem of uncertain consequences and no simple solutions. Coal, natural gas, gasoline, wood, and other organic fuels that cannot be burned without releasing CO_2 are central to our increasingly industrialized societies. Stabilizing CO_2 emissions will require concerted international effort and the acceptance of dramatic changes in both personal lifestyles and industrial processes. Many ecologists think that this effort suffered a major setback in 2001, when the United States pulled out of the Kyoto Protocol, a 1997 pledge by the industrialized nations to reduce their CO_2 output by about 5% over a ten-year period.

Depletion of Atmospheric Ozone

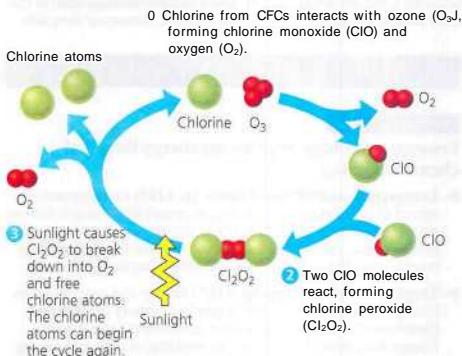

Life on Earth is protected from the damaging effects of ultraviolet (UV) radiation by a protective layer of ozone molecules (O_3) that is present in the lower stratosphere between 17 and 25 km above Earth's surface. Ozone absorbs UV radiation, preventing much of it from reaching organisms in the biosphere.

Satellite studies of the atmosphere suggest that the ozone layer has been gradually "thinning" since 1975 (Figure 54.26). The destruction of atmospheric ozone probably results mainly from the accumulation of chlorofluorocarbons (CFCs), chemicals used for refrigeration, as propellants in aerosol cans, and in certain manufacturing processes. When the breakdown products from these chemicals rise to the stratosphere, the chlorine they contain reacts with ozone, reducing it to molecular O_2 (Figure 54.27). Subsequent chemical reactions liberate

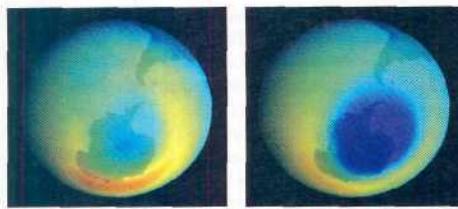

the chlorine, allowing it to react with other ozone molecules in a catalytic chain reaction. The effect is most apparent over Antarctica, where cold winter temperatures facilitate these atmospheric reactions. Scientists first described the "ozone hole" over Antarctica in 1985 and have since documented that it is a seasonal phenomenon that grows and shrinks in an annual cycle. However, the magnitude of ozone depletion and the size of the ozone hole have generally increased in recent years, and the hole sometimes extends as far as the southernmost portions of Australia, New Zealand, and South

• Figure 54.26 Thickness of the ozone layer over Antarctica in units called Dobsons.

• Figure 54.27 How free chlorine in the atmosphere destroys ozone.

(a) October 1979

(b) October 2000

A Figure 54.28 Erosion of Earth's ozone shield. The ozone hole over Antarctica is visible as the blue patch in these images based on atmospheric data.

America (**Figure 54.28**). At the more heavily populated middle latitudes, ozone levels have decreased 2–10% during the past 20 years.

The consequences of ozone depletion for life on Earth may be quite severe. Some scientists expect increases in both lethal and nonlethal forms of skin cancer and in cataracts among humans, as well as unpredictable effects on crops and natural communities, especially the phytoplankton that are responsible for a large proportion of Earth's primary production. The danger posed by ozone depletion is so great that 180 countries, including the United States, have signed the Montreal Protocol, which calls for the elimination of chemicals that deplete ozone. Many nations, again including the United States,

have ended the production of chlorofluorocarbons. As a consequence of these actions, there are signs that the rate of ozone depletion is slowing. Unfortunately, even if all chlorofluorocarbons were globally banned today, chlorine molecules that are already in the atmosphere will continue to influence stratospheric ozone levels for at least a century.

Destruction of Earth's ozone shield is one more example of how much humans have been able to disrupt the dynamics of ecosystems and the entire biosphere. In this book's final chapter, we'll explore how scientists in fields of conservation biology and restoration ecology are studying and responding to human impact on Earth's biodiversity.

Concept Check 54.5

- How can the addition of excess nutrients to a lake threaten its fish population?
- How can clear cutting a forest (removing all trees) damage the water quality of nearby lakes?
- In the face of biological magnification of toxins, is it healthier to feed at a lower or higher trophic level? Explain.
- There are vast stores of organic matter in the frozen soils of the Arctic. Why might this be a cause for concern by scientists studying global warming?

For suggested answers, see Appendix A.

Chapter 54 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 54.1

Ecosystem ecology emphasizes energy flow and chemical cycling

- Ecosystems and Physical Laws** (p. 1185) An ecosystem consists of all the organisms in a community and all the abiotic factors with which they interact. The laws of physics and chemistry apply to ecosystems, particularly in regard to the flow of energy. Energy is conserved, but degraded to heat during ecosystem processes.
- Trophic Relationships** (p. 1185) Energy and nutrients pass from primary producers (autotrophs) to primary consumers (herbivores) and then to secondary consumers (carnivores). Energy/flows through an ecosystem, entering as light and exiting as heat. Nutrients cycle within an ecosystem.
- Decomposition** (pp. 1185–1186) Decomposition connects all trophic levels. Detritivores, mainly bacteria and fungi, recycle

essential chemical elements by decomposing organic material and returning elements to inorganic reservoirs.

Concept 54.2

Physical and chemical factors limit primary production in ecosystems

- Ecosystem Energy Budgets** (pp. 1186–1188) The energy assimilated during photosynthesis is a tiny fraction of the solar radiation reaching Earth, but primary production sets the spending limit for the global energy budget. Gross primary production is the total energy assimilated by an ecosystem in a given time period. Net primary production, the energy accumulated in autotroph biomass, equals gross primary production minus the energy used by the primary producers for respiration. Only net primary production is available to consumers.
investigation How Do Temperature and Light Affect Primary Production?
- Primary Production in Marine and Freshwater Ecosystems** (pp. 1188–1190) In marine and freshwater ecosystems, light and nutrients limit primary production. Within the photic zone, the factor that most often limits primary production is a nutrient such as nitrogen or iron.

- **Primary Production in Terrestrial and Wetland Ecosystems** (pp. 1190-1191) In terrestrial and wetland ecosystems, climatic factors such as temperature and moisture affect primary production on a large geographic scale. More locally, a soil nutrient is often the limiting factor in primary production.

Concept 54.3

Energy transfer between trophic levels is usually less than 20% efficient

- * **Production Efficiency** (pp. 1191-1193) The amount of energy available to each trophic level is determined by the net primary production and the efficiencies with which food energy is converted to biomass at each link of the food chain. The percentage of energy transferred from one trophic level to the next, called trophic efficiency is generally 5-20%. Pyramids of production, biomass, and numbers reflect the relatively low trophic efficiency.

Activity *Pyramids of Production*

- * **The Green World Hypothesis** (pp. 1193-1194) According to the green world hypothesis, herbivores consume a small percentage of vegetation because predators, disease, competition, nutrient limitations, and other factors keep their populations in check.

Concept 54.4

Biological and geochemical processes move nutrients between organic and inorganic parts of the ecosystem

- **A General Model of Chemical Cycling** (p. 1195) Gaseous forms of carbon, oxygen, sulfur, and nitrogen occur in the atmosphere and cycle globally. Other less mobile elements, including phosphorus, potassium, and calcium, cycle on a more localized scale, at least over the short term. All elements cycle between organic and inorganic reservoirs.
- **Biogeochemical Cycles** (pp. 1195-1198) Water moves in a global cycle driven by solar energy. The carbon cycle primarily reflects the reciprocal processes of photosynthesis and cellular respiration. Nitrogen enters ecosystems through atmospheric deposition and nitrogen fixation by prokaryotes, but most of the nitrogen cycling in natural ecosystems involves local cycles between organisms and soil or water. The phosphorus cycle is relatively localized.

Activity *Energy Flow and Chemical Cycling*

Activity *The Carbon Cycle*

Activity *The Nitrogen Cycle*

- **Decomposition and Nutrient Cycling Rates** (p. 1198) The proportion of a nutrient in a particular form and its cycling time in that form vary among ecosystems, largely because of differences in the rate of decomposition.

- **Vegetation and Nutrient Cycling: The Hubbard Brook Experimental Forest** (pp. 1198-1199) Nutrient cycling is strongly regulated by vegetation. Long-term ecological research projects monitor ecosystem dynamics over relatively long periods of time. The Hubbard Brook study has shown that logging increases water runoff and can cause huge losses of minerals.

Concept 54.5

The human population is disrupting chemical cycles throughout the biosphere

- **Nutrient Enrichment** (pp. 1200-1201) Agriculture constantly removes nutrients from ecosystems, so large supplements are continually required. Considerable amounts of the nutrients in fertilizer pollute groundwater and surface-water aquatic

ecosystems, where they can stimulate excess algal growth (cultural eutrophication).

Activity *Water Pollution from Nitrates*

- **Acid Precipitation** (pp. 1201-1202) Combustion of fossil fuels is the main cause of acid precipitation. North American and European ecosystems downwind from industrial regions have been damaged by rain and snow containing nitric acid and sulfuric acid.

- **Toxins in the Environment** (pp. 1202-1203) Toxins can become concentrated in successive trophic levels of food webs. The release of toxic wastes has polluted the environment with harmful substances that often persist for long periods of time and become concentrated along the food chain by biological magnification.

- **Atmospheric Carbon Dioxide** (pp. 1203-1205) Because of the burning of wood and fossil fuels and other human activities, atmospheric concentration of CO₂ has been steadily increasing. The ultimate effects may include significant warming and other climate change.

Activity *The Greenhouse Effect*

Graph It *Atmospheric CO₂ and Temperature Changes*

- **Depletion of Atmospheric Ozone** (pp. 1205-1206) The ozone layer reduces the penetration of UV radiation through the atmosphere. Human activities, including release of chlorine-containing pollutants, are eroding the ozone layer, with dangerous results.

TESTING YOUR KNOWLEDGE

Evolution Connection

Some biologists, struck by the complex interdependence of biotic and abiotic factors that make up ecosystems, have suggested that ecosystems themselves are emergent, "living" systems capable of evolving. One manifestation of this is James Lovelock's Gaia hypothesis, which views Earth itself as a living, homeostatic entity—a kind of superorganism. Critique the idea that ecosystems and the biosphere can evolve by applying the principles of evolution you have learned in this book. If ecosystems are capable of evolving, is this a form of Darwinian evolution? Why or why not?

Scientific Inquiry

With two nearby ponds in a forest as your study site, how would you design a controlled experiment to measure the effect of falling leaves on net primary production in a pond?

Investigation *How Do Temperature and Light Affect Primary Production?*

Science, Technology, and Society

The amount of CO₂ in the atmosphere is increasing, and global temperature has increased over the past century. Most scientists agree that the two phenomena are related and say that greenhouse warming is under way. These scientists stress that we need to take action now to avoid drastic environmental change. However, some scientists say that it is still too soon to tell and we should gather more data before we act. What are the advantages and disadvantages of doing something now to slow global warming? What are the advantages and disadvantages of waiting until more data are available?

55 Conservation Biology and Restoration Ecology

A Figure 55.1 Tropical deforestation in West Kalimantan, Borneo.

Key Concepts

- 55.1 Human activities threaten Earth's biodiversity
- 55.2 Population conservation focuses on population size, genetic diversity, and critical habitat
- 55.3 Landscape and regional conservation aim to sustain entire biotas
- 55.4 Restoration ecology attempts to restore degraded ecosystems to a more natural state
- 55.5 Sustainable development seeks to improve the human condition while conserving biodiversity

Overview

The Biodiversity Crisis

Biology is the science of life. Thus, it is fitting that our final chapter focuses on two disciplines that seek to preserve life. **Conservation biology** integrates ecology (including behavioral ecology), physiology, molecular biology, genetics, and evolutionary biology to conserve biological diversity at all levels. Efforts to sustain ecosystem processes and stem the loss of biodiversity also connect the life sciences with the social sciences, economics, and humanities. **Restoration ecology** applies ecological principles in an effort to return degraded ecosystems to conditions as similar as possible to their natural, predegraded state.

To date, scientists have described and formally named about 1.8 million species of organisms. Some biologists think that about 10 million more species currently exist; others estimate the number to be as high as 200 million. These are not evenly distributed around the globe. Some of the greatest concentrations of species are found in the tropics.

Unfortunately in tropical areas, scenes such as the one in **Figure 55.1** are commonplace: Tropical forests are being destroyed at an alarming rate to make room for and support a burgeoning human population.

Throughout the biosphere, human activities are altering trophic structures, energy flow, chemical cycling, and natural disturbance—ecosystem processes on which we and other species depend (see Chapter 54). The amount of human-altered land surface is approaching 50%, and we use over half of all accessible surface fresh water. In the oceans, stocks of many fishes are being depleted by overharvesting, and some of the most productive and diverse aquatic areas, such as coral reefs and estuaries, are being severely stressed. By some estimates, we are in the process of doing more damage to the biosphere and pushing more species toward extinction than the large asteroid that may have triggered the mass extinctions at the close of the Cretaceous period 65.5 million years ago (see Figure 26.9). Globally, the rate of species loss may be as much as 1,000 times higher than at any time in the past 100,000 years.

In this chapter, we will take a closer look at the biodiversity crisis and examine some of the conservation and restoration strategies that biologists are using in attempting to slow the rate of species loss.

Concept 55.1

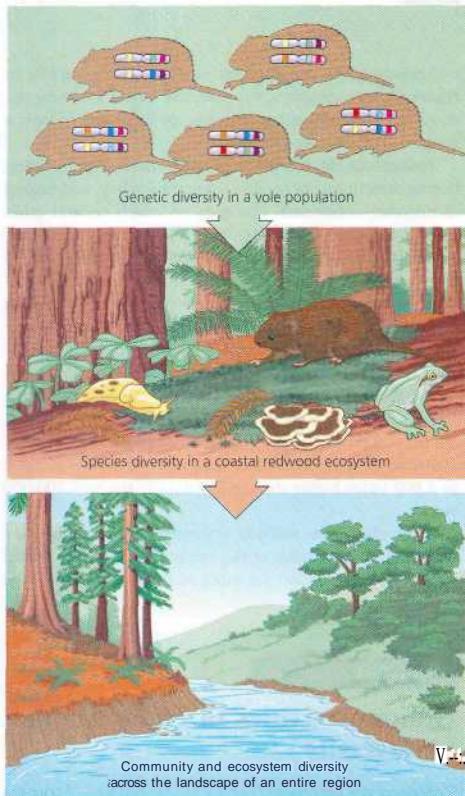

Human activities threaten Earth's biodiversity

Extinction is a natural phenomenon that has been occurring almost since life first evolved; it is the current rate of extinction that underlies the biodiversity crisis. Because we can only

estimate the number of species currently existing, we cannot determine the actual rate of species loss or the real magnitude of the biodiversity crisis. We do know for certain that the rate of species extinction is high and that it largely results from an escalating rate of ecosystem degradation by a single species—*Homo sapiens*. Simply put, humans are threatening Earth's biodiversity.

The Three Levels of Biodiversity

Biodiversity—short for biological diversity—has three main components, or levels: genetic diversity, species diversity, and ecosystem diversity (**Figure 55.2**). All three are being decreased by human activity.

A Figure 55.2 Three levels of biodiversity. The oversized chromosomes symbolize the genetic variation within the population.

Genetic Diversity

Genetic diversity comprises not only the individual genetic variation within a population, but also the genetic variation *between* populations that is often associated with adaptations to local conditions (see Chapter 23). If one population becomes extinct, then a species may have lost some of the genetic diversity that makes microevolution possible. This erosion of genetic diversity is, of course, detrimental to the overall adaptive prospects of the species. But the loss of genetic diversity throughout the biosphere also has implications for human welfare. For example, if we lose wild populations of plants closely related to agricultural species, we lose genetic resources that could potentially be used to improve certain crop qualities, such as disease resistance, through plant breeding.

Species Diversity

Much of the public discussion of the biodiversity crisis centers on species diversity—the variety of species in an ecosystem *or* throughout the entire biosphere, or what we called *species richness* in Chapter 53. The U.S. Endangered Species Act (ESA) defines an endangered species as one that is "in danger of extinction throughout all or a significant portion of its range." Also defined for protection by the ESA, threatened species are those that are considered likely to become endangered in the foreseeable future. Here are just a few statistics that illustrate the problem of species loss:

- According to the International Union for Conservation of Nature and Natural Resources (IUCN), 12% of the nearly 10,000 known species of birds and 24% of the nearly 5,000 known species of mammals in the world are threatened with extinction.
- A recent survey conducted by the Center for Plant Conservation showed that of the approximately 20,000 known plant species in the United States, 200 species have become extinct since such records have been kept. Another 730 plant species in the United States are endangered or threatened.
- About 20% of the known freshwater fishes in the world have either become extinct during historical times or are seriously threatened. One of the largest rapid extinction events yet recorded is the ongoing loss of freshwater fishes in East Africa's Lake Victoria. About 200 of the more than 500 species of cichlids in the lake have been lost, mainly as a result of the introduction of a nonnative predator species, the Nile perch, in the 1960s.
- Since 1900, 123 freshwater vertebrate and invertebrate species have become extinct in North America, and hundreds more species are threatened. Extinction rates for North American freshwater fauna are about five times higher than those for terrestrial animals.

» According to a 2004 report in the journal *Science* that was based on a global assessment of amphibians by more than 500 scientists, 32% of all known amphibian species are now either very near extinction or endangered.

I* Several researchers estimate that at current rates of extinction, more than half of all currently living plant and animal species will have disappeared by the end of the 21st century (Figure 55.3).

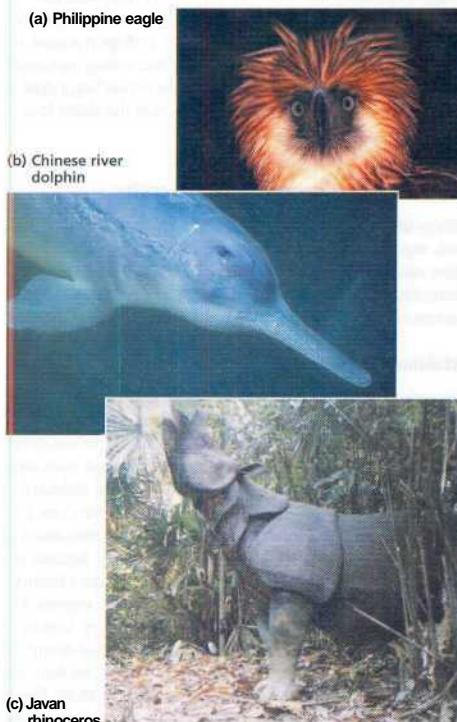

Extinction of species may be local; for example, a species may be lost in one river system but survive in an adjacent one. Global extinction of a species means that it is lost from *all* its locales. However, extinction is often an unseen process. To know for certain that a given species is extinct, we must know its exact distribution. Without a more complete catalog of species diversity and knowledge of the geographic distribution

and ecological roles of Earth's species, our efforts to understand the structure and function of ecosystems on which our survival depends will remain incomplete.

Ecosystem Diversity

The variety of the biosphere's ecosystems is the third level of biological diversity. Because of the network of community interactions among populations of different species within an ecosystem, the local extinction of one species—say, a keystone predator—can have a negative impact on the overall species richness of the community (see Figure 53.16). More broadly, each ecosystem has characteristic patterns of energy flow and chemical cycling that can affect the whole biosphere. For example, the productive "pastures" of phytoplankton in the oceans may help moderate the greenhouse effect by consuming massive quantities of CO₂ for photosynthesis and for building shells made of bicarbonate.

Some ecosystems have already been heavily impacted by humans, and others are being destroyed at an astonishing pace. For example, within the contiguous United States, wetland and riparian (riverbank) ecosystems have been altered dramatically within just a few centuries. Since European colonization, more than 50% of wetlands have been drained and converted to other ecosystems, primarily agricultural ones. Meanwhile, in California, Arizona, and New Mexico, approximately 90% of native riparian communities have been destroyed by overgrazing, flood control, water diversions, lowering of water tables, and invasive (nonnative) plants.

A **Figure 55.3 A hundred heartbeats from extinction.** These are just three of the members of what Harvard biologist E. O. Wilson grimly calls the Hundred Heartbeat Club, species with fewer than 100 individuals remaining on Earth.

Biodiversity and Human Welfare

Why should we care about the loss of biodiversity? Perhaps the purest reason is what E. O. Wilson calls *biophilia*, our sense of connection to nature and other forms of life. The belief that other species are entitled to life is a pervasive theme of many religions and the basis of a moral argument that we should protect biodiversity. There is also a concern for future human generations: Is it fair to deprive them of Earth's species richness? Paraphrasing an old proverb, G. H. Brundtland, a former prime minister of Norway, put it this way: "We must consider our planet to be on loan from our children, rather than being a gift from our ancestors." But species diversity brings us many practical benefits as well.

Benefits of Species and Genetic Diversity

Many species that are threatened could potentially provide crops, fibers, and medicines for human use, making biodiversity a crucial natural resource. In the United States, 25% of all prescriptions dispensed from pharmacies contain substances originally derived from plants. For example, in the 1970s, researchers discovered that the rosy periwinkle, which grows on Madagascar, an island off the coast of Africa, contains alkaloids

•3 Figure 55.4 The rosy periwinkle (*Catharanthus roseus*), a plant that saves lives.

that inhibit cancer cell growth (Figure 55.4). The result of this discovery for most people with either of two potentially deadly forms of cancer—Hodgkin's disease and a childhood leukemia—is remission. Madagascar is also home to five other species of periwinkles, one of which is approaching extinction. The loss of these species would mean the loss of any possible medicinal benefits they might offer.

The loss of species also means the loss of genes. Each species has certain unique genes, and biodiversity represents the sum of all the genomes of all organisms on Earth. Such enormous genetic diversity has the potential for great human benefit. Consider the historical example of the polymerase chain reaction (PCR), the gene-cloning technology based on an enzyme extracted from thermophilic prokaryotes from hot springs (see Figure 20.7). Currently, corporations anticipate using DNA extracted from the prokaryotes in the numerous hot springs in Yellowstone National Park to mass-produce useful enzymes. Many researchers and industry officials are enthusiastic about the potential that such "bioprospecting" holds for the development of new medicines, foods, petroleum substitutes, industrial chemicals, and other products. However, because many millions of species may become extinct before we even know about them, we stand to lose irretrievably the valuable genetic potential held in their unique libraries of genes.

Ecosystem Services

The benefits that individual species provide to humans are often substantial, but saving individual species is only part of the rationale for saving ecosystems. Humans evolved in Earth's ecosystems, and we are finely adjusted to these systems and the other species within them.

In the urban and suburban settings in which most of us live today, it is easy to lose sight of the ways our ecosystems support us. Ecosystem services encompass all the processes through which natural ecosystems and the species they contain help sustain human life on Earth. The following are just a few of these ecosystem services:

- Purification of air and water
- Reduction of the severity of droughts and floods
- Generation and preservation of fertile soils
- Detoxification and decomposition of wastes

- Pollination of crops and natural vegetation
- Dispersal of seeds
- Cycling of nutrients
- Control of many agricultural pests by natural enemies
- Protection of shorelines from erosion
- Protection from ultraviolet rays
- Moderation of weather extremes
- Provision of beauty and recreational opportunities

A growing body of evidence indicates that the functioning of ecosystems, and hence their capacity to perform services, is linked to biodiversity. As human activities reduce biodiversity, we may be reducing the capacity of Earth's ecosystems to perform processes critical to our own survival.

Perhaps it is because we don't attach a monetary value to the services of natural ecosystems that we generally undervalue them. In a 1997 article, ecologist Robert Costanza and his colleagues estimated the dollar value of Earth's ecosystem services at \$33 trillion per year, nearly twice the gross national product of all the countries on Earth (\$18 trillion). Perhaps it is more realistic, and more meaningful, to do the accounting on a small scale. What, for example, is the true price of building a dam or clear-cutting a patch of forest if we include the dollar loss of ecosystem services in the cost column?

Four Major Threats to Biodiversity

Many different human activities threaten biodiversity on a local, regional, and global scale. Of this long list, most species loss can be traced to four major threats: habitat destruction, introduced species, overexploitation, and disruption of "interaction networks" such as food webs.

Habitat Destruction

Human alteration of habitat is the single greatest threat to biodiversity throughout the biosphere. Massive destruction of habitats has been brought about by agriculture, urban development, forestry, mining, and pollution. When no alternative habitat is available or a species is unable to move, habitat loss may mean extinction. The International Union for Conservation of Nature and Natural Resources implicates destruction of physical habitat for 73% of the species that have become extinct, endangered, vulnerable, or rare during modern history.

Habitat destruction may occur over immense regions. For instance, approximately 98% of the tropical dry forests of Central America and Mexico have been cleared (cut down). In addition, many natural landscapes have been broken up, fragmenting habitat into small patches (Figure 55.5). Forest fragmentation is occurring at a rapid rate in tropical forests. For example, clearing of tropical rain forest, in the state of Veracruz, Mexico, mostly for cattle ranching, has resulted in the loss of approximately 91% of the original forest, leaving a fragmented archipelago of small forest islands.

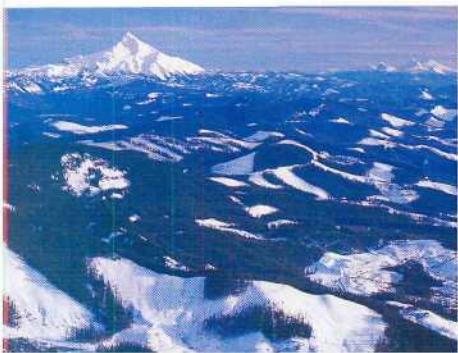

Figure 55.5 Habitat fragmentation in the Mount Hood National Forest, western United States.

In almost all cases, habitat fragmentation leads to species loss, since the smaller populations in habitat fragments have a higher probability of local extinction. The prairies of North America are an example: Prairie covered about 800,000 hectares of southern Wisconsin when Europeans first arrived, but now occupies less than 0.1% of its original area. Plant diversity surveys of 54 Wisconsin prairie remnants were conducted in 1948–1954 and then repeated in 1987–1988. During the few decades between surveys, the various prairie fragments lost between 8% and 60% of their plant species.

Though most studies have focused on terrestrial ecosystems, habitat loss is also a major threat to marine biodiversity, especially along continental coasts and around coral reefs. About 93% of coral reefs, among Earth's most species-rich aquatic communities, have been damaged by human activities. At the current rate of destruction, 40–50% of the reefs, home to one-third of marine fish species, could be lost in the next 30 to 40 years. Aquatic habitat destruction and species loss also result from the dams, reservoirs, channel modification, and flow regulation now affecting most of the world's rivers. Fishes that migrate up the heavily dammed Columbia River system in the northwestern United States, for example, have shown sharp declines in abundance.

Introduced Species

Introduced species, also called invasive, normative, or exotic species, are those that humans move, either intentionally or accidentally, from the species' native locations to new geographic regions. The modern ease of travel by ship and airplane has accelerated the transplant of species. Free from the predators, parasites, and pathogens that limit their populations in their native habitats, such transplanted species may spread through a new region at exponential rates.

Introduced species that gain a foothold usually disrupt their adopted community often by preying on native organisms or outcompeting them for resources. For instance, the brown tree snake was accidentally introduced to the island of Guam as a "stowaway" in military cargo after World War II (**Figure 55.6a**). Since then, 12 species of birds and 6 species of lizards on which the snakes prey have become extinct on Guam. Another particularly devastating accidental introduction is the fingernail-sized zebra mussel (*Dreissena polymorpha*), which was introduced into the Great Lakes of North America in 1988, most likely in the ballast water of ships arriving from Europe. Efficient suspension-feeding molluscs that attain high population densities, zebra mussels have extensively disrupted freshwater ecosystems, threatening native aquatic species. Zebra mussels have also clogged water intake structures, disrupting domestic and industrial water supplies and causing billions of dollars in damages.

Humans have deliberately introduced many species with good intentions but disastrous effects. For example, a Japanese plant called kudzu, which the U.S. Department of Agriculture introduced in the South to help control erosion, has taken over vast expanses of the southern landscape (**Figure 55.6b**). The

(a) Brown tree snake, introduced to Guam in cargo

(b) Introduced kudzu thriving in South Carolina

A Figure 55.6 Two introduced species.

European starling, brought intentionally into New York's Central Park in 1890 by a citizens' group intent on introducing all the plants and animals mentioned in Shakespeare's plays, quickly spread across North America, increasing to a population of more than 100 million and displacing many native songbirds.

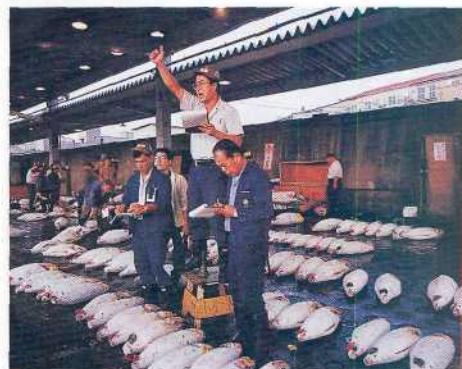

Introduced species are a worldwide problem, contributing to approximately 40% of the extinctions recorded since 1750 and costing billions of dollars annually in damage and control efforts. There are more than 50,000 introduced species in the United States alone.

Overexploitation

Overexploitation refers generally to the human harvesting of wild plants or animals at rates exceeding the ability of populations of those species to rebound. It is possible for overexploitation to endanger certain plant species, such as rare trees that produce valuable wood or some other commercial product. However, the term more often refers to commercial fishing, hunting, collecting, and trading of animals.

Especially susceptible to overexploitation are large organisms with low intrinsic reproductive rates, such as elephants, whales, and rhinoceroses. The decline of Earth's largest extant terrestrial animals, the African elephants, is a classic example of the impact of overhunting. Largely because of the trade in ivory, elephant populations have been declining in most of Africa during the last 50 years. Unfortunately, an international ban on the sale of new ivory resulted in increased poaching (illegal hunting), so the ban had little effect in central and east Africa. Only in South Africa, where once-decimated herds have been well protected for nearly a century, have elephant populations been stable or increasing (see Chapter 52).

Species with restricted habitats, such as small islands, are also very vulnerable to overexploitation. For example, by the 1840s, humans had hunted the great auk to extinction on islands in the Atlantic Ocean. This large, flightless seabird had been in great demand for its feathers, eggs, and meat. And many populations of commercially important marine fishes, once thought to be inexhaustible, have been dramatically reduced by overfishing. The exploding human population's increasing demand for protein, coupled with new harvesting technologies, such as long-line fishing and modern trawlers, have reduced these fish populations to levels that cannot sustain further exploitation. The fate of the North Atlantic bluefin tuna is just one example. Until the past few decades, this big tuna was considered a sport fish of little commercial value—just a few cents per pound for cat food. Then, in the 1980s, wholesalers began airfreighting fresh, iced bluefin to Japan for sushi and sashimi. In that market, the fish now brings up to \$100 per pound (**Figure 55.7**). With that kind of demand, it took just ten years to reduce the North American bluefin population to less than 20% of its

4 Figure 55.7 Overexploitation. North Atlantic bluefin tuna are auctioned in a Japanese fish market.

1980 size. The collapse of the northern cod fishery off Newfoundland in the 1990s is a more recent example of how it is possible to overharvest what was formerly a very common species.

Disruption of Interaction Networks

Ecosystem dynamics depend on the networks of interspecific interactions within biological communities. Like falling dominoes, the extinction of one species can doom others, particularly when the extinction involves a keystone species, an ecosystem engineer, or a species with a highly specialized relationship to others (see Chapter 53). Though this threat to biodiversity has been less explored than the other three we have discussed, there are many examples of how disruption of interaction networks can threaten other species.

Sea otters are a keystone species whose elimination over most of their historic range has led to major changes in the structure of shallow-water benthic communities along the west coast of North America (see Figure 53.17). And the extermination of beavers, one of the best-known ecosystem engineers, resulted in a large reduction in wetland and pond habitats across much of North America. In yet another example, global declines in native pollinators due to habitat destruction and excessive use of pesticides have the potential to disrupt reproduction in both wild and domesticated plants. Bats called "flying foxes" are important plant pollinators in the Pacific Islands, where they have been subject to increasing pressure from hunters who sell them as luxury food items (**Figure 55.8**). Because of this hunting pressure, conservation biologists are concerned about the fate of the native plants of the Samoan islands, where more than 79% of the trees depend on flying foxes for pollination or seed dispersal.

A Figure 55.8 Disruption of interaction networks. The endangered Marianas "flying fox" bat (*Pteropus mariannus*) is an important pollinator.

Concept Check 55.1

1. Explain why it is too narrow to define biodiversity as simply a loss of species.
2. Describe the four main threats to biodiversity and how each one damages diversity.
3. In what ways would humans benefit by preserving biodiversity?

For suggested answers, see Appendix A.

Concept 55.2

Population conservation focuses on population size, genetic diversity, and critical habitat

Biologists focusing on conservation at the population and species levels follow two main approaches—the small-population approach and the declining-population approach.

Small-Population Approach

A species is designated as endangered when its populations are very small. After such factors as habitat loss have taken their toll on population size, a population's smallness itself can drive it to extinction. Conservation biologists who adopt the small-population approach study the processes that can cause very small populations finally to become extinct.

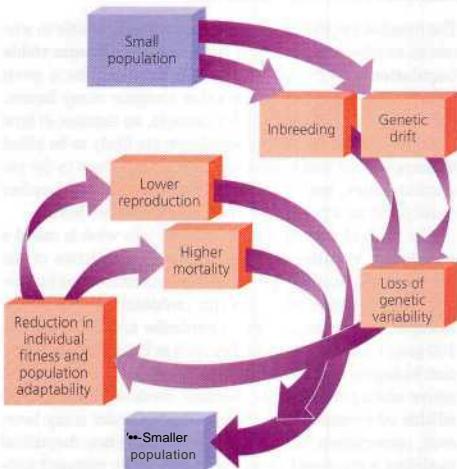

The Extinction Vortex

A small population is prone to positive-feedback loops of inbreeding and genetic drift that draw the population down an

extinction vortex toward smaller and smaller population size until no individuals exist (Figure 55.9). The key factor driving the extinction vortex is the loss of the genetic variation necessary to enable evolutionary responses to environmental change, such as new strains of pathogens. Both inbreeding and genetic drift can cause a loss of genetic variation (see Chapter 23), and the effects of both processes become more significant as a population shrinks.

Not all populations are doomed by low genetic diversity. Low genetic variability does not necessarily lead to permanently small populations. For example, as we discussed in Chapter 23, overhunting of northern elephant seals in the 1890s reduced the species to only 20 individuals—clearly a bottleneck with reduced genetic variation. Since that time, however, the northern elephant seal populations have rebounded to about 150,000 individuals today, though their genetic variation remains relatively low. Furthermore, a number of plant species, such as the lousewort *Pedicularis* and several grasses, seem to have inherently low genetic variability. Many populations of cord grass (*Spartina anglica*), which thrives in salt marshes, are genetically uniform at many loci. *S. anglica* arose from a few parent plants only about a century ago by hybridization and allotetraploidy (see Figure 24.9). Having spread by cloning, this species now dominates large areas of tidal mudflats in Europe and Asia. Thus, in some cases, low genetic diversity is associated with population expansion rather than decline, but these cases may stand out precisely because they are so unusual.

How small does a population have to be before it starts down an extinction vortex? The answer depends on the type

A Figure 55.9 Processes culminating in an extinction vortex.

of organism and several other factors, and must be determined case by case. For example, large predators that feed high on the food chain usually require very large individual ranges, resulting in very low population densities. Thus, not all rare species concern conservation biologists. Whatever the number, however, most populations presumably require some minimum size to remain viable.

Case Study: The Greater Prairie Chicken and the Extinction Vortex

When Europeans arrived in North America, the greater prairie chicken (*Tympanuchus cupido*) was common from New England to Virginia and all across the western prairies of the United States and Canada. Agriculture later fragmented the populations of the greater prairie chicken in the central and western states and provinces. For example, in Illinois alone, greater prairie chickens numbered in the millions in the 19th century but declined to 25,000 birds by 1933. By 1993, the Illinois population of prairie chickens was down to only 50, though large populations remained in Kansas, Minnesota, and Nebraska. Researchers found that the decline in the Illinois population was associated with a decrease in fertility. As a test of the extinction vortex hypothesis, the scientists imported genetic variation by transplanting more than 270 birds from larger populations in Kansas, Minnesota, and Nebraska (Figure 55.10). The Illinois population rebounded, confirming that it had been on its way down the extinction vortex until rescued by a transfusion of genetic variation.

Minimum Viable Population Size

The minimal population size at which a species is able to sustain its numbers and survive is known as the **minimum viable population (MVP)**. MVP is usually estimated for a given species using computer models that integrate many factors. The calculation may include, for example, an estimate of how many individuals in a small population are likely to be killed by some natural catastrophe such as a storm. Once in the extinction vortex, two or three years in a row of bad weather could finish off a population that is already below MVP.

The MVP of a population is factored into what is called a **population viability analysis (PVA)**. The objective of the analysis is to reasonably predict a population's chances for survival, usually expressed as a specific probability of survival (for example, a 99% chance) over a particular time (for instance, 100 years). Modeling approaches such as PVA allow conservation biologists to explore the potential consequences of alternative management plans. Because modeling depends on reliable information about the populations under study, however, conservation biology is most robust when theoretical modeling is combined with field studies of the managed populations. The case study on grizzly bears presented later in this section is an example of such an approach.

Figure 55.10

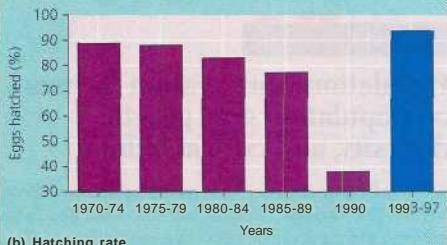

inquiry What caused the drastic decline of the Illinois greater prairie chicken population?

EXPERIMENT

Researchers observed that the population collapse of the greater prairie chicken was mirrored in a reduction in fertility, as measured by the hatching rate of eggs. Comparison of DNA samples from the Jasper County, Illinois, population with DNA from feathers in museum specimens showed that genetic variation had declined in the study population. In 1992, researchers began experimental translocations of prairie chickens from Minnesota, Kansas, and Nebraska in an attempt to increase genetic variation.

RESULTS

After translocation (blue arrow), the viability of eggs rapidly improved, and the population rebounded.

CONCLUSION

The researchers concluded that lack of genetic variation had started the Jasper County population of prairie chickens down the extinction vortex.

Effective Population Size

Genetic variation is the key issue in the small-population approach. The **total size** of a population may be misleading because only certain members of the population breed successfully and pass their alleles on to offspring. Therefore, a meaningful estimate of MVP requires the researcher to determine the **effective population size**, which is based on the breeding

potential of the population. The following formula incorporates the sex ratio of breeding individuals into the estimate of effective population size, abbreviated N_e :

$$N_e = \frac{4N_f N_m}{N_f + N_m}$$

where N_f and N_m are, respectively, the number of females and the number of males that successfully breed. Applying this formula to an idealized population whose total size is 1,000 individuals, N_e will also be 1,000 if every individual breeds and the sex ratio is 500 females to 500 males. In this case, $N_e = (4 \times 500 \times 500)/(500 + 500) \sim 1,000$. Deviation from these conditions (not all individuals breed and/or there is not a 1:1 sex ratio) reduces N_e . For instance, if the total population size is 1,000 but only 400 females and 400 males breed, then $N_e = (4 \times 400 \times 400)/(400 + 400) = 800$, or 80% of the total population size.

Numerous life history traits can influence N_e , and alternative formulas for estimating N_e take into account family size, maturation age, genetic relatedness among population members, the effects of gene flow between geographically separated populations, and population fluctuations.

In actual study populations, N_e is always some fraction of the total population. Thus, simply determining the total number of individuals in a small population does not provide a good measure of whether the population is large enough to avoid extinction. Whenever possible, conservation programs are geared to sustain total population sizes that include at least the minimum viable number of *reproductively active* individuals. The conservation goal of sustaining effective population size (\bar{N}_e) above MVP stems from the concern that populations retain enough genetic diversity to be evolutionarily adaptable.

Case Study: Analysis of Grizzly Bear Populations

One of the first population viability analyses was conducted in 1978 by Mark Shaffer, of Duke University, as part of a long-term study of grizzly bears in Yellowstone National Park and its surrounding areas (Figure 55.11). A threatened species in the United States, the grizzly bear (*Ursus arctos horribilis*) is currently found in only 4 of the 48 contiguous states. Its populations in those states have been drastically reduced and fragmented: In 1800, an estimated 100,000 grizzlies ranged over about 500 million hectares of more or less continuous habitat, while today there are six relatively isolated populations totaling about 1,000 individuals with a total range of less than 5 million hectares.

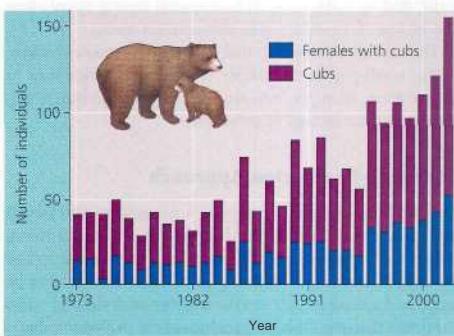

Shaffer attempted to determine viable sizes for the U.S. grizzly populations. Using life history data obtained for individual Yellowstone bears over a 12-year period, he simulated the effects of environmental factors on survival and reproduction. His models predicted that, given a suitable habitat, a total grizzly bear population of 70 to 90 individuals would have

A Figure 55.11 Long-term monitoring of a grizzly bear population. Studies by John and Frank Craighead, shown here placing a radio collar on a tranquilized grizzly bear, resulted in population estimates that were essential to Mark Shaffer's population viability analyses.

about a 95% chance of surviving for 100 years, whereas a population of 100 bears would have a 95% chance of surviving for 200 years.

How does the actual size of the Yellowstone grizzly population compare with Shaffer's estimates of a minimum viable population size? Several sources of information indicate that the grizzly population of Yellowstone is growing. One of the best indicators of that growth is the number of females observed with cubs each year. Increases in this number from 1973 to 2002 support the conclusion that the Yellowstone grizzly population has grown substantially (Figure 55.12). Moreover, since not all females with cubs are detected, the numbers shown in Figure 55.12 are minimal estimates. And because female grizzly bears have young approximately once every three years, the number of females with cubs each year is only about one-third

A Figure 55.12 Growth of the Yellowstone grizzly bear population, as indicated by the number of females observed with cubs and the number of cubs.

of the total number of mature females in the population. Adding immature males and females and mature males to estimates of mature females and cubs yields a total grizzly population size for the greater Yellowstone ecosystem exceeding 400.

The relationship of this estimate of the total grizzly population to the effective population size, N_e , is dependent on several factors. Usually, only a few dominant males breed, and it may be difficult for them to locate females, since individuals inhabit such extensive areas. Moreover, females may reproduce only when there is abundant food. As a result, N_e is only about 25% of the total population size, which for the Yellowstone population of about 400 would be only about 100 bears.

Because small populations tend to lose genetic variation over time, a number of research teams have analyzed proteins, mitochondrial DNA, and nuclear microsatellite DNA to assess the genetic variability in the Yellowstone grizzly bear population. All results to date indicate that the Yellowstone population has less genetic variability than other grizzly bear populations in North America. However, the isolation and decline in genetic variability in the Yellowstone grizzly bear population were gradual during the 20th century and not as severe as feared. Museum specimens collected in the early 1900s demonstrate that genetic variability among the Yellowstone grizzly bears has historically been low. These studies also indicate that the effective population size of the Yellowstone grizzly population is larger than formerly thought—approximately 80 individuals through most of the 20th century and now slightly over 100.

How might conservation biologists increase the effective size and genetic variation of the Yellowstone grizzly bear population? Migration between isolated populations of grizzlies could increase both effective and total population sizes. Computer models predict that introducing only two unrelated bears each decade into a population of 100 individuals would reduce the loss of genetic variation by about half. For the grizzly bear, and probably for many other species whose populations are very small, finding ways to promote dispersal among populations may be one of the most urgent conservation needs.

This case study, as well as that of the greater prairie chicken, bridge small-population theory to practical applications in conservation. Next, we look at an alternative approach to understanding the biology of extinction.

Declining-Population Approach

The declining-population approach focuses on threatened and endangered populations that show a downward trend, even if the population is far above minimum viable size. The distinction between a declining population (which may be small) and a small population (which may be declining) is less important than the different priorities of the two basic conservation approaches. The small-population approach emphasizes smallness itself as an ultimate cause of a population's extinction, especially through loss of genetic diversity. In contrast, the

declining-population approach emphasizes the environmental factors that caused a population decline in the first place. If, for example, an area is deforested, then species that depend on trees will decline and become locally extinct, whether or not they retain genetic variation.

Steps for Analysis and Intervention

The declining-population approach requires that population declines be evaluated on a case-by-case basis, with researchers carefully dissecting the causes of a decline before recommending or trying corrective measures. If, for example, the biological magnification of a particular toxic pollutant is causing a decline in some top-level consumer such as a predatory bird (see Chapter 54), then only reduction or elimination of the poison in the environment can save that particular species. Rarely is the situation so straightforward. However, the following steps for analyzing declining populations and determining interventions are useful even in complex cases.

1. Assess population trends and distribution to confirm that the species is presently in decline or that it was formerly more widely distributed or more abundant.
2. Study the natural history of this and related species, including reviewing the research literature, to determine the species' environmental requirements.
3. Develop hypotheses for all possible causes of the decline, including human activities and natural events, and list the predictions of each hypothesis.
4. Because many factors may be correlated with the decline, test the most likely hypothesis first. For example, remove the suspected agent of decline to see if the experimental population rebounds relative to a control population.
5. Apply the results of the diagnosis to management of the threatened species and monitor recovery.

The following case study is an example of how the declining-population approach was applied to one endangered species.

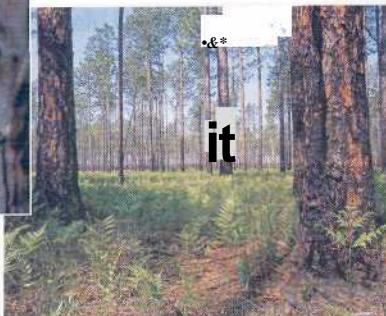

Case Study: Decline of the Red-Cockaded Woodpecker

The red-cockaded woodpecker (*Picoides borealis*) is an endangered species, endemic (found nowhere else) to the southeastern United States and once living throughout that region. This species requires mature pine forests, preferably ones dominated by the longleaf pine, for its habitat. Most woodpeckers nest in dead trees, but the red-cockaded woodpecker drills its nest holes in mature, living pine trees (Figure 55.13a). Red-cockaded woodpeckers also drill small holes around the entrance to their nest cavity, which causes resin from the tree to ooze down the trunk. The resin seems to repel certain predators, such as corn snakes, that eat bird eggs and nestlings.

Another critical habitat factor for this woodpecker species is that the understory of plants around the pine trunks must be low (Figure 55.13b). Breeding birds tend to abandon nests

(a) A red-cockaded woodpecker perches at the entrance to its nest site in a longleaf pine.

(b) Forest that can sustain red-cockaded woodpeckers has low undergrowth.

(c) Forest that cannot sustain red-cockaded woodpeckers has high, dense undergrowth that impacts the woodpeckers' access to feeding grounds.

4 Figure 55.13 Habitat requirements of the red-cockaded woodpecker.

when vegetation among the pines is thick and higher than about 15 feet (Figure 55.13c). Apparently, the birds require a clear flight path between their home trees and the neighboring feeding grounds. Historically, periodic fires swept through longleaf pine forests, keeping the undergrowth low.

One factor leading to decline of the red-cockaded woodpecker is the destruction or fragmentation of suitable habitats by logging and agriculture. Recognition of the key habitat factors, protection of some longleaf pine forests, and the use of controlled fires to reduce forest undergrowth have helped restore habitat that can support viable populations. However, designing a recovery program was complicated by the birds' social organization. Red-cockaded woodpeckers live in groups of one breeding pair and up to four "helpers," mostly males. Helpers are offspring who do not disperse and breed but remain behind and assist in incubating eggs and feeding nestlings. They may eventually attain breeding status within the flock when older birds die, but the wait may take years, and even then, helpers must compete to breed. Young birds that do disperse as members of new groups also have a tough path to reproductive success. New groups usually occupy abandoned territories or start at a new site and excavate nesting cavities, which can take several years. Individuals generally have a better chance of reproducing by remaining behind than by dispersing and excavating homes in new territories.

To test the hypothesis that this social behavior contributes to the decline of the red-cockaded woodpecker, Carole Copeyon, Jeffrey Walters, and Jay Carter, of North Carolina State University, constructed cavities in pine trees at 20 sites. The results were dramatic: cavities in 18 of the 20 sites were colonized by red-cockaded woodpeckers, and new breeding groups formed only in these sites. The experiment supported the hypothesis that this woodpecker species had been leaving much suitable habitat unoccupied because of an absence of breeding cavities.

On the basis of this experiment, a combination of habitat maintenance and excavation of new breeding cavities has enabled a once-endangered species to rebound.

Weighing Conflicting Demands

Determining population numbers and habitat needs is only part of the effort to save species. It is also necessary to weigh a species' biological and ecological needs against other conflicting demands. Conservation biology often highlights the relationship between science, technology, and society—one of the themes of this book. For example, an ongoing, sometimes bitter debate in the U.S. Pacific Northwest pits habitat preservation for northern spotted owl, timber wolf, grizzly bear, and bull trout populations against job opportunities in the timber, mining, and other resource extraction industries. Programs to restock wolves in Yellowstone Park are opposed by some recreationists concerned for human safety and by many ranchers concerned with potential loss of livestock.

Large, high-profile vertebrates are not always the focal point in such conflicts, but habitat use is almost always at issue. Should work proceed on a new highway bridge if it destroys the only remaining habitat of a species of freshwater mussel? If you were the owner of a coffee plantation growing varieties that thrive in bright sunlight, would you be willing to change to shade-tolerant coffee varieties that are less productive and less profitable but that support large numbers of songbirds?

Another important consideration is the ecological roles of species. Because we will not be able to save every endangered species, we must determine which are most important for conserving biodiversity as a whole. Species do not exert equal influence on community and ecosystem processes. Identifying keystone species and finding ways to sustain their populations can be central to the survival of whole communities.

Management aimed at conserving a single species carries with it the possibility of negatively affecting populations of other species. For example, management of pine forests for the red-cockaded woodpecker might impact migratory birds associated with broadleaf temperate forests. To test for such impacts, ecologists compared bird communities near clusters of nest cavities in managed pine forests with communities in forests not managed for the woodpeckers. Contrary to expectations, the managed sites supported higher numbers and a higher diversity of other birds than the control forests. In this case, managing for one bird species enhanced the diversity of an entire community of birds. In many situations, conservation must look beyond single species and consider the whole community and ecosystem as an important unit of biodiversity.

Concept Check 55.2

1. Why does the reduced genetic diversity of small populations make them more vulnerable to extinction?
2. Contrast the small-population and declining-population approaches in terms of the remedies they recommend for preventing extinction of a species.
3. Why is a population's effective size (N_e) almost always smaller than its total size (N)?

For suggested answers, see Appendix A.

Concept 55.3

Landscape and regional conservation aim to sustain entire biotas

Historically, most preservation efforts have focused on saving endangered species, but increasingly, conservation biology aims to sustain the biodiversity of entire communities, ecosystems, and landscapes. Such a broad view requires understanding and applying the principles of community, ecosystem, and landscape ecology as well as human population dynamics and economics. One goal of landscape ecology (see Chapter 50), of which ecosystem management is part, is to understand past, present, and future patterns of landscape use and to make biodiversity conservation part of land-use planning.

Landscape Structure and Biodiversity

The biodiversity of a given landscape is in large part a function of the structure of the landscape. Understanding landscape dynamics is critically important in conservation because many

species use more than one kind of ecosystem, and many live on the borders between ecosystems.

Fragmentation and Edges

The boundaries, or *edges*, between ecosystems (between a lake and the surrounding forest, for example, or between cropland and suburban housing tracts) and within ecosystems (roadsides and rock outcroppings, for instance) are defining features of landscapes (Figure 55.14). An edge has its own set of physical conditions, which differ from those on either side of it. For instance, the soil surface of an edge between a forest patch and a burned area receives more sunlight and is usually

(a) **Natural edges.** Grasslands give way to forest ecosystems in Yellowstone National Park.

(b) **Edges created by human activity.** Pronounced edges (roads) surround clear-cuts in this photograph of a heavily logged rain forest in Malaysia.

A **Figure 55.14 Edges between ecosystems.**

hotter and drier than the forest interior, but it is cooler and wetter than the soil surface in the burned area.

Some organisms thrive in edge communities because they have access to the resources of both adjacent areas. For instance, the ruffed grouse (*Bonasa umbellatus*) is a bird that needs forest habitat for nesting, winter food, and shelter, but it also needs forest openings with dense shrubs and herbs for summer food. White-tailed deer also thrive in edge habitats, where they can browse on woody shrubs; deer populations often expand when forests are logged and more edges are exposed.

The proliferation of edge species can have positive or negative effects on a community's biodiversity. For example, a 1997 study in Cameroon comparing edge and interior populations of the little greenbul (a tropical rain forest bird) suggested that forest edges may be important sites of speciation. On the other hand, communities in which edges have resulted from human alterations often have reduced biodiversity because the relatively large percentage of edge habitat leads to a preponderance of edge-adapted species. For example, the brown-headed cowbird (*Molothrus ater*) is an edge-adapted species that lays its eggs in the nests of other birds, particularly migratory songbirds. Cowbirds need forests, where they can parasitize the nests of other birds, and also open fields, where they forage on insects. Thus, their populations are burgeoning where forests are being heavily cut and fragmented, creating more edge habitat and open land. Increasing cowbird parasitism and loss of habitat are correlated with declining populations of several of the cowbirds' host species.

The influence of fragmentation on the structure of communities has been explored for two decades in the long-term Biological Dynamics of Forest Fragments Project. Located in the heart of the Amazon River basin, approximately 80 km north of the city of Manaus, the study area consists of a series

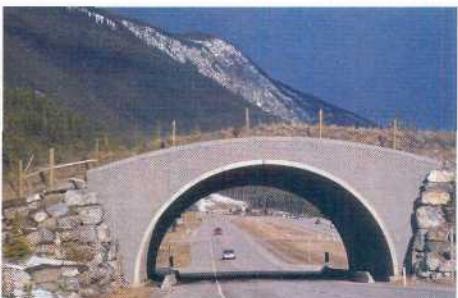

A **Figure 55.15** Amazon rain forest fragments, isolated sections of forest ranging in area from 1 to 100 ha.

of forest fragments (Figure 55.15). The fragments are isolated patches of forest separated from surrounding continuous tropical rain forest by distances of 80 to 1,000 m. Researchers from all over the world have clearly documented the physical and biological effects of this fragmentation in taxa ranging from bryophytes and beetles to birds. Among their findings is the repeated discovery of two groups of species—those that live in forest edge habitats and those that live in the forest interior. Species adapted to forest interiors show the greatest declines in the smallest fragments, suggesting that landscapes dominated by small fragments will support fewer species, mainly due to a loss of interior-adapted species.

Corridors That Connect Habitat Fragments

Where habitats have been severely fragmented, the presence of a movement corridor, a narrow strip or series of small clumps of quality habitat connecting otherwise isolated patches, can be a deciding factor in conserving biodiversity. Streamside habitats often serve as corridors, and in some nations, government policy prohibits destruction of these riparian areas. In areas of heavy human use, artificial corridors are sometimes constructed. For example, bridges or tunnels can reduce the number of animals killed trying to cross highways (Figure 55.16).

Movement corridors also can promote dispersal and reduce inbreeding in declining populations. Corridors have been shown to increase the exchange of individuals among subpopulations of a metapopulation in organisms including butterflies, voles, and various aquatic plants. Corridors are especially important to species that migrate between different habitats seasonally. However, a corridor can also be harmful—as, for example, in the spread of disease, especially among small populations in closely situated habitat patches. In a 2003 study, Agustín Estrada-Peña, of the University of Zaragoza, Spain, showed that habitat corridors facilitate the movement of disease-carrying ticks among forest patches in northern Spain. All the effects of

A **Figure 55.16** An artificial corridor. This bridge in Banff National Park, Canada, helps animals cross a human-created barrier.

corridors are not yet understood, and their impact is an area of active research in conservation biology and restoration ecology.

Establishing Protected Areas

Conservation biologists are applying their understanding of community, ecosystem, and landscape dynamics in establishing protected areas to slow the loss of biodiversity. Currently, governments have set aside about 7% of the world's land in various forms of reserves. Choosing locations for protection and designing nature reserves pose many challenges. If a community is subject to fire, grazing, and predation, for example, should the reserve be managed to minimize the risks of these processes to endangered or threatened species? Or should the reserve be left as natural as possible, with such processes as fires ignited by lightning allowed to play out without any human intervention? This is just one of the debates that arise among people who share an interest in the health of national parks and other protected areas. Much of the focus has been on hot spots of biological diversity.

Finding Biodiversity Hot Spots

A biodiversity hot spot is a relatively small area with an exceptional concentration of endemic species and a large number of endangered and threatened species (**Figure 55.17**). For example, nearly 30% of all bird species are confined to only about 2% of Earth's land area. And about 50,000 plant species, or about 17% of all known plant species, inhabit just 18 hot spots that comprise a total of only 0.5% of the global land surface. Together, the "hottest" of the biodiversity hot spots total less than 1.5% of Earth's land but are home to a third of all species of plants and vertebrates. Hot spots also include aquatic ecosystems, such as coral reefs and certain river systems.

Biodiversity hot spots are obviously good choices for nature reserves, but identifying them is not always straightforward. And even if all hot spots could be protected, that effort would fall woefully short of conserving the planet's biodiversity. One problem is that a hot spot for one taxonomic group, such as but-

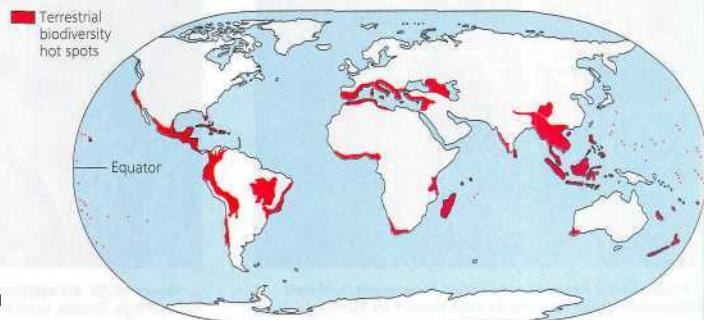

terflies, may not be a hot spot for some other taxonomic group, such as birds. Designating an area as a biodiversity hot spot is often biased toward saving vertebrates and plants, with less attention paid to invertebrates and microorganisms. Some biologists are also concerned that the hot-spot strategy focuses too much of the conservation effort on such a small fraction of Earth's land.

Philosophy of Nature Reserves

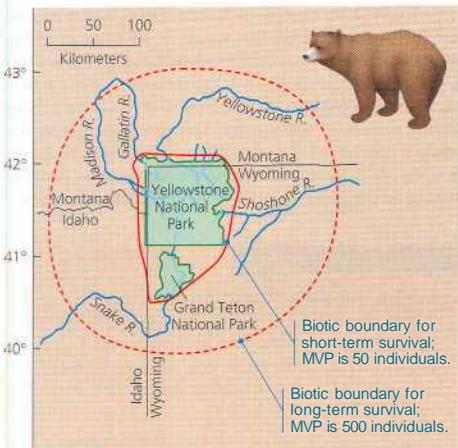

Nature reserves are biodiversity islands in a sea of habitat degraded to varying degrees by human activity. It is important to realize, however, that protected "islands" are not isolated from their surroundings and that the nonequilibrium model we described in Chapter 53 applies to nature reserves as well as to the larger landscapes in which they are embedded.

An earlier policy—that protected areas should be set aside to remain unchanged forever—was based on the concept that ecosystems are balanced, self-regulating units. However, as we saw in Chapter 53, disturbance is a functional component of all ecosystems, and management policies that ignore natural disturbances or attempt to prevent them have generally proved to be self-defeating. For instance, setting aside an area of a fire-dependent community, such as a portion of a tallgrass prairie, chaparral, or dry pine forest, with the intention of saving it is unrealistic if periodic burning is excluded. Without the dominant disturbance, the fire-adapted species are usually outcompeted by other species, and biodiversity is reduced.

Because human disturbance and fragmentation are increasingly common landscape features, the dynamics of disturbance, population dynamics, edges, and corridors are important in the design and management of protected areas. A major conservation question is whether it is better to create one large reserve or a group of smaller reserves. One argument for extensive preserves is that large, far-ranging animals with low-density populations, such as the grizzly bear, require extensive habitats. In addition, more extensive areas have proportionately smaller perimeters than smaller areas and are therefore less affected by edges. As conservation

P- Figure 55.17 Earth's terrestrial biodiversity hot spots.

A Figure 55.18 The legal (green border) and biotic (red borders) boundaries for grizzly bears in Yellowstone and Grand Teton National Parks. The biotic boundaries are defined by the entire watershed for this region and the area necessary to support a minimum viable population (MVP) of grizzly bears.

biologists learn more about the requirements for achieving minimum viable population sizes for endangered species, it is becoming clear that most national parks and other reserves are far too small. For example, **Figure 55.18** compares the boundaries of Yellowstone and Grand Teton National Parks with the actual area required to prevent extinction of grizzly bears. The *biotic boundary*, the area needed to sustain the grizzly, is more than ten times as large as the *legal boundary*, the actual area of the parks. Given political and economic realities, it is unlikely that many existing parks will be enlarged, and most newly created reserves will also be too small. Areas of private and public land surrounding reserves will likely have to contribute to biodiversity conservation. On the other side of the argument, smaller, unconnected preserves may slow the spread of disease throughout a population.

In practical terms, land use by humans may outweigh all other considerations and ultimately dictate the size and shape of protected areas. Much of the land left for conservation efforts is useless for exploitation by agriculture or forestry. But in some cases, as when reserve land is surrounded by commercially viable property, the use of land for agriculture or forestry must be integrated into conservation strategies.

Zoned Reserves

Several nations have adopted a zoned reserve approach to landscape management. A zoned reserve is an extensive region of land that includes one or more areas undisturbed by humans surrounded by lands that have been changed by hu-

(a) Boundaries of the zoned reserves are indicated by black outlines.

(b) Local schoolchildren marvel at the diversity of life in one of Costa Rica's reserves.

A Figure 55.19 Zoned reserves in Costa Rica.

man activity and are used for economic gain. The key challenge of the zoned reserve approach is to develop a social and economic climate in the surrounding lands that is compatible with the long-term viability of the protected core area. These surrounding areas continue to be used to support the human population, but with regulations that prevent the types of extensive alterations likely to impact the protected area. As a result, the surrounding tracts of land serve as buffer zones against further intrusion into the undisturbed area.

The small Central American nation of Costa Rica has become a world leader in establishing zoned reserves (**Figure 55.19**). In an international agreement that reduced its financial debt to other countries, the Costa Rican government established eight zoned reserves, called "conservation areas," which contain designated national park land. Costa Rica is

making progress toward managing its zoned reserves, and the buffer zones provide a steady, lasting supply of forest products, water, and hydroelectric power and also support sustainable agriculture and tourism. An important goal is providing a stable economic base for people living there. As University of Pennsylvania ecologist Daniel Janzen, a leader in tropical conservation, has said, "The likelihood of long-term survival of a conserved wildland area is directly proportional to the economic health and stability of the society in which that wildland is embedded." Destructive practices that are not compatible with long-term ecosystem conservation and from which there is often little local profit, such as massive logging, large-scale single-crop agriculture, and extensive mining, are ideally confined to the outermost fringes of the buffer zones and are gradually being discouraged.

Costa Rica looks to its zoned reserve system to maintain at least 80% of its native species, but the system is not without negative aspects. A 2003 analysis of land cover change between 1960 and 1997 showed negligible deforestation within Costa Rica's national parks and a gain in forest cover in the 1-km buffer around the parks. However, significant losses in forest cover were discovered in the 10-km buffer zones around all national parks, which threatens to turn the parks into isolated habitat islands.

The continued high rate of human exploitation of ecosystems leads some analysts to predict that considerably less than 10% of the biosphere will ever be protected as nature reserves. Sustaining biodiversity often involves working in landscapes that are almost entirely human dominated. Even vast marine ecosystems have become heavily impacted by human exploitation. For example, commercially important fish populations around the world have collapsed in the face of mounting fishing pressure from increasingly sophisticated equipment that puts nearly all potential fishing grounds within reach. In response, Fiona Gell and Callum Roberts of the University of

York, England, have proposed the establishment of marine reserves around the world that would be off limits to fishing (Figure 55.20). Gell and Roberts present strong evidence that a patchwork of marine reserves can serve as a means of both increasing fish populations within the reserves and improving fishing success in nearby areas. Their proposed system is a modern application of a centuries-old practice in the Fiji Islands in which some areas have historically remained closed to fishing—a traditional example of the zoned reserve concept.

Concept Check 55.3

1. What is a biodiversity hot spot?
2. How do zoned reserves provide economic incentives for long-term protection of protected areas?
3. How can corridors connecting habitat fragments help protect endangered populations? How might such corridors harm populations?

For suggested answers, see Appendix A.

Concept 55.4

Restoration ecology attempts to restore degraded ecosystems to a more natural state

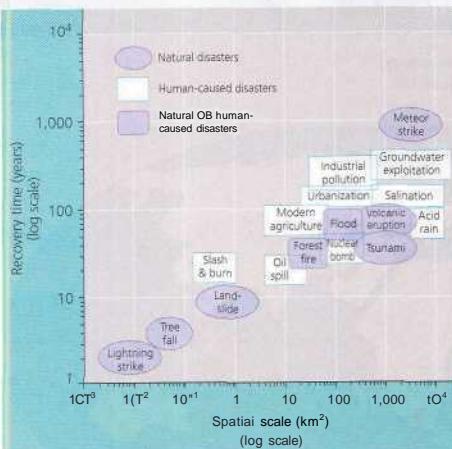

Eventually, some areas that are altered by human activity are abandoned. For instance, the soils of many tropical areas become unproductive and are abandoned fewer than five years after being cleared for farming. Mining activities may last for several decades, but the lands are then abandoned in a degraded state. Many ecosystems are also damaged inadvertently by the dumping of toxic chemicals or such mishaps as oil spills. Such degraded habitats and ecosystems are increasing in area because the natural rate of recovery by successional processes is slower than the rate of degradation by human activities.

Given enough time, biological communities can recover naturally from many types of disturbances through the various stages of ecological succession that we discussed in Chapter 53. The amount of time required for such natural recovery is more closely related to the spatial scale of the disturbance than the type of disturbance: The larger the area disturbed, the longer the time required for recovery. Whether the disturbance is natural or caused by humans seems to make little difference in this size-time relationship (Figure 55.21).

One of the basic assumptions of restoration ecology is that most environmental damage is reversible, but this optimism must be balanced by a second assumption—that communities are not infinitely resilient. Restoration ecologists

A Figure 55.20 A monitoring team preparing to count and measure clams inside an intertidal marine reserve in Fiji.

* **Figure 55.21** The size-time relationship for community recovery from natural and human-caused disasters. Note that the scales are logarithmic.

work to identify and manipulate the processes that most limit the speed of recovery in order to reduce the time it takes for a community to bounce back from the impact of disturbances. It is important to remember, however, that natural disturbance such as periodic fire or flooding is part of the dynamics of many ecosystems and needs to be considered in restoration strategies.

Two key strategies in restoration ecology are bioremediation and augmentation of ecosystem processes.

Bioremediation

Bioremediation is the use of living organisms, usually prokaryotes, fungi, or plants, to detoxify polluted ecosystems (see Chapter 27). For example, some plants adapted to soils containing heavy metals are capable of accumulating high concentrations of potentially toxic metals such as zinc, nickel, lead, and cadmium. Restoration ecologists can use these plants to revegetate sites polluted by mining and other human activities and then harvest the plants to remove the metals from the ecosystem. A number of researchers are also focusing on the ability of certain prokaryotes and lichens to concentrate metals. Researchers in the United Kingdom discovered a lichen species that grows on soil polluted with uranium dust left over from mining. The lichen concentrates uranium in a dark pigment, making it useful as a biological monitor and potentially as a remediator. Restoration ecologists have also achieved some success in using the bacterium *Pseudomonas* to clean up oil spills on beaches. More common

still is the use of certain prokaryotes to metabolize toxins in dump sites. In the future, genetic engineering may become increasingly important as a tool for improving the performance of certain species as bioremediators.

Biological Augmentation

In contrast to bioremediation, which is a strategy for *removing* harmful substances, biological augmentation uses organisms to *add* essential materials to a degraded ecosystem. Augmenting ecosystem processes requires determining what factors, such as chemical nutrients, have been removed from an area and thus are limiting its rate of recovery. Encouraging the growth of plants that thrive in nutrient-poor soils often speeds up the rate of successional changes that can lead to recovery of damaged sites. An example is the rapid regrowth of indigenous plant communities along roadsides in Puerto Rico, which was overseen by Ariel Lugo, director of the U.S. Forest Service's Institute of Tropical Forestry in Puerto Rico. Lugo used *Albizia procera*, a nonnative plant that thrives on nitrogen-poor soils, to colonize roadside areas after the original forest was removed and soils were depleted of nutrients. Apparently, the rapid buildup of organic material from dense stands of *Albizia* enabled indigenous plants to recolonize the area and overgrow the introduced plant in a relatively brief time.

Exploring Restoration

Because of the newness of restoration ecology as a discipline, the complexity of ecosystems, and the unique features of each situation, restoration ecologists usually must learn as they go. Many restoration ecologists advocate adaptive management: experimenting with several promising types of management to learn what works best. The key to adaptive management, and the key to restoration ecology, is to consider alternative ways of accomplishing goals and to learn from mistakes as well as successes. The long-term objective of restoration is to speed the reestablishment of an ecosystem as similar as possible to the predisturbance ecosystem. **Figure 55.22**, on the next two pages, identifies several ambitious and successful restoration projects around the world. The great number of such projects, the dedication of the people engaged in them, and the successes that have been achieved suggest that this is just the beginning.

Concept Check 55.4

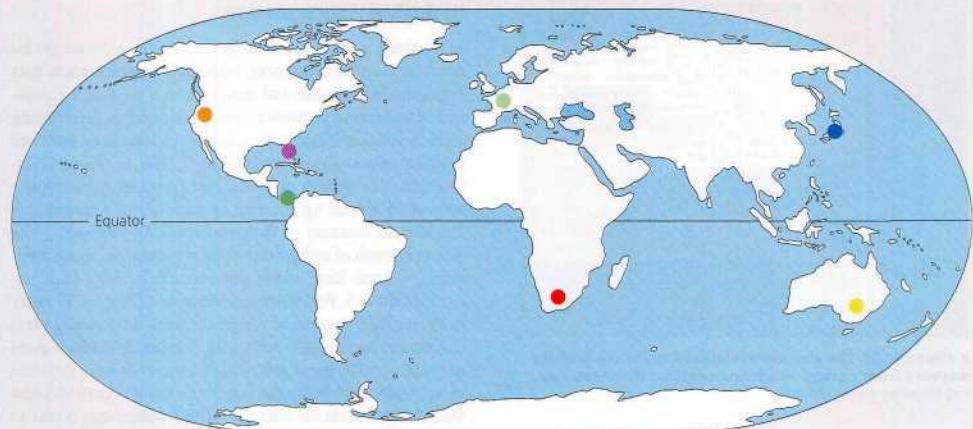

- What are the goals of restoration ecology?
- How do bioremediation and biological augmentation differ?

For suggested answers, see Appendix A.

Figure 55.22

Exploring Restoration Ecology Worldwide

The examples highlighted on these pages are just a few of the many restoration ecology projects taking place around the world. The color-coded dots on the map indicate the locations of the projects.

It* Truckee River, Nevada. Damming and water diversions during the 20th century reduced flow in the Truckee River, Nevada, leading to declines in riparian forests. Restoration ecologists worked with water managers to ensure that sufficient water would be released during the short season of seed release by the native cottonwood and willow trees for seedlings to become established. Nine years of contralined-flow release led to the result shown here: a dramatic recovery of cottonwood-willow riparian forest.

0 Kissimmee River, Florida. The Kissimmee River in south-central Florida was converted from a meandering river into a 90-km canal, with significant negative impacts on fish and wetland bird populations. Kissimmee River restoration has filled 12 km of drainage canal and reestablished 24 km of the original 167 km of natural river channel. Pictured here is a section of the Kissimmee canal that has been plugged (wide, light strip on right side of photo), diverting flow into remnant river channels in the center of the photo. The project will also restore the natural flow regime, which will foster self-sustaining populations of wetland birds and fishes.

● Australia. One of the most difficult aspects of restoration ecology is determining how human activity has altered ecosystems and what the goals of restoration should be. In Australia, environmental narratives from people who have lived on the land are an invaluable source of scarce baseline information to help create restoration goals.

● **Tropical dry forest, Costa Rica.** Clearing for agriculture, mainly for livestock grazing, eliminated approximately 98% of tropical dry forest in Central America and Mexico. In a reversal of roles, tropical dry forest restoration in Costa Rica has used domestic livestock to disperse the seeds of native trees into open grasslands. The photo shows one of the first trees (right center), dispersed as seed by livestock, to colonize former pastureland. This project is a model for joining restoration ecology with the local economy and educational institutions.

● **Rhine River, Europe.** Centuries of dredging and channeling for navigation (see the barges in the wide, main channel on the right side of the photo) have straightened the once-meandering Rhine River and disconnected it from its floodplain and associated wetlands. The countries along the Rhine, particularly France, Germany, Luxembourg, the Netherlands, and Switzerland, are cooperating to reconnect the river to side channels, such as the one shown on the left side of the photo. Such side channels increase the diversity of habitats available to aquatic biota, improve water quality, and provide flood protection.

● **Succulent Karoo, South Africa.** In this desert region of southern Africa, as in many arid regions, overgrazing by livestock has damaged vast areas. Reversing this trend, private landowners and government agencies in South Africa are restoring large areas of this unique region. The photo shows a small sample of the exceptional plant diversity of the Succulent Karoo; its 5,000 plant species include the highest diversity of succulent plants in the world.

● **Coastal Japan.** Seaweed and seagrass beds are important nursery grounds for a wide variety of fishes and shellfish. Once extensive but now reduced by development, these beds are being restored in the coastal areas of Japan. Techniques include construction of suitable seafloor habitat, transplantation from natural beds using artificial substrates, and hand seeding (shown in this photograph).

Concept 55.5

Sustainable development seeks to improve the human condition while conserving biodiversity

Facing increasing loss and fragmentation of habitats, how can we best manage Earth's resources? If we are to conserve most of a nation's species, which habitat patches are most crucial? Among the choices, which areas are most practical to protect and manage if we are to save endangered species or the greatest number of species?

Sustainable Biosphere Initiative

We must understand the complex interconnections of the biosphere in order to make sensible decisions about how to conserve these networks. To this end, many nations, scientific societies, and private foundations have embraced the concept of **sustainable development**, the long-term prosperity of human societies and the ecosystems that support them. The forward-looking Ecological Society of America, the world's largest organization of professional ecologists, endorses a research agenda called the Sustainable Biosphere Initiative. The goal of this initiative is to define and acquire the basic ecological information necessary for the intelligent and responsible development, management, and conservation of Earth's resources. The research agenda includes studies of global change, including interactions between climate and ecological processes; biological diversity and its role in maintaining ecological processes; and the ways in which the productivity of natural and artificial ecosystems can be sustained. This initiative requires a strong commitment of human and economic resources.

Sustainable development is *not just* about science. To sustain ecosystem processes and stem the loss of biodiversity, we must connect life science with the social sciences, economics, and humanities. And equally important, we must reassess our values. Those of us living in affluent developed nations are responsible for the greatest amount of environmental degradation. Reality demands that we learn to revere the natural processes that sustain us, and reduce our orientation toward short-term personal gain. The following case study illustrates how the combination of scientific and personal efforts can make a significant difference in creating a truly sustainable world.

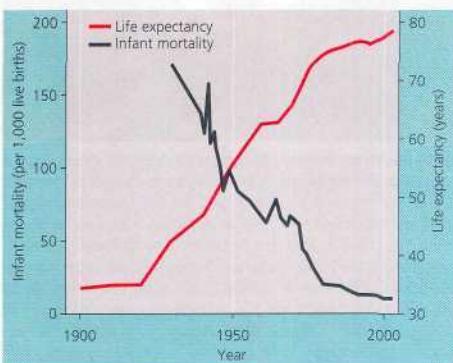

Case Study: Sustainable Development in Costa Rica

The success of conservation in Costa Rica that we discussed in Concept 55.3 has involved leadership by the national government as well as an essential partnership between the national

government, nongovernment organizations (NGOs), and private citizens. For instance, many nature reserves established by individuals have been recognized by the government as national wildlife reserves and given significant tax benefits. However, conservation and restoration of biodiversity is only one side of sustainable development; the other key facet is improving the human condition.

How have the living conditions of the Costa Rican people fared as the country pursued its conservation goals? We can gain insights into conditions through population statistics. As we discussed in Chapter 52, two of the most fundamental indicators of living conditions are infant mortality rate and life expectancy. **Figure 55.23** shows that the infant mortality rate in Costa Rica declined sharply during the 20th century, and life expectancy at birth increased. In 1930, out of each 1,000 live births, over 170 infants died. By 2003, infant mortality had fallen to 10 per 1,000 live births. Meanwhile, life expectancy climbed from just over 35 years in 1900 to over 78 years in 2003, which is approximately one year longer than in the United States, where life expectancy in 2003 was just over 77 years. Another indicator of living conditions is literacy rate. The 2003 literacy rate in Costa Rica was 96%, compared to 97% in the United States.

Such statistics show that living conditions in Costa Rica have improved greatly over the period in which the country dedicated itself to conservation and restoration. While a correlation does not confirm a cause-effect relationship, we can certainly infer that Costa Rica's conservation initiatives have not compromised human welfare. And we can say that development in Costa Rica has attended to both nature and people. Nevertheless, many problems remain. One of the challenges that the country will have to face is maintaining its commitment to conservation in the face of a growing population.

A Figure 55.23 Infant mortality and life expectancy at birth in Costa Rica.

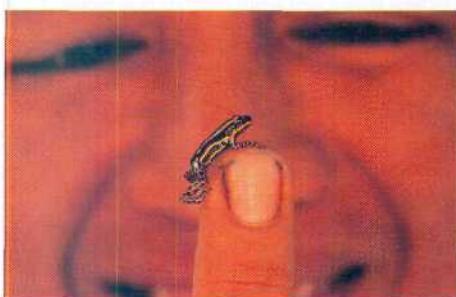

Costa Rica is in the middle of a rapid demographic transition (see Chapter 52), and even though birth rates are dropping rapidly, its population continues to grow at about 1.5% annually (compared to 0.9% growth in the United States). Costa Rica's population, which is currently about 4 million, is predicted to continue to grow until the middle of this century, when it will level off at approximately 6 million. Given their recent history, it seems probable that the Costa Rican people will confront the remaining challenges of sustainable development with the same energy and optimism that they have shown in the past.

Biophilia and the Future of the Biosphere

Despite the uncertainties about the future of the biosphere, now is not the time for gloom and doom but the time to reconnect with the rest of nature. Not many people today live in truly wild environments or even visit such places often. Our modern lives are very different from those of early humans, who hunted and gathered and painted wildlife murals on cave

(a) Detail of animals in a Paleolithic mural, Lascaux, France

(b) Biologist Carlos Rivera Gonzales examining a tiny tree frog in Peru

A **Figure 55.24** Biophilia, past and present.

walls (**Figure 55.24a**). But our behavior reflects remnants of our ancestral attachment to nature and the diversity of life—the concept of *biophilia* that we introduced early in this chapter. We evolved in natural environments rich in biodiversity, and we still have an affinity for such settings (**Figure 55.24b**). E. O. Wilson makes the case that our biophilia is innate, an evolutionary product of natural selection acting on a brainy species whose survival depended on a close connection to the environment and a practical appreciation of plants and animals.

It will come as no surprise that most biologists have embraced the concept of biophilia. After all, these are people who have turned their passion for nature into careers. But biophilia strikes a harmonic chord with biologists for another reason. If biophilia is evolutionarily embedded in our genome, then there is hope that we can become better custodians of the biosphere. If we all pay more attention to our biophilia, a new environmental ethic could catch on among individuals and societies. That ethic is a resolve never to allow a species to become extinct or any ecosystem to be destroyed through human activities as long as there are reasonable ways to prevent such ecological violence. It is an environmental ethic that balances out another human trait—our tendency to “subdue” Earth. Yes, we should be motivated to preserve biodiversity because we depend on it for food, medicine, building materials, fertile soil, flood control, habitable climate, drinkable water, and breathable air. But maybe we can also work harder to prevent the extinction of other forms of life just because it is the ethical thing for us to do as the most thoughtful species in the biosphere. Again, Wilson sounds the call: “Right now, we’re pushing the species of the world through a bottleneck. We’ve got to make it a major moral principle to get as many of them through this as possible. It’s the challenge now and for the next century. And there’s one good thing about our species: We like a challenge!”

It is appropriate that we end this textbook with a discussion of biophilia, for biology is a scientific expression of our desire to know nature. We are most likely to protect what we appreciate, and we are most likely to appreciate what we understand. By learning about the processes and diversity of life, we also become more aware of ourselves and our place in the biosphere. We hope this book serves you well in this lifelong adventure.

Concept Check 55.5

1. What is meant by the term *sustainable development*?
2. How might biophilia influence environmental ethics?

For suggested answers, see Appendix A.

Chapter 55 Review

Go to the Campbell Biology website (www.campbellbiology.com) or CD-ROM to explore Activities, Investigations, and other interactive study aids.

SUMMARY OF KEY CONCEPTS

Concept 55.1

Human activities threaten Earth's biodiversity

- **The Three Levels of Biodiversity** (pp. 1210–1211) Biodiversity consists of the varied ecosystems in the biosphere, the species richness within those ecosystems, and the genetic variation within and among populations of each species.
- **Biodiversity and Human Welfare** (pp. 1211–1212) Our biophilia enables us to recognize the value of biodiversity for its own sake. Other species also provide humans with food, fiber, medicines, and ecosystem services.
- **Four Major Threats to Biodiversity** (pp. 1212–1215) The four major threats to biodiversity are habitat destruction, introduced species, overexploitation, and disruption of interaction networks.

Activity *Madagascar and the Biodiversity Crisis*

Activity *Introduced Species: Fire Ants*

Graph It *Forestation Changes*

Graph It *Global Fisheries and Overfishing*

Graph It *Municipal Solid Waste Trends in the U.S.*

Concept 55.2

Population conservation focuses on population size, genetic diversity, and critical habitat

- **Small-Population Approach** (pp. 1215–1218) When a population drops below a minimum viable population (MVP) size, its loss of genetic variation due to nonrandom mating and genetic drift can trap it in an extinction vortex.
- **Declining-Population Approach** (pp. 1218–1219) The declining-population approach focuses on the environmental factors that cause decline, regardless of absolute population size. It follows a step-by-step proactive conservation strategy.
- **Weighing Conflicting Demands** (pp. 1219–1220) Conserving species often requires resolving conflicts between the habitat needs of endangered species and human demands.

Concept 55.3

Landscape and regional conservation aim to sustain entire biotas

- **Landscape Structure and Biodiversity** (pp. 1220–1222) The structure of a landscape can strongly influence biodiversity. As habitat fragmentation increases and edges become more extensive, biodiversity tends to decrease. Movement corridors can promote dispersal and help sustain populations.
- **Establishing Protected Areas** (pp. 1222–1224) Biodiversity hot spots are also hot spots of extinction and thus prime candidates for protection. Sustaining biodiversity in parks and reserves requires management to ensure that human activities in the surrounding landscape do not harm the protected habitats. The zoned reserve model recognizes that conservation efforts often involve working in landscapes that are largely human dominated.

Concept 55.4

Restoration ecology attempts to restore degraded ecosystems to a more natural state

- **Bioremediation** (p. 1225) Restoration ecologists are harnessing living organisms to detoxify polluted ecosystems.
- **Biological Augmentation** (p. 1225) Ecologists also use organisms to add essential materials to ecosystems.
- **Exploring Restoration** (pp. 1225–1227) The newness and complexity of restoration ecology require scientists to consider alternative solutions and adjust approaches based on experience, *investigation How Are Potential Prairie Restoration Sites Analyzed?*

Concept 55.5

Sustainable development seeks to improve the human condition while conserving biodiversity

- **Sustainable Biosphere Initiative** (p. 1228) The goal of the Sustainable Biosphere Initiative is to acquire the ecological information needed for the development, management, and conservation of Earth's resources.
- **Case Study: Sustainable Development in Costa Rica** (pp. 1228–1229) Costa Rica's success in conserving tropical biodiversity has involved partnerships between the government, other organizations, and private citizens. Human living conditions in Costa Rica have improved along with ecological conservation. Activity *Conservation Biology Review*
Graph It *Global Freshwater Resources*
Graph It *Prospects for Renewable Energy*
- **Biophilia and the Future of the Biosphere** (p. 1229) Our innate sense of connection to nature may eventually motivate a realignment of our environmental priorities.

TESTING YOUR KNOWLEDGE

Evolution Connection

One factor favoring rapid population growth by an introduced species is the absence of the predators, parasites, and pathogens that controlled its population in the region where it evolved. Over the long term, how should evolution by natural selection influence the rate at which the native predators, parasites, and pathogens in a region of introduction attack an introduced species?

Scientific Inquiry

Suppose that you are in charge of planning a forest reserve, and one of your main goals is to help sustain local populations of woodland birds suffering from parasitism by the brown-headed cowbird. Reading research reports, you note that female cowbirds are usually reluctant to penetrate more than about 100 m into a forest and that nest parasitism is reduced when some woodland birds nest only in denser, more central forest regions. The forested area you have to work with is about 1,000 m by 6,000 m. A recent logging opera-

tion removed about half of the trees on one of the 6,000-m sides; the other three sides are adjacent to deforested pastureland. Your plan must include space for a small maintenance building, which you estimate to take up about 100 m². It will also be necessary to "build a road. 10 m by 1,000 m, across the reserve. Where would you construct the road and the building, and why?

investigation flow *Are Potential Prairie Restoration Sites Analyzed?*

Science, Technology, and Society

Some organizations, such as the Ecological Society of America, are starting to envision a sustainable society—one in which each generation inherits sufficient natural and economic resources and a relatively stable environment. The Worldwatch Institute estimates that to reach sustainability by 2030, we must begin shaping a sustainable society during the next ten years or so. In what ways is our current system not sustainable? What might we do to work toward sustainability, and what are the major roadblocks to achieving it? How would your life be different in a sustainable society?

APPENDIX A Answers

Answers

CHAPTER 1

Concept Check 1.1

- Examples: A molecule consists of atoms bonded together. Each organelle has an orderly arrangement of molecules. Photosynthetic plant cells contain the *organelles* called chloroplasts. An animal tissue consists of a group of similar *cells*. Organs such as the heart are constructed from several tissues. A complex organism, such as a plant, has several types of *organs*, including leaves and roots, in the case of the plant. A population is a set of organisms of the same species. A community consists of *populations* of the various species inhabiting a specific area. An ecosystem consists of a biological *community* along with the nonliving factors important to life, such as air, soil, and water. The biosphere is made up of all of Earth's *ecosystems*.
- DNA is the chemical substance of genes. Genes are the hereditary units arranged along DNA molecules. The DNA molecules are built into the cellular structures called chromosomes.
- Both plants and animals consist of eukaryotic cells, while the cells of bacteria are prokaryotic.

Concept Check 1.2

- The meaning of a sentence is a property that emerges from the specific sequence of letters and spaces.
- High-throughput data collection is the source of the enormous and expanding databases of biological information that make bioinformatics a necessary and productive field.
- Negative feedback

Concept Check 1.3

- An address pinpoints a location by tracking from broader to narrower categories—a state, city, zip, street, and house or apartment number. This is analogous to the groups-subordinate-to-groups structure of biological taxonomy
- Organisms of domain Eukarya are made of eukaryotic cells, in contrast to the prokaryotic cells of domains Bacteria and Archaea.

Concept Check 1.4

- Natural selection does not "create" the variation that makes adaptation possible, but "edits" by selecting in favor of certain heritable traits in a naturally varying population.

2. Plants Fungi Animals

Concept Check 1.5

- Inductive reasoning derives generalizations from specific cases; deductive reasoning predicts specific outcomes from general premises.
- It's usually impossible to exclude all unwanted variables; instead, a controlled experiment cancels out those variables by comparing an experimental group with a control group that differs only in the variable of interest.
- To test the prediction of the mimicry hypothesis that king snakes will only benefit from their coral snake coloration in environments where poisonous coral snakes also live
- Compared to a hypothesis, a scientific theory is usually more general and more substantiated by an accumulation of evidence.

Concept Check 1.6

- Example: Scientific inquiry and the technology it informs have an enormous impact on society

CHAPTER 2

Concept Check 2.1

- Table salt consists of two elements, whereas oxygen consists of only one.
- Carbon, oxygen, hydrogen, and nitrogen

Concept Check 2.2

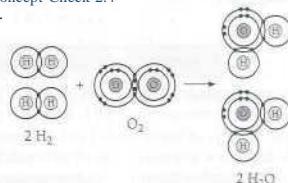

1. 7
2. Atomic number = 7; mass number = 15; fN
3. Atomic number = 12; 12 protons, 12 electrons; three electron shells; 2 electrons in the valence shell
4. The electrons in the shell farthest from the nucleus have the most potential energy, and the electrons in the shell closest to the nucleus have the least.
5. 9 electrons; two electron shells; Is, 2s, 2p (three of them); 1 unpaired electron

Concept Check 2.3

- Each carbon atom has only three covalent bonds instead of the required four.
- The attractions between oppositely charged ions form ionic bonds.

Concept Check 2.4

1.

- At equilibrium, the forward and reverse reactions occur at the same rate.

CHAPTER 3

Concept Check 3.1

- Electronegativity is the attraction of an atom for the electrons of a covalent bond. Since oxygen is more electronegative than hydrogen, the oxygen atom in H2O pulls electrons toward itself, resulting in a partial negative charge on the oxygen atom and partial positive charges on the hydrogen atoms. Oppositely charged ends of water molecules are attracted to each other, forming a hydrogen bond.
- The hydrogen atoms of one molecule, with their partial positive charges, would repel the hydrogen atoms of the adjacent molecule.

Concept Check 3.2

- Hydrogen bonds hold neighboring water molecules together; this cohesion helps the molecules resist the downward pull of gravity. Adhesion between water molecules and the walls of water-conducting cells also counters the downward pull of gravity. As water evaporates from the leaves, the chain of water molecules in water-conducting cells moves upward.
- High humidity hampers cooling by suppressing the evaporation of sweat.
- "Water expands as it freezes, because the water molecules move farther apart in forming ice crystals. When there is water in a crevice of a boulder, expansion of the water due to freezing may crack the rock.
- The molecular mass of NaCl is 58.5 daltons. A mole would have a mass of 58.5 g, so you would measure out 0.5 mole, or 29.3 g of NaCl, and gradually add water, stirring until it is dissolved. You would add water to bring the final volume to 1 L.

Concept Check 3.3

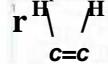

- 10^6 , or 100,000
- $(H^+)^{-} = 0.01 \text{ M} = 10^{-2} \text{ M}$, so $pH = 2$

CHAPTER 4

Concept Check 4.1

- Urea is a molecule synthesized by living organisms and found in urine. Its synthesis from gases of the primitive atmosphere on Earth demonstrated that life's molecules could initially have been synthesized from nonliving molecules.

Concept Check 4.2

- The butanes in (b) are structural isomers, as are the butenes in (c).
- Both consist largely of hydrocarbon chains.

Concept Check 4.3

- It has both an amino group ($-\text{NH}_2$) and a carboxyl group ($-\text{COOH}$), which makes it *s*. carboxylic acid.
- The ATP molecule loses a phosphate, becoming ADP

CHAPTERS

Concept Check 5.1

- Proteins, carbohydrates, lipids, and nucleic acids
- Nine, with one water required to hydrolyze each connected pair of monomers
- The amino acids in the apple protein are released in hydrolysis reactions, and incorporated into your proteins in dehydration reactions.

Concept Check 5.2

- $\text{C}_6\text{H}_{12}\text{O}_6$ or $\text{C}_5(\text{H}_2\text{O})_3$
- $\text{C}_{12}\text{H}_{22}\text{O}_n$
- Both molecules are polymers of glucose made by plants, but the glucose monomers are arranged differently. Starch functions mainly for sugar storage. Cellulose is a structural polysaccharide that is the main material of plant cell walls.

Concept Check 5.3

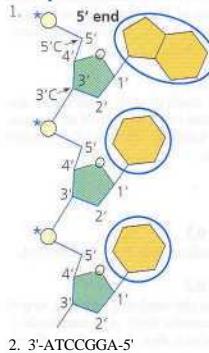

- Both have a glycerol molecule attached to fatty acids. The glycerol of a fat has three fatty acids attached, whereas the glycerol of a phospholipid is attached to two fatty acids and one phosphate group.
- The fatty acids on a saturated fat have no double bonds in their hydrocarbon chains, whereas at least one fatty acid on an unsaturated fat has a double bond. Saturated fats tend to be solid at room temperature, while unsaturated fats are liquid.
- Human sex hormones are steroids, a type of hydrophobic compound.

Concept Check 5.4

- The function of each protein is a consequence of its specific shape, which is lost when a protein becomes denatured.

- Secondary structure involves hydrogen bonds between atoms of the polypeptide backbone. Tertiary structure involves bonding between atoms of the R groups of the amino acid subunits.
- Primary structure, the amino acid sequence, affects the secondary structure, which affects the tertiary structure, which affects the quaternary structure (if any); in short, the amino acid sequence affects the shape of the protein, and the function of a protein depends on its shape.

Concept Check 5.5

CHAPTER 6

Concept Check 6.1

- (a) Light microscope, (b) scanning electron microscope, (c) transmission electron microscope

Concept Check 6.2

- See Figure 6.9.

Concept Check 6.3

- Ribosomes in the cytoplasm translate the genetic message, carried from the DNA in the nucleus by mRNA, into a polypeptide chain.
- Chromatin is composed of DNA and associated proteins; it carries the cell's genetic information. Nucleoli consist of RNA and proteins and are associated with particular regions of the DNA. In the nucleoli, rRNA is synthesized and ribosomal subunits are assembled.

Concept Check 6.4

- The primary distinction between rough and smooth ER is the presence of bound ribosomes on the rough ER. While both types of ER synthesize phospholipids, membrane proteins are all produced on the ribosomes of the rough ER. The smooth ER also functions in detoxification, carbohydrate metabolism, and storage of calcium ions.
- The mRNA is synthesized in the nucleus, then passes out through a nuclear pore to be

translated on a bound ribosome, attached to the rough ER. The protein is synthesized into the lumen of the ER and perhaps modified there. A transport vesicle carries the protein to the Golgi apparatus. After further modification in the Golgi, another transport vesicle carries it back to the ER, where it will perform its cellular function.

- Transport vesicles move membranes and substances they enclose between other components of the endomembrane system.

Concept Check 6.5

- Both organelles are involved in energy transformation, mitochondria in cellular respiration and chloroplasts in photosynthesis. They are both composed of two or more separate membranes.
- Mitochondria and chloroplasts contain DNA, which encodes some of their proteins. They are not connected physically or via transport vesicles to organelles of the endomembrane system.

Concept Check 6.6

- Microtubules are hollow tubes that resist bending; microfilaments are more like strong cables that resist stretching. These opposing properties work together to define and maintain cell shape. Intermediate filaments also resist stretching, and they are more permanent tension-bearing elements that reinforce the shape of the cell.
- Dynein arms, powered by ATP, move neighboring doublets of microtubules relative to one another. Because they are anchored within the organelle and with respect to each other, the doublets bend instead of sliding past one another.

Concept Check 6.7

- The most obvious difference is the presence of direct cytoplasmic connections between cells of multicellular plants (plasmodesmata) and animals (gap junctions). These connections result in the cytoplasm being continuous between adjacent cells.
- The cell wall or ECM must be permeable to the materials that enter and leave the cell, and to molecules that provide information about the cell's environment.

CHAPTER?

Concept Check 7.1

- Plants adapted to cold environments would be expected to have more unsaturated fatty acids in their membranes, since those remain fluid at lower temperatures. Plants adapted to hot environments would be expected to have more saturated fatty acids, which would allow the fatty acids to "stack" more closely, making the membranes less fluid and therefore helping them to stay intact at higher temperatures.
- They are on the inner side of the transport vesicle membrane.

Concept Check 7.2

- O_2 and CO_2 are both small, uncharged molecules that can easily pass through the hydrophobic core of a membrane.
- Water is a very polar molecule, so it cannot pass very rapidly through the hydrophobic region in the middle of a phosphoplipid bilayer.

Concept Check 7.3

- The activity of the *Pammecium's* contractile vacuole would decrease. The vacuole pumps out excess water that flows into the cell; this flow occurs only in a hypotonic environment.

Concept Check 7.4

- The pump would use ATE To establish a voltage, ions would have to be pumped against their gradient, which requires energy.
- Each ion is being transported against its electrochemical gradient. If either ion were flowing down its electrochemical gradient, this would be considered cotransport.

Concept Check 7.5

- Exocytosis. When a transport vesicle fuses with the plasma membrane, the vesicle membrane becomes part of the plasma membrane.
- Receptor-mediated endocytosis, because in this case one specific molecule needs to be taken up at a particular time; pinocytosis takes up substances in a nonspecific manner.

CHAPTER 8**Concept Check 8.1**

- The second law is the trend toward randomness. Equal concentrations of a substance on both sides of a membrane is a more random distribution than unequal concentrations. Diffusion of a substance to a region where it is initially less concentrated increases entropy, as mandated by the second law.
- Energy is the capacity to cause change, and some forms of energy can do work.
- The apple has potential energy in its position hanging on the tree, and the sugars and other nutrients it contains have chemical energy. The apple has kinetic energy as it falls from the tree to the ground. Finally, thermal energy is lost as the apple is digested and its molecules broken down.

Concept Check 8.2

- Cellular respiration is a spontaneous and exergonic process. The energy released from glucose is used to do work in the cell, or is lost as heat.
- H^+ ions can perform work only if their concentrations on each side of a membrane differ. When the H^+ concentrations are the same, the system is at equilibrium and can do no work.

Concept Check 8.3

- By phosphorylations, the addition of phosphate groups: ATP transfers energy to endergonic processes by phosphorylating other molecules. Exergonic processes phosphorylate ADP to regenerate ATP.

Appendix A

- A set of coupled reactions can transform the first group into the second group. Since, overall, this is an exergonic process, AG is negative and the first group must have more free energy.

Concept Check 8.4

- A spontaneous reaction is a reaction that is exergonic. However, if it has a high activation energy that is rarely attained, the rate of the reaction may be low.
- Only the specific substrate^a will fit into the active site of an enzyme, the part of the enzyme that carries out catalysis.
- As a competitive inhibitor, malonate binds to the active site of succinate dehydrogenase and so prevents the normal substrate, succinate, from binding.

Concept Check 8.5

- The activator binds in such a way that it stabilizes the active conformation of an enzyme, whereas the inhibitor stabilizes the inactive conformation.

CHAPTER 9**Concept Check 9.1**

- $CH_3C=O$ is oxidized and NAD^{+} is reduced.

Concept Check 9.2

- NAD^{+} acts as the oxidizing agent in step 6, accepting electrons from glyceraldehyde-3-phosphate, which thus acts as the reducing agent.

Concept Check 9.3

- $NADH$ and $FADH_2$; they will donate electrons to the electron transport chain.
- CO_2 is removed from pyruvate, which is produced by glycolysis, and CO , is produced by the citric acid cycle.

Concept Check 9.4

- Oxidative phosphorylation would stop entirely, resulting in no ATP production. Without oxygen to "pull" electrons down the electron transport chain, H^+ would not be pumped into the mitochondrion's intermembrane space and chemiosmosis would not occur.
- Because addition of H^+ (decreasing the pH) would establish a proton gradient even without the function of the electron transport chain, we would expect ATP synthase to function and synthesize ATP. (In fact, it was experiments like this one that provided support for chemiosmosis as an energy-coupling mechanism.)

Concept Check 9.5

- A derivative of pyruvate—either acetaldehyde during alcohol fermentation or pyruvate itself during lactic acid fermentation; oxygen
- The cell would need to consume glucose at a rate about 19 times the consumption rate in the aerobic environment (2 ATP are generated by fermentation versus up to 38 ATP by cellular respiration).

Concept Check 9.6

- The fat is much more reduced: it has many $-CH_2-$ units. The electrons present in a carbohydrate molecule are already somewhat oxidized, as some of them are bound to oxygen.
- When we consume more food than necessary for metabolic processes, our bodies synthesize fat as a way of storing energy for later.
- AMP will accumulate, stimulating phosphofructokinase, which increases the rate of glycolysis. Since oxygen is not present, the cell will convert pyruvate to lactate in lactic acid fermentation, providing a supply of ATP.

CHAPTER 10**Concept Check 10.1**

- CO_2 enters leaves via stomata, and water enters via roots and is carried to leaves through veins.
- Using a heavy isotope of oxygen as a label, O. van Niel was able to show that the oxygen produced during photosynthesis originates in water, not in carbon dioxide.
- The Calvin cycle depends on the NADPH and ATP that the light reactions generate, and the light reactions depend on the NAD^+ and $ADP + \text{Pi}$ that the Calvin cycle generates.

Concept Check 10.2

- Green, because green light is mostly transmitted and reflected—not absorbed—by photosynthetic pigments
- In chloroplasts, light-excited electrons are trapped by a primary electron acceptor, which prevents them from dropping back to the ground state. In isolated chlorophyll, there is no electron acceptor, so the photoexcited electrons immediately drop back down to the ground state, with the emission of light and heat.
- Water (H_2O) is the electron donor; $NADP^+$ accepts electrons at the end of the electron transport chain, becoming reduced to $NADPH$.

Concept Check 10.3

- 6, 18, 12
- The more potential energy that a molecule stores, the more energy and reducing power required for the formation of that molecule. Glucose is a valuable energy source because it is highly reduced, storing lots of potential energy in its electrons. To reduce CO_2 to glucose, much energy and reducing power are required in the form of a high number of ATP and NADPH molecules, respectively.
- The light reactions require ADP and $NADP^+$, which would not be formed from ATP and NADPH if the Calvin cycle stopped.

Concept Check 10.4

- Photorespiration decreases photosynthetic output by adding oxygen, instead of carbon dioxide, to the Calvin cycle. As a result, no sugar is generated (no carbon is fixed), and O_2 is used rather than generated.
- C_4 and CAM species would replace many of the C₃ species.

CHAPTER 11

Concept Check 11.1

1. The secretion of neurotransmitter molecules at a synapse is an example of local signaling. The electrical signal that travels along a very long nerve cell and is passed to the next nerve cell can be considered an example of long-distance signaling. (Note, however, that local signaling at the synapse between two cells is necessary for the signal to pass from one cell to the next.)
2. No glucose-1-phosphate is generated, because the activation of the enzyme requires an intact cell membrane with an intact receptor in the membrane. The enzyme cannot be activated directly by interaction with the signal molecule in the test tube.

Concept Check 11.2

1. The NGF receptor is in the plasma membrane. The water-soluble NGF molecule cannot pass through the lipid membrane to reach intracellular receptors, as steroid hormones can.

Concept Check 11.3

1. A protein kinase is an enzyme that transfers a phosphate group from ATP to a protein, usually activating that protein (often a second type of protein kinase). Many signal transduction pathways include a series of such interactions, in which each phosphorylated protein kinase, in turn phosphorylates the next protein kinase in the series. Such phosphorylation cascades carry a signal from outside the cell to the cellular protein(s) that will carry out the response.
2. Protein phosphatases reverse the effects of the kinases.
3. The IP₃-gated channel opens, allowing calcium ions to flow out of the ER, which raises the cytosolic Ca²⁺ concentration.

Concept Check 11.4

1. By a cascade of sequential activations, at each step of which one molecule may activate numerous molecules functioning in the next step
2. Scaffolding proteins hold molecular components of signaling pathways in a complex with each other. Different scaffolding proteins would assemble different collections of proteins, leading to different cellular responses in the two cells.

CHAPTER 12

Concept Check 12.1

1. 32 cells
2. 2
3. 39; 39; 78; 39

Concept Check 12.2

1. From the end of S phase of interphase through the end of metaphase of mitosis
2. 4; 8

3. Cytokinesis results in two genetically identical daughter cells in both plant cells and animal cells, but the mechanism of dividing the cytoplasm is different between animals and plants. In an animal cell, cytokinesis occurs by cleavage, which divides the parent cell in two with a contractile ring of actin filaments. In a plant cell, a cell plate forms in the middle of the cell and grows until its membrane fuses with the plasma membrane of the parent cell. A new cell wall is also produced from the cell plate, resulting in two daughter cells.

4. They elongate the cell during anaphase.
5. Sample answer: Each type of chromosome consists of a single molecule of DNA with attached proteins. If stretched out, the molecules of DNA would be many times longer than the cells in which they reside. During cell division, the two copies of each type of chromosome actively move apart, and one copy ends up in each of the two daughter cells.

Concept Check 12.3

1. G₁
2. The nucleus on the right was originally in the G₁ phase; therefore, it had not yet duplicated its chromosome. The nucleus on the left was in the M phase, so it had already duplicated its chromosome.
3. A sufficient amount of MPF has to build up for a cell to pass the G₂ checkpoint.
4. The cells might divide even in the absence of PDGF, in which case they would not stop when the surface was covered; they would continue to divide, piling on top of one another.
5. Most body cells are not in the cell cycle, but rather are in a nondividing state called G₀.
6. Both types of tumors consist of abnormal cells. A benign tumor stays at the original site and can usually live "agelessly" or "forever". Cancer cells from a malignant tumor spread from the original site by metastasis and may impair the functions of one or more organs.

CHAPTER 13

Concept Check 13.1

1. Parents pass genes to their offspring that program cells to make specific enzymes and other proteins whose cumulative action produces an individual's inherited traits.
2. Such organisms reproduce by mitosis, which generates offspring whose genomes are virtually exact copies of the parents' genome.
3. Offspring resemble their parents but are not genetically identical to them or their siblings because sexual reproduction generates different combinations of genetic information.

Concept Check 13.2

1. A female has two X chromosomes; a male has an X and Y.
2. In meiosis, the chromosome count is reduced from diploid to haploid; the union of two haploid gametes in fertilization restores the diploid chromosome count.

3. Haploid number (n) is 39; diploid number (2n) is 78.

4. Meiosis is involved in the production of gametes in animals. Mitosis is involved in the production of gametes in plants and most fungi (see Figure 13.6).

Concept Check 13.3

1. In mitosis, a single replication of the chromosomes is followed by one division of the cell, so the number of chromosome sets in daughter cells is the same as in the parent cell. In meiosis, a single replication of the chromosomes is followed by two cell divisions that reduce the number of chromosome sets from two (diploid) to one (haploid).
2. The chromosomes are similar in that each is composed of two sister chromatids, and the individual chromosomes are positioned similarly on the metaphase plate. The chromosomes differ in that in a mitotically dividing cell, sister chromatids of each chromosome are genetically identical, but in a meiotically dividing cell, sister chromatids are genetically distinct because of crossing over in meiosis I. Moreover, the chromosomes in metaphase of mitosis can be composed of a diploid set or a haploid set, but the chromosomes in metaphase of meiosis II always consist of a haploid set.

Concept Check 13.4

1. Even in the absence of crossing over, independent assortment of chromosomes during meiosis I theoretically can generate 2ⁿ possible haploid gametes, and random fertilization can produce 2ⁿ x 2ⁿ possible diploid zygotes. Since the haploid number (n) of honeybees is 16 and that of fruit flies is 4, two honeybees would be expected to produce a greater variety of zygotes than would two fruit flies.
2. If the segments of the maternal and paternal chromatids that undergo crossing over are genetically identical, then the recombinant chromosomes will be genetically equivalent to the parental chromosomes. Crossing over contributes to genetic variation only when it involves rearrangement of different versions of genes.

CHAPTER 14

Concept Check 14.1

1. First, all the F₁ plants had flowers with the same color (purple) as the flowers of one of the parental varieties, rather than an intermediate color as predicted by the "blending" hypothesis. Second, the reappearance of white flowers in the F₂ generation indicates that the allele controlling the white-flower trait was not lost in the F₁ generation; rather its phenotypic effect was masked by the effect of the dominant purple-flower allele.
2. According to the law of independent assortment, 25 plants (Vie of the offspring) are predicted to be *aa tt*, or recessive for both characters. The actual result is likely to differ slightly from this value.

Concept Check 14.2

- V2 dominant homozygous CCC, 0 recessive homozygous (cc), and V2 heterozygous (Cc)
- 'A BBDD; 'A BbDD; 'A BBDd; 'A BbDd
- 0; since only one of the parents has a recessive allele for each character, there is no chance of producing homozygous recessive offspring that would display the recessive traits.

Concept Check 14.3

- The black and white alleles are incompletely dominant, with heterozygotes being gray in color. A cross between a gray rooster and a black hen should yield approximately equal numbers of gray and black offspring.
- Height is at least partially hereditary and appears to exhibit polygenic inheritance with a wide norm of reaction, indicating that environmental factors have a strong influence on phenotype.

Concept Check 14.4

- 0% (Since cystic fibrosis is caused by a recessive allele, Beth and Tom's siblings who have CF must be homozygous recessive. Therefore, each parent must be a carrier of the recessive allele. Since neither Beth nor Tom has CF, this means they each have a $\frac{2}{3}$ chance of being a carrier. If they are both carriers, there is a $\frac{1}{4}$ chance that they will have a child with CF. $\frac{2}{3} \times \frac{2}{3} = \frac{4}{9}$. A = Ye; 0 (Both Beth and Tom would have to be carriers to produce a child with the disease.)
- Joan's genotype is Dd. Because the allele for polydactyly (D) is dominant to the allele for five digits per appendage (d), the trait is expressed in people with either the DD or Dd genotype. If Joan's mother were homozygous dominant (DD), then all of her children would have polydactyly. But since some of Joan's siblings do not have this condition, her mother must be heterozygous (Dd). All the children born to her mother (Dd) and father (dd) have either the dd genotype (normal phenotype) or the Dd genotype (polydactyly phenotype).

Genetics Problems

- Parental cross is AARR X aarr. Genotype of F1 is AaRr, phenotype is all axial-pink. Genotypes of F2 are 4 AaRr : 2 AaRR : 2 AARr : 2 aaRr : 2 Aarr : 1 AAPk : 1 aapR : 1 AArr : 1 aarr. Phenotypes of F2 are 6 axial-pink : 3 axial-red : 3 axial-white : 2 terminal-pink : 1 terminal-white : 1 terminal-red.
- V54 b. VM C. Va d. Y32
- Albino (b) is a recessive trait; black (B) is dominant. First cross: parents BB X bb; gametes B and b; offspring all Bb (black coat). Second cross: parents Bb X bb; gametes V2 B and V2 b (heterozygous parent) and b; offspring V2 Bb and h bb.
- a. PPLI X PPLI, PPLI X PpLI, or PPLI X ppLI b. ppLI X ppLI c. PPLI X any of the 9 possi-

ble genotypes or PPI1 X ppLL d. PpLI X Ppli. e. PpLI X PpLI.

- Man A; woman I^B; child H. Other genotypes for children are 'A I^V, 'A Iⁱ, 'A I^b.
- a. $\frac{3}{4}A \times \frac{3}{4}A \times \frac{3}{4}A = \frac{27}{64}/M$
b. $1 - \frac{27}{64} = \frac{37}{64}/M$
c. 'A X 'A X 'A = Vo4
d. $1 - \frac{1}{64} = \frac{63}{64}/V$
- a. Y256 b. Yie c. Y256 d. Ye4 e. Y128
- a. I b. Y32 c. Ys d. Y2
9. V)

- Matings of the original mutant cat with true-breeding noncurl cats will produce both curl and noncurl F1 offspring if the curl allele is dominant, but only noncurl offspring if the curl allele is recessive. You would obtain some true-breeding offspring homozygous for the curl allele from matings between the F₁ cats resulting from the original curl X noncurl crosses whether the curl trait is dominant or recessive. You know that cats are true-breeding when curl X curl matings produce only curl offspring. As it turns out, the allele that causes curled ears is dominant.

- Yis
- 25% will be cross-eyed; all of the cross-eyed offspring will also be white.
- The dominant allele I is epistatic to the P/p locus, and thus the genotypic ratio for the F₁ generation will be 9 $I\text{pp}_-$ (colorless) : 3 $l\text{pp}$ (colorless) : 3 UP_- (purple) : 1 $l\text{pp}$ (red). Overall, the phenotypic ratio is 12 colorless : 3 purple : 1 red.
- Recessive. All affected individuals (Arlene, Tom, Wilma, and Carla) are homozygous recessive aa. George is Aa, since some of his children with Arlene are affected. Sam, Ann, Daniel, and Alan are each Aa, since they are all unaffected children with one affected parent. Michael also is Aa, since he has an affected child (Carla) with his heterozygous wife Ann. Sandra, Tina, and Christopher can each have the AA or Aa genotype.

- Y2
- Yie
- 9 B_A- (agouti) : 3 B_aa (black) : 3 $bbA-$ (white) : 1 $bbaa$ (white). Overall, 9 agouti : 3 black : 4 white.

CHAPTER 15

Concept Check 15.1

- The law of segregation relates to the inheritance of alleles for a single character; the physical basis is the separation of homologues in anaphase I. The law of independent assortment of alleles relates to the inheritance of alleles for two characters; the physical basis is the alternative arrangements of homologous chromosome pairs in metaphase I.
- About $\frac{3}{4}$ of the F₂ offspring would have red eyes, and about Y4 would have white eyes. About half of the white-eyed flies would be female and half would be male; about half of

the red-eyed flies would be female and half would be male.

Concept Check 15.2

- Crossing over during meiosis I in the heterozygous parent produces some gametes with recombinant genotypes for the two genes. Offspring with a recombinant phenotype arise from fertilization of the recombinant gametes by homozygous recessive gametes from the double-mutant parent.

- In each case, the alleles contributed by the female parent determine the phenotype of the offspring because the male only contributes recessive alleles in this cross.
- No, the order could be A-C-B or C-A-B. To determine which possibility is correct, you need to know the recombination frequency between B and C.

Concept Check 15.3

- Because the gene for this eye-color character is located on the X chromosome, all female offspring will be red-eyed and heterozygous $QC\ X^A$; all male offspring will be white-eyed X^WY .

- V4; Y2 chance that the child will inherit a Y chromosome from the father and be male X Y2 chance that he will inherit the X carrying the disease allele from his mother.

Concept Check 15.4

- At some point during development, one of the embryo's cells may have failed to carry out mitosis after duplicating its chromosomes. Subsequent normal cell cycles would produce genetic copies of this tetraploid cell.
- In meiosis, a combined 14-21 chromosome will behave as one chromosome. If a gamete receives the combined 14-21 chromosome and a normal copy of chromosome 21, trisomy 21 will result when this gamete combines with a normal gamete during fertilization.
- An aneuploid male cat with more than one X chromosome could have a tortoiseshell phenotype if its X chromosomes have different alleles of the fur-color gene.

Concept Check 15.5

- Inactivation of an X chromosome in females and genomic imprinting. Because of X inactivation, the effective dose of genes on the X chromosome is the same in males and females. As a result of genomic imprinting, only one allele of certain genes is phenotypically expressed.
- The genes for leaf coloration are located in plastids within the cytoplasm. Normally, only the maternal parent transmits plastid genes to offspring. Since variegated offspring are produced only when the female parent is of the B variety, we can conclude that variety B contains both the wild-type and mutant alleles of pigment genes, producing variegated leaves.
- Each cell contains numerous mitochondria, and in affected individuals, most cells contain a variable mixture of normal and abnormal mtDNA.

Genetics Problems

1. 0; Vi, Vi₆
2. Recessive; if the disorder were dominant, it would affect at least one parent of a child born with the disorder. The disorder's inheritance is sex-linked because it is seen only in boys. For a girl to have the disorder, she would have to inherit recessive alleles from both parents. This would be very rare, since males with the recessive allele on their X chromosome die in their early teens.
3. 1/4 for each daughter (V₂ chance that child will be female X V₂ chance of a homozygous recessive genotype); 1/4 for first son
4. 17%
5. 6%. Wild type (heterozygous for normal wings and red eyes) X recessive homozygote with vestigial wings and purple eyes
6. The disorder would always be inherited from the mother.
7. The inactivation of two X chromosomes in XXX women would leave them with one genetically active X, as in women with the normal number of chromosomes. Microscopy should reveal two Barr bodies in XXX women.
8. D-A-B-C
9. Fifty percent of the offspring would show phenotypes that resulted from crossovers. These results would be the same as those from a cross where A and B were not linked. Further crosses involving other genes on the same chromosome would reveal the linkage and map distances.
10. Between I and A. 12%; between A and 5, 5%
11. Between T and S, 18%; sequence of genes is TA-5
12. No. The child can be either I^hi or J^hIL. An ovum with the genotype ii could result from nondisjunction in the mother, while a sperm of genotype I^hi could result from nondisjunction in the father.
13. 450 each of blue-oval and white-round (parentals) and 50 each of blue-round and white-oval (recombinants)
14. About one-third of the distance from the vestigial-wing locus to the brown-eye locus

CHAPTER 16

Concept Check 16.1

1. DNA from the dead pathogenic S cells was somehow taken up by the living, nonpathogenic R cells. The DNA from the S cells enabled the R cells to make a capsule, which protected them from the mouse's defenses. In this way, the R cells were transformed into pathogenic S cells.
2. When the proteins were radioactively labeled (batch 1), the radioactivity would have been found in the pellet of bacterial cells.
3. Chargaff's rules state that in DNA, the percentages of A and T and of C and G are essentially the same, and the fly data are consistent with those rules. (Slight variations are most likely due to limitations of analytical technique.)

4. Each A hydrogen-bonds to a T, so in a DNA double helix, their numbers are equal; the same is true for G and C.

Concept Check 16.2

1. Complementary base pairing ensures that the two daughter molecules are exact copies of the parent molecule. When the two strands of the parent molecule separate, each serves as a template on which nucleotides are arranged, by the base-pairing rules, into new complementary strands.
2. DNA pol III covalently adds nucleotides to new DNA strands and proofreads each added nucleotide for correct base pairing.
3. The leading strand is initiated by an RNA primer, which must be removed and replaced with DNA, a task performed by DNA pol I. To Figure 16.16 just to the left of the origin of replication, DNA pol I would replace the primer of the leading strand with DNA nucleotides.
4. The ends of eukaryotic chromosomes become shorter with each round of DNA replication, and telomeres at the ends of DNA molecules ensure that genes are not lost after numerous rounds of replication.

CHAPTER 17

Concept Check 17.1

1. The non-template strand would read 5'-TGGTTTGCTCA-3'. The 5' → 3' direction is the same as that for the mRNA; the base sequence is the same except for the presence of U in the mRNA where there is T in the non-template strand of DNA.
2. A polypeptide made up of 10 Gly (glycine) amino acids

Concept Check 17.2

1. Both assemble nucleic acid chains from monomer nucleotides using complementary base pairing to a template strand. Both synthesize in the 5' → 3' direction, antiparallel to the template. DNA polymerase requires a primer, but RNA polymerase can start a nucleotide chain from scratch. DNA polymerase uses nucleotides with the sugar deoxyribose and the base T, whereas RNA polymerase uses nucleotides with the sugar ribose and the base U.
2. Upstream end
3. In a prokaryote, RNA polymerase recognizes the gene's promoter and binds to it. In a eukaryote, transcription factors mediate the binding of RNA polymerase to the promoter.
4. A prokaryotic primary transcript is immediately usable as mRNA, but a eukaryotic primary transcript must be modified before it can be used as mRNA.

Concept Check 17.3

1. The 5' cap and poly-A tail facilitate mRNA export from the nucleus, prevent the mRNA from being degraded by hydrolytic enzymes, and facilitate ribosome attachment.

2. snRNPs join with other proteins and form spliceosomes that cut introns out of a pre-mRNA molecule and join its exons together.
3. Alternative RNA splicing produces different mRNA molecules from a pre-mRNA molecule depending on which exons are included in the mRNA and which are not. By yielding more than one version of mRNA, a single gene can code for more than one polypeptide.

Concept Check 17.4

1. First, each aminoacyl-tRNA synthetase specifically recognizes a single amino acid and will only attach it to an appropriate tRNA. Second, a tRNA charged with its specific amino acid has an anticodon that will only bind to an mRNA codon for that amino acid.
2. Polyribosomes enable the cell to produce multiple copies of a polypeptide in a short amount of time.
3. A signal peptide on the leading end of the polypeptide being synthesized is recognized by a signal-recognition particle that brings the ribosome to the ER membrane. There the ribosome attaches and continues to synthesize the polypeptide, depositing it in the ER lumen.

Concept Check 17.5

1. RNA can form hydrogen bonds with either DNA or RNA, take on a specific three-dimensional shape, and catalyze chemical reactions. These abilities enable RNA to interact functionally with all the major types of molecules in a cell.

Concept Check 17.6

1. The RNA polymerase farthest to the right is first, since it has traveled the farthest along the DNA (and its mRNA is longest). The first ribosome is at the top of each mRNA, because it has traveled the farthest along the mRNA starting from the 5' end; the second is immediately below it, and so on.
2. No, the processes of transcription and translation are separated in space and time in a eukaryotic cell, a result of the eukaryotic cell's compartmental organization.

Concept Check 17.7

1. In the mRNA, the reading frame downstream from the deletion is shifted, leading to a long string of incorrect amino acids in the polypeptide and, in most cases, premature termination. The polypeptide will most likely be nonfunctional.
2. The amino acid sequence of the wild-type protein is Met-Asn-Arg-Leu. The amino acid sequence of the mutant protein sequence would be the same, because the mRNA codons 5'-CUA-3' and 5'-UUA-3' both code for Leu.

CHAPTER 18**Concept Check 18.1**

- Lytic phages can only carry out lysis of the host cell, whereas lysogenic phage may either lyse the host cell or integrate into the host chromosome. In the latter case, the viral DNA (prophage) is simply replicated along with the host chromosome. Under certain conditions, a prophage may exit the host chromosome and initiate a lytic cycle.
- The genetic material of these viruses is RNA, which is replicated inside the infected cell by special enzymes encoded by the virus. The viral genome (or a complementary copy of it) serves as mRNA for the synthesis of viral proteins.
- Because it synthesizes DNA from its RNA genome, this is the reverse ("retro") of the usual DNA → RNA information flow.

Concept Check 18.2

- Mutations can lead to a new strain of a virus that can no longer be recognized by the immune system, even if an animal has been exposed to the original strain; a virus can jump from one species to a new host; and a rare virus can spread if a population becomes less isolated.
- In horizontal transmission, a plant is infected from an external source of virus, which could enter through a break in the plant's epidermis due to damage by insects or other animals. In vertical transmission, a plant inherits viruses from its parent either via infected seeds (sexual reproduction) or via an infected cutting (asexual reproduction).
- A source of infection, such as prion-infected cattle, may show no symptoms for many years. Beef prepared from such animals before symptoms appear would not be recognized as hazardous and could transmit infection to people who eat the meat.

Concept Check 18.3

- In transformation, naked, foreign DNA from the environment is taken up by a bacterial cell. In transduction, phage DNA carries bacterial genes from one bacterial cell to another. In conjugation, a bacterial cell directly transfers plasmid or chromosomal DNA to another cell via a mating bridge that temporarily connects the two cells.
- Both are episomes—that is, they can exist as part of the bacterial chromosome or independently. However, phage DNA can leave the cell in a protein coat (as a complete phage), whereas a plasmid cannot. Also, plasmids are generally beneficial to the cell, while phage DNA can direct the production of complete phages that may harm or kill the cell.
- In an F⁺ X F⁻ mating, only plasmid genes are transferred, but in an Hfr X F⁻ mating, bacterial genes may be transferred, because the F factor is integrated into the donor cell's chromosome. In the latter case, the transferred genes may then recombine with the recipient F⁻ cell's chromosome.

Appendix A**Concept Check 18.4**

- The cell would continuously produce β-galactosidase and the two other enzymes for lactose utilization, even in the absence of lactose, thus wasting cell resources.
- Binding by the *trp* corepressor (tryptophan) activates the *trp* repressor, shutting off transcription of the *trp* operon; binding by the *lac* inducer (allolactose) inactivates the *lac* repressor, leading to transcription of the *lac* operon.

CHAPTER 19**Concept Check 19.1**

- A nucleosome is made up of eight histone proteins, two each of four different types, around which DNA is wound. Linker DNA runs from one nucleosome to the next one.
- Histones contain many basic (positively charged) amino acids, such as lysine and arginine, which can form weak bonds with the negatively charged phosphate groups on the sugar-phosphate backbone of the DNA molecule.
- RNA polymerase and other proteins required for transcription do not have access to the DNA in tightly packed regions of a chromosome.

Concept Check 19.2

- Histone acetylation is generally associated with gene expression, while DNA methylation is generally associated w/Li lack of expression.
- General transcription factors function in assembling the transcription initiation complex at the promoters for all genes. Specific transcription factors bind to control elements associated with a particular gene and once bound either increase (activators!) or decrease (repressors) transcription of that gene.
- The three genes should have some similar or identical sequences in the control elements of their enhancers. Because of this similarity, the same specific transcription factors could bind to the enhancers of all three genes and stimulate their expression coordinately.
- Degradation of the mRNA, regulation of translation, activation of the protein (by chemical modification, for example), and protein degradation

Concept Check 19.3

- The protein product of a proto-oncogene is usually involved in a pathway that stimulates cell division. The protein product of a tumor-suppressor gene is usually involved in a pathway that inhibits cell division.
- A cancer-causing mutation in a proto-oncogene usually makes the gene product overactive, whereas a cancer-causing mutation in a tumor-suppressor gene usually makes the gene product nonfunctional.
- When an individual has inherited an oncogene or a mutant allele of a tumor-suppressor gene.

Concept Check 19.4

- The number of genes is 5–15 times higher in mammals, and the amount of noncoding DNA is about 10,000 times greater. The presence of tons in mammalian genes makes them about 27 times longer, on average, than prokaryotic genes.
- Introns are interspersed within the coding sequences of genes. Many copies of each transposable element are scattered throughout the genome. Simple sequence DNA is concentrated at the centromeres and telomeres.
- In the rRNA gene family, identical transcription units encoding three different RNA products are present in long, tandemly repeated arrays. The large number of copies of the rRNA genes enable organisms to produce the rRNA for enough ribosomes to carry out active protein synthesis. Each globin gene family consists of a relatively small number of nonidentical genes clustered near each other. The differences in the globin proteins encoded by these genes result in production of hemoglobin molecules adapted to particular developmental stages of the organism.

Concept Check 19.5

- If cytokinesis is lanky, two copies of the entire genome can end up in a single cell. Errors in crossing over during meiosis can lead to one segment being duplicated while another is deleted. During DNA replication, slippage backward along the template strand can result in a duplication.
- Gene duplication and divergence by mutation. Movement of genes to different chromosomes also occurred.
- For either gene, a mistake in crossing over during meiosis could have occurred between the two copies of that gene, such that one ended up with a duplicated exon. This could have happened several times, resulting in the multiple copies of a particular exon in each gene.
- Homologous transposable elements scattered throughout the genome provide sites where recombination can occur between different chromosomes. Movement of these elements into coding or regulatory sequences may change expression of genes. Transposable elements also can carry genes with them, leading to dispersion of genes and in some cases different patterns of expression. Or transport of an exon during transposition and its insertion into a gene may add a new functional domain to the originally encoded protein, a type of exon shuffling.

CHAPTER 20**Concept Check 20.1**

- White (no functional *kuZ* gene is present).
- A cDNA library, made using mRNA from developing red blood cells, which would be expected to contain many copies of β-globin mRNAs.
- Some human genes are too large to be incorporated into bacterial plasmids. Bacterial cells

lack [he means to process RNA transcripts, and even if the need for RNA processing is avoided by using cDNA, bacteria lack enzymes to catalyze the post-translational processing that many human proteins undergo.

Concept Check 20.2

1. Any restriction enzyme will cut genome's DNA in many places, generating such a large number of fragments that they would appear as a smear rather than distinct bands when the gel is stained after electrophoresis.
2. RFLPs are inherited in a Mendelian fashion, and variations in RFLPs among individuals can be detected by Southern blotting.

Concept Check 20.3

1. In a genetic linkage map, genes and other markers are ordered with respect to each other, but only the relative distances between them are known. In a physical map, the actual distances between markers, expressed in base pairs, are known.
2. The three-stage approach employed in the Human Genome Project involves genetic mapping, physical mapping, and then sequencing of short, overlapping fragments that previously have been ordered relative to each other (see Figure 20.11). The shotgun approach eliminates the genetic mapping and physical mapping stages; instead, short fragments generated by multiple restriction enzymes, are sequenced and then subsequently ordered by computer programs that identify overlapping regions (see Figure 20.13).

Concept Check 20.4

1. Alternative splicing of RNA transcripts from a gene and post-translational processing of polypeptides
2. It allows expression of thousands of genes to be examined simultaneously, thus providing a genome-wide view of which genes are expressed in different tissues, under particular conditions, or at different stages of development.
3. Because the human species arose more recently than many other species, there has been less time for genetic variations in coding and noncoding DNA to accumulate.

Concept Check 20.5

1. Stem cells continue to reproduce themselves.
2. Herbicide resistance, pest resistance, disease resistance, delayed ripening, and improved nutritional value

CHAPTER 21

Concept Check 21.1

1. Cells undergo differentiation during embryonic development, becoming different from each other; in the adult organism, there are many highly specialized cell types.
2. During animal development, movement of cells and tissues is a major mechanism, which is not the case in plants. In plants, growth and morphogenesis continue throughout the

life of the plant. This is true of only a few types of animal cells.

Concept Check 21.2

1. Information deposited by the mother in the egg (cytoplasmic determinants) is required for embryonic development.
- 2- No, primarily because of subtle (and perhaps not so subtle) differences in their environments
3. By binding to a receptor on the receiving cells >urface and triggering a signal transduction pathway that affects gene expression

Concept Check 21.3

1. Because their products, made by the mother, determine the head and tail ends, as well as the back and belly, of the egg (and eventually the adult fly)
2. The prospective vulval cells require an inductive signal from the anchor cell before they can differentiate into vulval cells.
3. A shoot is a differentiated structure, yet some of the cells that make it up are able to dedifferentiate and redifferentiate, forming all of the organs of an entire new plant.

Concept Check 21A

1. Homeotic genes differ in their homeobox sequences, which determine their interactions with other transcription factors and hence which genes are regulated by the homeotic genes. These differ in the two organisms, as do the expression patterns of the homeobox genes.

CHAPTER 22

Concept Check 22.1

1. Aristotle, Linnaeus, and Cuvier viewed species as fixed (though Cuvier noted that species present in a particular location could change over time). Lamarck, Erasmus Darwin, and Charles Darwin thought species could change.
2. Lamarck observed evidence of changes in species over time and noted that evolution could result in organisms' adaptations to their environments, though his theory was based on an incorrect mechanism for evolution: that modifications an organism acquires during its lifetime can be passed to its offspring.

Concept Check 22.2

1. Species have the potential to produce more offspring than survive (overproduction), leading to a struggle for resources, which are limited. Populations exhibit a range of heritable variations, some of which confer advantages to their bearers that make them more likely to leave more offspring than less well-suited individuals. Over time this natural selection can result in a greater proportion of favorable traits in a population (evolutionary adaptation).
2. Though an individual may become modified during its lifetime through interactions with its environment, this does not represent evolution. Evolution can only be measured as a change in proportions of heritable variations from generation to generation.

Concept Check 22.3

1. An environmental factor such as a drug does not create new traits such as drug resistance, but rather selects for traits among those that are already present in the population.
2. Despite their different functions, the forelimbs of different mammals are structurally similar because they all represent modifications of a structure found in the common ancestor. The similarities between the sugar glider and flying squirrel indicate that similar environments selected for similar adaptations despite different ancestry
3. If molecular biology or biogeography indicates a particular branching pattern of descent from a single group of ancestral organisms, representatives of the ancestral group should appear earlier in the fossil record than representatives of the later organisms. Likewise, the many transitional forms that link ancient organisms to present-day species are evidence of descent with modification.

CHAPTER 23

Concept Check 23.1

1. Mendel showed that inheritance is punctate, and subsequently it was shown that this type of inheritance can preserve the variation on which natural selection acts.
2. 750. Half the loci (250) are fixed, meaning only one allele exists for each locus: $250 \times 1 = 250$. There are two alleles each for the other loci: $250 \times 2 = 500$, $250 + 500 = 750$.
3. $2pq + q^2$ ($2pq$ represents heterozygotes with one PKU allele and q^2 represents homozygotes with two PKU alleles)

Concept Check 23.2

1. Most mutations occur in somatic cells that do not produce gametes and so are lost when the organism dies. Other mutations that do occur in cell lines that produce gametes, many do not have a phenotypic effect on which natural selection can act. Others have a harmful effect and are thus unlikely to spread in a population from generation to generation because they decrease the reproductive success of their bearers.
2. A population contains a vast number of possible mating combinations, and fertilization brings together the gametes of individuals with different genetic backgrounds. Sexual reproduction reshuffles alleles into fresh combinations every generation.

Concept Check 23.3

1. Natural selection is more "predictable" in that it tends to increase or decrease the frequency of alleles that correspond to variations that increase or decrease an organism's fitness in its environment. Alleles subject to genetic drift all have the same likelihood of increasing or decreasing.

2. Genetic drift results from chance fluctuations of allele frequencies from generation LO generation; ii tends to decrease variation over time. Gene flow is the exchange of alleles between populations; it tends to increase variation within a population but decrease allele frequency differences between populations.

Concept Check 23.4

- No: many nucleotides are in noncoding portions of DNA or in pseudogenes that have been inactivated by mutations. A change in a nucleotide may not even change the amino acid encoded because of the redundancy of the genetic code.
- Zero, because fitness includes reproductive contribution to the next generation, and a sterile mule cannot produce offspring.
- In sexual selection, organisms may compete for mates through behaviors or displays of secondary sexual characteristics; only the competing sex is selected for these characteristics.
- Only half of the members (the females) of a sexual population actually produce offspring, while all the members of an asexual population can produce offspring.

CHAPTER 24

Concept Check 24.1

- Since the birds are known to breed successfully in captivity the reproductive barrier in nature must be prezygotic. Given the species differences in habitat preference, the reproductive barrier is most likely to be habitat isolation.
- a. All species concepts except the biological species concept can be applied to both asexual and sexual species because they define species on the basis of characteristics other than ability to reproduce, b. The biological species concept can only be applied to extant sexual species, c. The easiest species concept to apply on a field trip would be the morphological species concept because it is based only on the appearance of the organism. Additional information about its ecological habits, evolutionary history, and reproduction are not required.

Concept Check 24.2

- Continued gene flow between mainland populations and those on a nearby island reduces the chance that enough genetic divergence will take place for allopatric speciation to occur.
- The diploid and tetraploid watermelons are separate species. Their hybrids are triploid and as a result are sterile because of problems carrying out meiosis.
- According to the model of punctuated equilibrium, in most cases the time during which speciation (that is, the distinguishing evolutionary changes) occurs is relatively short compared with the overall duration of the species' existence. Thus, on the vast geologic time scale of the fossil record, the transition of one species to another seems abrupt, and instances of gradual change in the fossil

record are rare. Furthermore, some of the changes that transitional species underwent may not be apparent in fossils.

Concept Check 24.3

- Such complex structures do not evolve all at once, but in increments, with natural selection selecting for adaptive variants of the earlier versions.
- Although an exaptation is co-opted for new or additional functions in a new environment, it existed in the first place because it worked as an adaptation to the original environment.
- The timing of different developmental pathways in organisms can change in different ways (heterochrony). This can result in differential growth patterns, such as those producing different patterns of webbing in salamander feet.

CHAPTER 25

Concept Check 25.1

- (a) Analogy, since porcupines and cacti are not closely related and also most other animals and plants do not have similar structures; (b) homology, since cats and humans are both mammals and have homologous forelimbs, of which the hand and paw are the lower part; (c) analogy, since owls and hornets are not closely related, and also the structure of their wings is very different.
- The latter is more likely, since just small genetic changes can produce divergent physical appearances, but if genes have diverged greatly, that implies the lineages have been separate for some time.

Concept Check 25.2

- We are classified the same down to the class level; both the leopard and human are mammals. Leopards belong to order Carnivora, whereas humans do not.
- The branching pattern of the tree indicates that the skunk and the wolf share a common ancestor that is more recent than the ancestor these two animals share with the leopard.

Concept Check 25.3

- No; hair is a shared primitive character common to all mammals and thus cannot be helpful in distinguishing different mammalian subgroups.
- The principle of maximum parsimony states that the theory about nature we investigate first should be the simplest explanation found to be consistent with the facts. But nature does not always take the simplest course; thus, the most parsimonious tree (reflecting the fewest evolutionary changes) may not reflect reality.

Concept Check 25.4

- Proteins are gene products. Their amino acid sequences are determined by the nucleotide sequences of the DNA that codes for them. Thus, differences between comparable proteins in two species reflect underlying genetic differences.

- Orthologous genes are homologous genes that have ended up in different gene pools, whereas paralogous genes are found in multiple copies in a single genome because they are the result of gene duplication.

Concept Check 25.5

- The molecular clock is a method of estimating the actual time of evolutionary events based on numbers of base changes in orthologous genes. It is based on the assumption that the regions of genomes being compared evolve at constant rates.
- There are many portions of the genome that do not code for genes, in which, many base changes could accumulate through drift without affecting an organism's fitness. Even in coding regions of the genome, some mutations may not have a critical effect on genes or proteins.

CHAPTER 26

Concept Check 26.1

- The hypothesis that conditions on the early Earth could have permitted the synthesis of organic molecules from inorganic ingredients.
- In contrast to random mingling of molecules in an open solution, segregation of molecular systems by membranes could concentrate organic molecules, and electrical charge gradients across the membrane could assist biochemical reactions.
- An RNA molecule that functions as a catalyst

Concept Check 26.2

- 22,920 years (four half-life reductions)
- About 2,000 million years, or 2 billion years

Concept Check 26.3

- Prokaryotes must have existed at least 3.5 billion years ago, when the oldest fossilized stromatolites were formed.
- Free oxygen attacks chemical bonds and can inhibit enzymes and damage cells. Some organisms were able to adapt, however.

Concept Check 26.4

- All eukaryotes have mitochondria or genetic remnants of these organelles, but not all eukaryotes have plastids.
- The chimera of Greek mythology contained parts from different animals. Similarly, a eukaryotic cell contains parts from various prokaryotes: mitochondria from one type of bacterium, plastids from another type, and a nuclear genome from parts of the genomes of these endosymbionts and at least one other prokaryote.

Concept Check 26.5

- A single-celled organism must carry out all of the functions required to stay alive. Most multicellular organisms have many types of specialized cells, and life functions are divided among specific cell types.
- Fossils of most major animal phyla appear suddenly in the first 20 million years of the

Appendix A

Cambrian period. Molecular clocks suggest that many animal phyla originated much earlier.

Concept Check 26.6

1. Protista, Plantae, Fungi, and Animalia
2. Monera included both bacteria and archaea, but archaea are more closely related to eukaryotes than to bacteria.

CHAPTER 27

Concept Check 27.1

1. Adaptations include the capsule (shields prokaryotes from host's immune system), plasmids (confer "contingency" functions such as antibiotic resistance), and the formation of endospores (enable cells to survive harsh conditions and to revive when the environment becomes favorable).
2. Prokaryotic cells generally lack the internal compartmentalization of eukaryotic cells. Prokaryotic genomes have much less DNA than eukaryotic genomes, and most of this DNA is contained in a single ring-shaped chromosome located in a nucleoid region rather than within a true membrane-bound nucleus. In addition, many prokaryotes also have plasmids, small ring-shaped DNA molecules containing a few genes.
3. Rapid reproduction enables a favorable mutation to spread quickly through a prokaryotic population by natural selection.

Concept Check 27.2

1. Chemoautotrophy; the bacterium must rely on chemical sources of energy, since it is not exposed to light, and it must be a heterotroph if it requires an organic source of carbon rather than CO_2 .
2. *Anabaena* is a photoautotroph that obtains its carbon from CO_2 . As a nitrogen-fixing prokaryote, *Anabaena* obtains its nitrogen from N_2 .

Concept Check 27.3

1. Before molecular systematics, taxonomists classified prokaryotes according to phenotypic characters that did not clarify evolutionary relationships. Molecular comparisons indicate key divergences in prokaryotic lineages.
2. Both diseases are caused by spirochetes.
3. The ability of various archaea to use hydrogen, sulfur, and other chemicals as energy sources and to survive or even thrive without oxygen enables them to live in environments where more commonly needed resources are not present.

Concept Check 27.4

1. Although prokaryotes are small, mostly unicellular organisms, they play key roles in ecosystems by decomposing wastes, recycling chemicals, and providing nutrients to other organisms.

2. *Bacteroides* [het.aiotcicwikkor], which lives inside the human intestine, benefits by obtaining nutrients. From the digestive system and by receiving protection from competing bacteria from host-produced antimicrobial compounds to which it is not sensitive. The human host benefits because the bacterium manufactures carbohydrates, vitamins, and other nutrients.

3. During conjugation, two ciliates exchange micronuclei, but no new individuals are produced.

Concept Check 28.5

1. A pair of flagella, one hairy and one smooth
2. Oomycetes acquire nutrition mainly as decomposers or parasites; golden algae are photosynthetic, but some also absorb dissolved organic compounds or ingest food particles and bacteria by phagocytosis.
3. The holdfast anchors the alga to the rocks, while the wide, flat blades provide photosynthetic surfaces. The cellulose and algin in the alga's cell walls cushion the thallus from waves and protect it from drying out.

Concept Check 28.6

1. Because foram tests are hardened with calcium carbonate, they form long-lasting fossils in marine sediments and sedimentary rocks.
2. Forams feed by extending their pseudopodia through pores in their tests. Radiolarians ingest smaller microorganisms by phagocytosis using their pseudopodia; cytoplasmic streaming carries the engulfed prey to the main part of the cell.

Concept Check 28.7

1. Amoebozoans have lobe-shaped pseudopodia, whereas forams have threadlike pseudopodia.
2. Slime molds are fungus-like in that they produce fruiting bodies that aid in the dispersal of spores, and they are animal-like in that they are motile and ingest food. However, slime molds are more closely related to gymnamoebas and entamoebas than to fungi or animals.
3. In the life cycle of a cellular slime mold, individual amoebas may congregate in response to a chemical signal, forming a sluglike aggregate form that can move. Then some of the cells form a stalk that supports an asexual fruiting body.

Concept Check 28.8

1. Many algae contain an accessory pigment called phycoerythrin, which gives them a reddish color and allows them to carry out photosynthesis in relatively deep coastal water. Also unlike brown algae, red algae have no flagellated stages in their life cycle and must depend on water currents to bring gametes together for fertilization.
2. *Ulva*'s thallus contains many cells and is differentiated into leaflike blades and a rootlike holdfast. *Caulerpa*'s thallus is composed of multinucleate filaments without cross-walls, so it is essentially one large cell.

CHAPTER 29

Concept Check 29.1

1. Land plants share some key traits only with charophyceans: rosette cellulose-producing complexes, presence of peroxisome enzymes, similarity in sperm structure, and similarity

in cell division (the formation of a phragmoplast). Comparisons of nuclear and chloroplast genes also point to a common ancestry.

Concept Check 29.2

1. Spore walls toughened by sporopollenin; multicellular, dependent embryos; cuticle
2. a. diploid; b. haploid; c. haploid; d. diploid; e. haploid; f. haploid

Concept Check 29.3

1. Bryophytes are described as nonvascular plants because they do not have an extensive transport system. Another difference is that their life cycle is dominated by gametophytes rather than sporophytes.
2. Answers may include the following: large surface area of protonema enhances absorption of water and minerals; the vase-shaped archegonia protect eggs during fertilization and transport nutrients to the embryos via placental transfer cells; the stalklike seta conducts nutrients from the gametophyte to the capsule where sperm are produced; the peristome enables gradual spore discharge; stomata enable CO₂/O₂ exchange while minimizing water loss. Lightweight spores are wind-dispersed; mosses can lose water without drying and rehydrate when moisture is available.

Concept Check 29.4

1. Some characteristics that distinguish seedless vascular plants from bryophytes are a sporophyte-dominant life cycle, the presence of xylem and phloem, and the evolution of true roots and leaves. A key similarity is flagellated sperm requiring moisture for fertilization.
2. Most lycophytes have microphylls, whereas ferns and most fern relatives have megaphylls.

CHAPTER 30

Concept Check 30.1

1. To have any chance of reaching the eggs, the flagellated sperm of seedless vascular plants must rely on swimming through a film of water, usually limited to a range of less than a few centimeters. In contrast, the sperm of seed plants are produced within durable pollen grains that can be carried long distances by wind or by animal pollinators. Although flagellated in some species, the sperm of most seed plants do not require water because pollen tubes convey them directly to the eggs.

2. The reduced gametophytes of seed plants are nurtured by sporophytes and protected from stress, such as drought conditions and UV radiation. Pollen grains have tough protective coats and can be carried long distances, facilitating widespread sperm transfer without reliance on water. Seeds are more resilient than spores, enabling better resistance to environmental stresses and wider distribution.

Concept Check 30.2

1. Although gymnosperms are similar in not having their seeds enclosed in ovaries and fruits, their seed-bearing structures vary greatly. For instance, cycads have large cones, whereas some gymnosperms, such as *Ginkgo* and *Gnetum*, have small cones that look somewhat like berries, even though they are not fruits. Leaf shape also varies greatly, from the needles of many conifers to the palmlike leaves of cycads to *Gnetum* leaves that look like those of flowering plants.
2. The life cycle illustrates heterospory, as ovulate cones produce megasporangia and pollen cones produce microsporangia. The reduced gametophytes are evident in the form of the microscopic pollen grains and the microscopic female gametophyte within the megasporangium. The egg is shown developing within an ovule, and the pollen tube is shown conveying the sperm. The figure also shows the protective and nutritive features of a seed.

Concept Check 30.3

1. In the oaks life cycle, the tree (the sporophyte) produces flowers, which contain gametophytes in pollen grains and ovules; the eggs in ovules are fertilized; the mature ovaries develop into dry fruits called acorns; and the acorn seeds germinate, resulting in embryos giving rise to seedlings and finally to mature trees, which produce flowers and then acorns.
2. Pine cones and flowers both have sporophylls, modified leaves that produce spores. Pine trees have separate pollen cones (with pollen grains) and ovulate cones (with ovules inside cone scales). In flowers, pollen grains are produced by the anthers of stamens, and ovules are within the ovaries of carpels. Unlike pine cones, many flowers produce both pollen and ovules.
3. Traditionally, angiosperms have been classified as either monocots or dicots, based on certain traits, such as the number of cotyledons. However, recent molecular evidence reveals that while monocots are a clade, dicots are not. Based on phylogenetic relationships, most dicots form a clade, now known as eudicots.

Concept Check 30.4

1. Because extinction is irreversible, it decreases the total diversity of plants, many of which may have brought important benefits to humans.

CHAPTER 31

Concept Check 31.1

1. Both a fungus and a human are heterotrophs. A fungus digests its food externally by secreting enzymes into the food and then absorbing the small molecules that result from digestion. In contrast, humans (and other animals) ingest relatively large pieces of food and digest the food within their bodies.

2. The extensive network of hyphae puts a large surface area in contact with the food source, and rapid growth of the mycelium extends hyphae into new territory.

Concept Check 31.2

1. The majority of the fungal life cycle consists of haploid stages, whereas the majority of the human life cycle consists of diploid stages.
2. The two mushrooms might be reproductive structures of the same mycelium (the same organism). Or they might be parts of two separate organisms that have arisen from a single parent organism through asexual reproduction and thus carry the same genetic information.

Concept Check 31.3

1. The fungal lineage thought to be the most primitive, the chytrids, have posterior flagella, as do most other opisthokonts. This suggests that other fungal lineages lost their flagella after diverging from the chytrid lineage.
2. This indicates that fungi had already established symbiotic relationships with plants by the date those fossils formed.

Concept Check 31.4

1. Flagellated spores
2. Most plants form arbuscular mycorrhizae with glomeromycetes; without the fungi, the plants would be poorly nourished.
3. Possible answers include the following: In zygomycetes, the sturdy, thick-walled zygosporangium can withstand harsh conditions and then undergo karyogamy and meiosis when the environment is favorable for reproduction. In ascomycetes, the asexual spores (conidia) are produced in chains or clusters at the tips of conidiophores, where they are easily dispersed by wind. The often cup-shaped ascocarps house the sexual spore-forming asci. In basidiomycetes, the basidioспор supports and protects a large surface area of basidia, from which spores are dispersed.

Concept Check 31.5

1. A suitable environment for growth, retention of water and minerals, protection from sunlight, and protection from being eaten
2. A hardy spore stage enables dispersal to host organisms through a variety of mechanisms: their ability to grow rapidly in a favorable new environment enables them to capitalize on the host's resources.

CHAPTER 32

Concept Check 32.1

1. Plants are autotrophs; animals are heterotrophs. Plants have cell walls that provide structural support; animals lack strong cell walls (their bodies are held together by structural proteins, including collagen). Animals have unique cell types and tissues (muscle and nerve) and unique patterns of development, including the multicellular blastula stage.

2. These basic patterns of early development arose early in animal evolution and have been conserved across the diverse phyla within this clade today.

Concept Check 32.2

1. c, b, a, d

2. This diversification may have resulted from such external factors as changing ecological relationships (for instance, predator-prey interactions) and environmental conditions (for instance, increased oxygen levels) and from such internal factors as the evolution of the *Hox* complex.

Concept Check 32.3

1. Grade-level characteristics are those that multiple lineages share regardless of evolutionary history. Some grade-level characteristics may have evolved multiple times independently. Features that unite clades are those that were possessed by a common ancestor and were passed on to the various descendants.

2. Snail has spiral and determinate cleavage pattern; human has radial, indeterminate cleavage. Snail has schizocoelous development (characterized by a coelomic cavity formed by splitting of mesoderm masses); human has enterocoelous development (coelom forms from folds of archenteron). In a snail, the mouth forms from the blastopore; in a human, the anus develops from the blastopore.

Concept Check 32.4

1. Cnidarians possess true tissues, while sponges do not. Also unlike sponges, cnidarians exhibit body symmetry, though it is radial and not bilateral as in other animal phyla.
2. The morphology-based tree divides Braviaea into two clades: Deuterostomia and Protostomia. The molecule-based tree recognizes three clades: Deuterostomia, Ecdysozoa, and Lophotrochozoa, as well as the phylum Rotifera.
3. Each type of data contributes to scientists' ability to test hypotheses about relationships; the more lines of data that support a particular hypothesis, the more likely it is to be valid.

CHAPTER 33

Concept Check 33.1

1. The flagella of choanocytes draw water through their collars, which trap food particles. The particles are engulfed by phagocytosis and digested, either by choanocytes or by amoebocytes.
2. Sponges release their sperm into the surrounding water; changes in current direction will affect the odds that the sperm will be drawn into neighboring individuals.

Concept Check 33.2

1. Both the polyp and the medusa are composed of an outer epidermis and an inner gastrodermis separated by a gelatinous layer.

the mesoglea. The polyp is a cylindrical form that adheres to the substrate by its aboral end; the medusa is a flattened, mouth-down form that moves freely in the water.

2. Cnidarian stinging cells (cnidocytes) function in defense and prey capture. They contain capsule-like organelles (cnidae), which in turn contain inverted threads. The threads either inject poison or stick to and entangle small prey.

Concept Check 33.3

1. Tapeworms can absorb food from their environment and release ammonia into their environment through their body surface because their body is very flat.
2. No. Rotifers are microscopic but have an alimentary canal, whereas tapeworms can be very large but lack any digestive system.
3. Ectoprocts and corals are both sessile animals that collect suspended food with their tentacles and build reefs with their exoskeletons.

Concept Check 33.4

1. The function of the foot reflects the locomotion required in each class. Gastropods use their foot as a holdfast or to move slowly on the substrate. In cephalopods, the foot functions as a siphon and tentacles.
2. The shell has become divided in two halves connected by a hinge, and the mantle cavity has enlarged gills that function in feeding as well as gas exchange. The radula has been lost, as bivalves have become adapted to suspension feeding.

Concept Check 33.5

1. The inner tube is the alimentary canal, which runs the length of the body. The outer tube is the body wall. The two tubes are separated by the coelom.
2. Each segment is surrounded by longitudinal and circular muscles. These muscles work against the fluid-filled coelom, which acts as a hydrostatic skeleton. Coordinated contraction of the muscles produces movement.

Concept Check 33.6

1. Incomplete cooking doesn't kill nematodes and other parasites that might be present in the meat.
2. Nematodes lack body segments and a true coelom; annelids have both.

Concept Check 33.7

1. Arthropod mouthparts are modified appendages, which are bilaterally paired.
2. Two-thirds of all known animal species are arthropods, which are found in nearly all habitats of the biosphere.
3. The arthropod exoskeleton, which had already evolved in the ocean, allowed terrestrial species to retain water and support their bodies on land. Wings allowed them to disperse quickly to new habitats and to find food and mates.

Concept Check 33.8

1. Both echinoderms and cnidarians have radial symmetry. However, the ancestors of echinoderms had bilateral symmetry, and adult echinoderms develop from bilaterally symmetrical larvae. Therefore, the radial symmetry of echinoderms and cnidarians is analogous (resulting from convergent evolution), not homologous.

2. Each tube foot consists of an ampulla and a podium. When the ampulla squeezes, it forces water into the podium and makes the podium expand. When the muscles in the wall of the podium contract, they force water back into the ampulla, making the podium shorten and bend.

CHAPTER 34

Concept Check 34.1

1. In humans, these characters are present only in the embryo. The notochord becomes disks between the vertebrae, the tail is almost completely lost, and the pharyngeal clefts develop into various adult structures.
2. As water passes through the slits, food particles are filtered from the water and transported to the digestive system.

Concept Check 34.2

1. *Haikouichthys*; it had a skull and thus was a craniate, as are humans. *Haikouella* did not have a skull.
2. Hagfishes have a head and skull made of cartilage, plus a small brain, sensory organs, and tooth-like structures. They have a neural crest, gill slits, and more extensive organ systems. In addition, hagfishes have slime glands that ward off predators and may repel competing scavengers.

Concept Check 34.3

1. Lampreys have a round, rasping mouth, which they use to attach to fish. Conodonts had two sets of mineralized dental elements, which may have been used to impale prey and cut it into smaller pieces.
2. Mineralized dental elements allowed vertebrates to become scavengers and predators. In armored jawless vertebrates, bone served as external defensive armor.

Concept Check 34.4

1. Both are gnathostomes and have jaws, four clusters of *Hox* genes, enlarged forebrains, and lateral line systems. Sharks secondarily lost much mineralization in their skeletons, which consist mainly of cartilage, whereas tuna have bony skeletons. Sharks also have a spiral valve. Tuna have an operculum and a swim bladder, as well as flexible rays supporting their fins.
2. Coelacanths live in deep marine waters, lungfishes live in ponds and swamps, and terrestrial vertebrates live on land.

Concept Check 34.5

- No. Though it had four limb-like fins with fully formed legs, ankles, and digits, its pectoral and pelvic girdles could not carry its body on land. It had gills and a tail fin that propelled it in water.
- Some fully aquatic species are paedomorphic, retaining larval features as adults. Species that live in dry environments may avoid dehydration by burrowing or living under moist leaves, and they protect their eggs with foam nests, viviparity, and other adaptations.

Concept Check 34.6

- The amniotic egg is not an entirely closed system. Nutrients used by the embryo are stored within the egg (in the yolk sac and allantois) as are some metabolic wastes produced by the embryo (in the allantois). However, the embryo exchanges oxygen and carbon dioxide with the outside environment via the chorion, allantois, and egg shell.
- Birds have weight-saving modifications, including having no teeth or urinary bladder and only one ovary in females. The wings and feathers are adaptations that facilitate flight, as well as an efficient respiratory and circulatory system that support a high metabolic rate.

Concept Check 34.7

- Momotremes lay eggs. Marsupials give birth to very small live young that remain attached to the mother in a pouch. Eutherians give birth to more developed live young.
- Hands and feet adapted for grasping, flat nails, large brain, forward-looking eyes on a flat face, parental care, mobile big toe and thumb

Concept Check 34.8

- Hominoids are a clade including gibbons, orangutans, gorillas, chimpanzees, bonobos, and humans, along with extinct species that descended from the same ancestor. Hominids are a clade including humans and all species more closely related to humans than other living hominoids.
- Homo ergaster* was fully upright, bipedal, and tall as modern humans, but its brain was significantly smaller than that of modern humans. This difference in the evolutionary change of different body parts is known as mosaic evolution.

CHAPTER 35**Concept Check 35.1**

- The vascular tissue system connects leaves and roots, allowing sugars to move from leaves to roots in the phloem, and allowing water and minerals to move to the leaves in the xylem.
- Here are a few examples: The tubular, hollow structures of the tracheids and vessel elements of the xylem and the sieve plates in the sieve-tube members of the phloem facilitate transport. Root hairs aid in absorption of water and nutrients. The cuticle in leaves and stems protects from desiccation and

pathogens. Leaf trichomes protect from herbivores and pathogens. Collenchyma and sclerenchyma cells have thick walls that provide support for plants.

- The dermal tissue system is the leaf's protective covering. The vascular tissue system consists of the transport tissues xylem and phloem. The ground tissue system performs metabolic functions such as photosynthesis.

Concept Check 35.2

- Your dividing cells are normally limited in the types of cells they can form. In contrast, the products of cell division in a plant meristem differentiate into all the diverse types of plant cells.
- Primary growth arises from apical meristems and involves the production and elongation of organs. Secondary growth arises from lateral meristems and adds to the girth of roots and stems.

Concept Check 35.3

- Lateral roots emerge from the root's interior (from the pericycle), pushing through cortical and epidermal cells. In contrast, shoot branches arise on the exterior of a shoot (from axillary buds).
- In roots, primary growth occurs in three successive stages, moving away from the root tip: the zones of cell division, elongation, and maturation. In shoots, it occurs at the tip of terminal buds, with leaf primordia arising along the sides of apical meristems. Most growth in length occurs in older internodes below the shoot apex.
- Veins are a network of vascular tissue that provide water and minerals to leaf cells and carry organic products of photosynthesis to other parts of the plant.

Concept Check 35.4

- The sign is still 2 m above the ground because only secondary growth occurs in this part of the tree.
- A hollow tree can survive because water, minerals, and organic nutrients are conducted by the younger secondary vascular tissues, some of which remain intact: the outer secondary xylem (sapwood) and youngest secondary phloem. However, girdling removes an entire ring of secondary phloem (pan of the bark), completely preventing transport of organic nutrients from the shoots to the roots.

Concept Check 35.5

- Differential gene expression.
- In *liss* mutants, the arrangement of microtubules is disrupted so that the preprophase band does not form. This results in random planes of cell division, rather than the ordered planes of division that normally occur. Disruption of microtubule organization also prevents the alignment of cellulose microfibrils that sets the plane of cell elongation. Because of this randomness, directional

growth is disrupted, and the plant becomes stubby instead of elongated.

CHAPTER 36**Concept Check 36.1**

- The relatively high concentration of salts might cause the soil's water potential to be more negative, thereby reducing water uptake by lowering the water potential gradient from the soil to the roots.
- The cell's $v_i/v_s = 0.7$ MPa. In a solution with a v_i/v_s of -0.4 MPa, the cells v_i/v_p at equilibrium would be 0.3 MPa.

Concept Check 36.2

- The fungicide may kill the mycorrhizal fungi that function in phosphate uptake.
- The endodermis regulates the passage of water-soluble solutes by requiring all such molecules to cross a selectively permeable membrane.

Concept Check 36.3

- By lowering the solute potential (and water potential) of the soil, the fertilizer would make it harder for the plant to absorb water.
- The humid air has higher water potential than the leaves.
- After the flowers are cut, transpiration from any leaves and from the petals (which are modified leaves) will continue to draw water up the xylem. If cut flowers are transferred directly to a vase, air pockets in xylem vessels prevent delivery of water from the vase to the flowers. Cutting stems again underwater, a few centimeters from the original cut, will sever the xylem above the air pocket. The water droplets prevent another air pocket from forming while placing flowers in a vase.

Concept Check 36.4

- Accumulation of potassium by guard cells results in osmotic water uptake, and the turgid condition of the cells keeps the stomata open. This enables the mold to grow into the leaf interior via the stomata.
- A sunny, warm, but not hot, day; high humidity; low wind speed

Concept Check 36.5

- In both cases, the long-distance transport is a bulk flow driven by a pressure difference at opposite ends of tubes. Pressure is generated at the source end of a sieve tube by the loading of sugar and resulting osmotic flow of water into the phloem, and this pressure pushes sap from the source end to the sink end of the tube. In contrast, transpiration generates a negative pressure (tension) as a force that pulls the ascent of xylem sap.
- Under low temperature, the higher sugar content of a growing potato tuber would lower the solute potential (and water potential) of the tuber and reduce the bulk flow of sugar into it.

CHAPTER 37

Concept Check 37.1

- Table 37.1 shows that CO_2 is the source of 90% of a plant's dry weight, supporting Hales' view that plants are nourished mostly by air. However, van Helmont's hypothesis is correct with respect to a plant's overall increase in size, which is based mainly on accumulation of water in cell vacuoles.
- because even though macronutrients are required in greater amounts, all essential elements are necessary for the plant to complete its life cycle.
- because deficiencies of nutrients that are more mobile show up first in older leaves, whereas deficiencies in nutrients that are less mobile show up first in younger leaves.

Concept Check 37.2

- The topsoil has a mixture of larger particles (which provide aeration) and smaller particles (which facilitate water and mineral retention), as well as an adequate amount of humus (which supplies mineral nutrients) and suitable pH.
- Overwatering deprives roots of oxygen and can lead to mold, and overfertilizing can result in waste and pollution of groundwater.

Concept Check 37.3

- Nitrogen-fixing bacteria provide the long-term supply of nitrogenous minerals essential for the survival of plants, which are directly or indirectly the source of food for humans.

Concept Check 37.4

- Both involve mutualistic symbiotic relationships in which other organisms interact with plant roots. Root nodules involve nitrogen-fixing bacteria, whereas mycorrhizae involve fungi that facilitate absorption of both water and minerals. In both relationships, the plant provides organic compounds. Unlike root nodules, mycorrhizae occur in most plant species, but both relationships are important agriculturally.
- Epiphytes use another plant as a substratum without stealing nutrients from the other plant. In contrast, parasitic plants extract nutrients from their host plants.

CHAPTER 38

Concept Check 38.1

- Sepals usually protect the unopened floral bud, and petals often help attract animal pollinators to a flower. Stamens, the pollen-producing parts, are long structures that facilitate distribution of pollen. Carpel, parts that produce female gametophytes, have stigmas, platforms that facilitate receipt of pollen. The ovary of a carpel provides protection for developing eggs in ovules. Variations in arrangement of floral organs reflect adaptations to animal pollinators and may also re-

duce self-fertilization, as in the case of "pin" and "thrumb" flower types.

- In angiosperms, pollination is the transfer of pollen from an anther to a stigma. It is the subsequent development of the pollen tube that eventually enables fertilization, the fusion of egg and sperm to form the zygote.
- In the short term, selfing may be advantageous in a population that is so dispersed and sparse that pollen delivery is unreliable. In the long term, however, selfing is an evolutionary dead end because it leads to a loss of genetic diversity that may preclude adaptive evolution, including reversion from selfing to outcrossing.

Concept Check 38.2

- Fifty percent of the ovules would have XXX endosperm and XX embryos, and 50% would have XYY endosperm and XY embryos.
- Seeds contain endosperm that nourishes a developing embryo and have a seed coat that protects the embryo until conditions are suited for germination. Fruits, regardless of whether they are dry or fleshy, enhance seed dispersal by being eaten by animals or carried by wind.
- Seed dormancy prevents the premature germination of seeds. A seed will germinate only when the environmental conditions are optimal for the survival of its embryo as a young seedling.

Concept Check 38.3

- Sexual reproduction produces genetic variety, which may be advantageous in an unstable environment. The likelihood is better that at least one offspring of sexual reproduction will survive in a changed environment. Asexual reproduction can be advantageous in a stable environment because individual plants that are well-suited to that environment pass on all their genes to offspring without mates. Asexual reproduction also generally results in offspring that are less fragile than the seedlings produced by sexual reproduction. However, sexual reproduction offers the advantage of dispersal of tough seeds.
- Asexually propagated crops lack genetic diversity. Genetically diverse populations are less likely to become extinct in the face of an epidemic because there is a greater likelihood that a few individuals in the population may be resistant.

Concept Check 38.4

- Traditional breeding and genetic engineering both involve artificial selection for desired traits. However, genetic engineering techniques facilitate faster gene transfer and are not limited to transferring genes between closely related varieties or species.
- GM crops may be more nutritious and less susceptible to insect damage or pathogens that invade insect-damaged plants. They also do not require as much chemical spraying. However, continued field testing of GM crops remains important to avoid adverse effects on

human health and nontarget organisms and the possibility of transgene escape.

CHAPTER 39

Concept Check 39.1

- No. Viagra, like injection of cyclic GMP, should cause only a partial de-etiolation response.
- Cycloheximide should inhibit de-etiolation by preventing the synthesis of new proteins necessary for de-etiolation.

Concept Check 39.2

- The plant will exhibit a constitutive triple response. Because the kinase that normally prevents the triple response is dysfunctional, the plant will undergo the triple response regardless of whether ethylene is present or the ethylene receptor is functional.
- The pathogen might induce an increase in cytokinin concentration or a decrease in auxin concentration in the infected host plant.
- Fusicoccin, like auxin, causes an increase in plasma H^+ pump activity and, like auxin, leads to a promotion of stem cell elongation.

Concept Check 39.3

- It is impossible to say. To establish that this species is a short-day plant, it would be necessary to establish the critical night length for flowering and that this species only flowers when the night is longer than the critical night length.
- The use of far-red light would maintain phytochrome in its Pr form, allowing flowering to occur.
- An experiment could involve use of an action spectrum to determine which wavelengths of light are most effective. If the action spectrum indicates phytochrome, further testing could involve red/far-red experiments to check for photosensitivity.

Concept Check 39.4

- A plant that overproduces ABA would undergo less evaporative cooling because its stomata would be less open.
- Plants growing close to the aisle may be more subject to mechanical stresses caused by passing workers and air currents within the greenhouse. The plants nearer to the center of the bench may also be taller as a result of shading.

Concept Check 39.5

- Mechanical damage breaches a plant's first line of defense against infection, its protective dermal tissue.
- Perhaps the breeze dilutes the local concentration of a volatile defense compound that the plants have produced.

CHAPTER 40

Concept Check 40.1

- The small intestine, the lungs, and the kidneys contain internal exchange surfaces through which nutrients, gases, and chemicals, respectively, flow. A large surface area fa-

Appendix A

cilitates this exchange and enables the body to carry out the exchange more efficiently than if there were less surface area available.

Concept Check 40.2

- The glandular epithelium lining the inner surface of the stomach secretes mucus, which lubricates and protects the surface, and the tight packing of the epithelial tissue ensures that digestive juices don't leak from the stomach and damage underlying tissues.
- Connective tissue is an important part of most organs, and sheets of connective tissue support many of die body's organs.
- Both nervous tissue and muscle tissue are required to carry out a response to a stimulus. Muscle tissue contracts in response to nerve impulses transmitted by nerve cells.

Concept Check 40.3

- The mouse, because it is an endotherm and therefore has a higher basal metabolic rate than the ectothermic lizards standard metabolic rate
- Intense activity quickly depletes existing ATP. Because alligators are ectotherms, they are relatively slow to generate more ATP at aerobic respiration.
- The house cat; the smaller the animal, the higher its metabolic rate per gram and thus the demand for more food per unit of body mass.

Concept Check 40.4

- No; even though an animal regulates some aspects of its internal environment, often by negative feedback mechanisms, the internal environment fluctuates slightly around a set point. Homeostasis is a dynamic state. And some changes, such as radical increases in hormones at particular times in development, are programmed to occur.
- In negative feedback, a change triggers control mechanisms that counteract further change in that direction. But in positive feedback, a change triggers mechanisms that amplify the change.

Concept Check 40.5

- Yes, ectotherms in the deep sea and in constant-temperature freshwater springs have constant body temperatures. And terrestrial ectotherms can maintain relatively constant body temperatures by behavioral means.
- Heat loss through convection
- Food and water supplies may be short during the dry season, and torpor enables animals to survive at a much lower metabolic rate.

CHAPTER 41

Concept Check 41.1

- Body weight is stable when caloric intake (food) is balanced by caloric expenditure (metabolic rate).
- Over the long term, the body converts excess calories to fat whether those calories are consumed as fat, carbohydrate, or protein.

3. Both hormones have appetite-suppressing effects on the brain's satiety center. During the course of a day, PYY, secreted by the small intestine, suppresses appetite after meals. Over the longer term, leptin, produced by adipose tissue, normally reduces appetite as fat storage increases.

Concept Check 41.2

- Undernutrition is a deficiency of calories in the diet. In contrast, malnutrition results from a deficiency of one or more essential nutrients, even though total caloric intake may be adequate.
- A balanced vegetarian meal combines vegetables and fruits that complement one another, each providing certain essential amino acids that may be deficient in the other food items.
- Vitamins and minerals are essential nutrients required in relatively small daily amounts. Vitamins are organic nutrients, whereas minerals are inorganic nutrients.

Concept Check 41.3

- A gastrovascular cavity is a digestive sac with a single opening that functions in both ingestion and elimination; an alimentary canal is a digestive tube with a separate mouth and anus on opposite ends.
- As long as nutrients are within the cavity of the alimentary canal, they are in a compartment that is continuous with the outside environment via the mouth and anus and have not yet crossed a membrane to enter the body.

Concept Check 41.4

- Peristalsis can squeeze food through the esophagus even without the help of gravity.
- The acid breaks down the tissues in plant and animal materials by its harsh, nonenzymatic, chemical attack. The acid also activates the protein-digesting enzyme pepsin and destroys any bacteria that may have been ingested with food.
- The partially digested meal entering from the stomach as acid chyme + pancreatic juice containing hydrolytic enzymes + intestinal juice with enzymes + bile, which includes bile salts that aid in digestion by emulsifying fats
- The villi and microvilli of the intestinal epithelium provide an enormous surface area for absorption, the transport of nutrients from the lumen of the small intestine into blood capillaries and lacteals.
- Long-term use of antibiotics can kill colon bacteria that augment nutrition by producing vitamin K.
- As it receives acid chyme from the stomach, the duodenum secretes the hormone cholecystokinin (CCK), which reaches the pancreas via the bloodstream and stimulates release of pancreatic juice.

Concept Check 41.5

- The sharp incisors are adapted for cutting pieces of meat and plants. The broad, ridged surfaces of molars are adapted for grinding tough foods, especially fibrous fruits and vegetables and large pieces of meat.

- The tadpole is herbivorous (eats mostly algae), while the adult frog is carnivorous (eats insects, for example).
- The cud is a regurgitated brew of material from the rumen—once-chewed vegetation with fatty acids and other metabolic byproducts of the rumen bacteria. After a second chewing, which increases surface area of the plant material, the cow swallows the cud, where microbial action in the stomach chambers continues to convert cellulose to a diversity of nutrients.

CHAPTER 42

Concept Check 42.1

- The inefficiency of diffusion to deliver nutrients and remove wastes at high enough rates to sustain a large organism
- Advantage: high rate of delivery of nutrients and removal of wastes. Disadvantage: requires more energy to build, operate, and maintain.
- Two main advantages of separate respiratory and systemic circuits are higher blood pressure in the systemic circuit and a higher rate of blood circulation.

Concept Check 42.2

- This condition would reduce the oxygen content by mixing O₂-depleted blood returned to the right ventricle from the systemic circuit with the O₂-rich blood of the left ventricle.
- The delay ensures that the atria empty completely before the ventricles contract.

Concept Check 42.3

- The large total cross-sectional area of the capillaries
- These changes increase the capacity for action by increasing the rate of blood circulation and delivery of oxygen and nutrients to the skeletal muscles.
- Plasma proteins remaining in the blood in a capillary maintain fairly constant osmotic pressure, whereas blood pressure drops from the arteriole end to the venule end. This difference allows fluid to reenter the capillary at the venule end; if plasma proteins are deficient, fluid will remain in the tissues and cause swelling.

Concept Check 42.4

- About 200 billion, or 2.08×10^{11} , calculated by dividing the total number of cells, 2.5×10^{13} , by 120 days
- An increase in leukocytes may indicate that the person is combating an infection.
- Bone marrow stem cells divide repeatedly and are pluripotent.

Concept Check 42.5

- If the respiratory surfaces of lungs extended out into the terrestrial environment, they would quickly dry out, and diffusion of O₂ and CO₂ across the membrane would stop.
- The countercurrent results in a diffusion gradient for O₂ over the entire length of capillaries in the gill lamellae. As water flows over the gill

lamellae, the opposite direction of blood flow in the capillaries enables the blood to continue loading O₂ because the O₂-rich blood "downstream" encounters the even more O₂-rich water just beginning to flow over the lamellae.

Concept Check 42.6

- An increase in CO₂ in the blood increases the rate of CO₂ diffusion into the cerebrospinal fluid, where the CO₂ combines with water, forming carbonic acid. Dissociation of carbonic acid releases hydrogen ions, decreasing the pH of cerebrospinal fluid.
- Increased heart rate increases the rate at which CO₂-rich blood is delivered to the lungs, where it is removed.
- Air flow in the lungs of birds passes through the lungs in one direction only.

Concept Check 42.7

- Differences in partial pressure; gases diffuse from areas of higher partial pressure to areas of lower partial pressure.
- The Bohr shift causes hemoglobin to release oxygen at a lower pH, which occurs in the vicinity of tissues with high rates of respiration and carbon dioxide release.
- The decrease in concentration of CO₂ in the plasma as it diffuses into the alveolar spaces causes the carbonic acid within the red blood cells to break down, yielding CO₂, which diffuses into the plasma.
- Examples: more blood volume relative to body mass; much larger spleen; more oxygen-storing myoglobin in muscles; heart rate and metabolic rate decrease during dive

CHAPTER 43

Concept Check 43.1

- Macrophages have receptors that bind to polysaccharides present on the surface of bacterial cells but not on body cells.
- Vessel dilation, which allows enhanced blood flow, and increased vessel permeability result in the common signs of inflammation. These vascular changes aid in delivering clotting factors, antimicrobial proteins, and phagocytic cells to the tissue of the affected region; all of these help in repairing tissue damage and stopping the spread of infection.
- The exoskeleton of insects provides an external barrier similar to the skin and mucous membranes of vertebrates. Phagocytic cells and antimicrobial proteins also contribute to innate defenses in both insects and vertebrates.

Concept Check 43.2

- See Figure 43.8a; a secreted antibody lacks a transmembrane region and cytoplasmic tails.
- B cell receptors bind intact extracellular antigens present on the surface of microbes or free in body fluids. T cell receptors bind small fragments of intracellular antigens that are complexed with class I or class II MHC molecules.

3. Specificity: Only B cells with receptors that bind to the antigen are selected to proliferate and differentiate into plasma cells secreting antibodies specific for the antigen and memory B cells bearing receptors specific for the same antigen. **Memory:** The large number of memory B cells generated respond more rapidly to that same antigen the next time it enters the body

4. 40 V X 5 J - 200 possible light chains; 51 V X 6 J X 27 D = 8,262 possible heavy chains. Each antigen-binding site is formed from a region on a light chain and heavy chain. The number of possible random combinations is 200 light chains X 8,262 heavy chains = 1.65 X 10⁹ possible antigen-binding specificities.

Concept Check 43.3

- An activated helper T cell secretes cytokines that promote activation of both cytotoxic T cells and B cells. An activated cytotoxic T cell kills infected cells and tumor cells by apoptosis. An activated B cell differentiates into plasma cells that secrete antibodies.
- A child lacking a thymus would have no functional T cells. Without helper T cells to help activate B cells, the child would be unable to produce antibodies against extracellular bacteria. Without cytotoxic T cells or helper T cells to help activate them, the child's immune system would be unable to kill virus-infected cells.
- Antibodies bound to viruses can block their attachment to potential host cells (viral neutralization). Coating of bacteria or other particles by antibodies bound to surface antigens increases their phagocytosis by macrophages (opsonization). Antibodies bound to antigens on bacterial cells also can activate a cascade of complement proteins leading to lysis of the bacteria (complement activation). Cross-linking of antigens on many bacterial cells or viruses by binding of multiple antibody molecules can lead to formation of large clumps (agglutination), which are then phagocytized.
- Passive immunization, the transfer of antibodies from one individual to another, is protective only as long as the antibody molecules last. Active immunization, the introduction of antigen, induces an immune response in the recipient that can lead to the generation of long-lived memory cells. Someone who is actively immunized may be immune to that antigen for life.

Concept Check 43.4

- Because individuals with type AB blood do not produce antibodies against either the A or the B antigens, they can safely receive type A blood, type B blood, type AB blood, or type O blood—that is, they are universal recipients. In the case of donated type O blood, packed cells should be used, since the donor serum (fluid part of blood) would contain antibodies to A and to B, which could react with the recipient's red blood cells.
- The danger of the graft rejecting the host arises because transplanted bone marrow

contains lymphocytes that could react against components of the recipient's body.

- An autograft will not trigger a rejection reaction.

Concept Check 43.5

- A person with a macrophage deficiency would have frequent infections. This would be due to poor innate responses, particularly diminished phagocytosis and inflammation, and poor acquired responses because of the role of macrophages in presenting antigens to helper T cells.
- Binding of antigens by IgE molecules attached to mast cells induces degranulation of these cells, releasing histamine and other inflammatory agents, which cause typical allergy symptoms. Drugs that block the degranulation response prevent the release of inflammatory agents and hence the symptoms they cause.
- Myasthenia gravis is considered an autoimmune disease because the immune system produces antibodies against self molecules (acetylcholine receptors).
- To enter a host cell, HIV requires CD4 and a co-receptor. The co-receptor for HIV normally functions as a chemokine receptor. If a person's chemokine receptors are faulty, HIV cannot use them for entry into cells.

CHAPTER 44

Concept Check 44.1

- Because the salt is moved against the concentration gradient, from a hypotonic environment to a hypertonic environment.
- A freshwater osmroncon former would have body fluids too dilute to carry out life's processes.
- By maintaining high concentrations of urea and TMAO in their blood, sharks reduce the osmotic gradient between their blood and seawater.

Concept Check 44.2

- The aquatic larvae can dispose of the very toxic ammonia continuously by secreting it across epithelium into the surrounding water. The adult conserve water by excreting the nontoxic uric acid.
- The liver is the site of urea synthesis.
- Because uric acid is insoluble in water, it can be excreted as a semisolid paste, thereby reducing an animal's water loss.

Concept Check 44.3

- Filtration (of blood, hemolymph, or coelomic fluid) and selective reabsorption or secretion of solutes
- A large surface area for exchange of water and solutes

Concept Check 44.4

- A decline in blood pressure in the afferent arteriole would reduce the rate of filtration.
- The kidney medulla would absorb less water and thus the drug would increase water loss in the urine.

3. Bowman's capsule, proximal tubule, loop of Henle, distal tubule

Concept Check 44.5

- Alcohol inhibits the release of ADH, causing an increase in urinary water loss and increasing the chance of dehydration.
- Consuming salty food increases the osmolarity of the blood, which triggers the thirst center in the hypothalamus to stimulate drinking and the pituitary to release ADH, which increases the rate of water reabsorption by the distal tubules and collecting ducts.
- The capacity to conserve water by producing hyperosmotic urine

Concept Check 44.6

- Numerous nephrons and well-developed glomeruli are characteristic of the kidneys of freshwater fishes, while reduced numbers of nephrons and smaller glomeruli indicate marine environments. The numerous nephrons and well-developed glomeruli of freshwater fishes produce urine at a high rate, while small numbers of nephrons and smaller glomeruli produce urine at a low rate.

CHAPTER 45

Concept Check 45.1

- Hormones are produced by endocrine cells, whereas neurohormones are produced by specialized nerve cells called neurosecretory cells. Both hormones and neurohormones are secreted into the blood and act on target tissues. See Figure 45.2a and b.
- In negative feedback, the effector response reduces the initial stimulus, so eventually the response ceases as the variable being controlled reaches the set point. In positive feedback, the effector response causes an increase in the stimulus, leading to an even greater response.

Concept Check 45.2

- Water-soluble hormones, which cannot penetrate the plasma membrane, bind to cell-surface receptors. This interaction triggers an intracellular multicomponent signal transduction pathway that ultimately alters the activity of a preexisting cytoplasmic protein and/or changes transcription of specific genes in the nucleus. Steroid hormones are lipid-soluble and can cross the plasma membrane into the cell interior, where they bind to receptors located in the cytoplasm or nucleus. In both cases, the hormone-receptor complex functions directly as a transcription factor that binds to the cell's DNA and activates or inhibits transcription of specific genes.
- A particular hormone may cause diverse responses in target cells having different receptors for the hormone, different signal transduction pathways, and/or different proteins for carrying out the response.
- Once secreted, local regulators can diffuse rapidly to their nearby target cells. Hormones circulate in the bloodstream from their sites of synthesis to their target tissues, a slower process.

Appendix A

Concept Check 45.3

- The posterior pituitary, an extension of the hypothalamus that contains the axons of neurosecretory cells, is the storage and release site for two neurohormones, oxytocin and antidiuretic hormone (ADH). The anterior pituitary, derived from tissue of the embryonic mouth, contains endocrine cells that make at least six different hormones. Secretion of anterior pituitary hormones is controlled by hypothalamic hormones that travel via portal vessels to the anterior pituitary.
- Tropic hormones control the synthesis and/or secretion of hormones from other endocrine tissues. Releasing and inhibiting hormones produced in the hypothalamus control hormone secretion by the anterior pituitary. The anterior pituitary produces several tropic hormones that control the hormonal function of the thyroid gland, adrenal cortex, and gonads.
- (a) Prolactin functions in a simple neuroendocrine pathway, (b) ACTH functions in a complex neuroendocrine pathway, (c) Oxytocin functions in a neurohormone pathway.

Concept Check 45.4

- By negative feedback on the hypothalamus and anterior pituitary (see Figure 45.9)
- The hormone-secreting cells themselves monitor the blood Ca^{2+} levels. An increase in blood Ca^{2+} above the set point stimulates the thyroid gland to release calcitonin. By promoting deposition of Ca^{2+} in the bones and excretion of Ca^{2+} by the kidneys, calcitonin decreases the blood Ca^{2+} level. PTH, secreted by the parathyroid glands in response to low blood Ca^{2+} , has the opposite effects on bones and kidneys, thereby increasing blood Ca^{2+} . The response to one hormone triggers release of the antagonistic hormone, a feedback mechanism that minimizes extreme deviations of blood Ca^{2+} from the set point.
- In a diabetic, the initial increase in blood glucose is greater than in a nondiabetic, and it remains high for a prolonged period. In a nondiabetic, insulin released in response to the initial rise in blood glucose stimulates uptake of glucose by body cells. In a diabetic, however, inadequate production of insulin or nonresponsiveness of target cells decreases the body's ability to clear excess glucose from the blood.
- The levels of these hormones in the blood would become very high owing to the absence of negative feedback on the secretion of ACTH from the hypothalamus.

Concept Check 45.5

- During larval stages, neurosecretory cells produce a tropic hormone (brain hormone) that stimulates production of ecdysone, the molting hormone, by endocrine cells in the prothoracic glands.
- Juvenile hormone promotes the retention of larval characteristics. In insecticides, it prevents larvae from maturing into adults that can reproduce.

CHAPTER 46

Concept Check 46.1

- The offspring of sexual reproduction are genetically diverse.
- The term could be considered misleading in the sense that a sequentially hermaphroditic organism is never of two sexes (hermaphroditic) at the same time; first it is of one sex and later of the other sex.

Concept Check 46.2

- Fertilization allows the sperm to reach the egg without either gamete drying out.
- (a) Animals with external fertilization tend to release many gametes at once, resulting in the production of enormous numbers of zygotes. This increases the chances that some will survive to adulthood. (b) Animals with internal fertilization produce fewer offspring but generally exhibit greater care of the embryos and the young.

Concept Check 46.3

- Seminiferous tubule, epididymis, vas deferens, urethra
- The fluid from the seminal vesicles provides most of the fluid in which the sperm swim; furthermore, it includes a sugar that is a source of energy for the sperm and prostaglandins that cause changes in the uterus that help move the sperm toward the egg after coitus; also, its alkalinity helps neutralize the acidic vaginal environment, which could harm the sperm. The fluid from the prostate contains another sperm nutrient and anticoagulants that help the sperm swim by keeping the semen liquid. The fluid from the bulbourethral glands, secreted just before ejaculation, neutralizes any acidic urine remaining in the urethra.
- Primarily the penis and clitoris, but also the testes, labia, breasts, and outer third of the vagina

Concept Check 46.4

- In the testis, FSH stimulates the Sertoli cells, which nourish developing sperm. LH stimulates the production of androgens (mainly testosterone), which in turn stimulate sperm production. In both females and males, FSH encourages the growth of cells that support and nourish developing gametes; (follicle cells in females and Sertoli cells in males), and LH stimulates the production of sex hormones that promote gametogenesis (estrogen in females and androgens, especially testosterone, in males).
- In estrous cycles, which occur in most female mammals, the endometrium is reabsorbed (rather than shed) if fertilization does not occur. Estrous cycles often occur just one or a few times a year, and the female is usually receptive to copulation only during the period around ovulation. Menstrual cycles are found only in humans and some other primates.
- Hormones produced in the ovarian cycle control the uterine cycle (see Figure 46.13).

Also, the occurrence of pregnancy (implantation in the uterus) turns off the ovarian cycle.

4. Ovulation is triggered by a surge in LH. The secretion of LH has been stimulated by the influence of a rising estrogen level on GnRH.

Concept Check 46.5

- The embryo is a blastocyst, a ball of cells containing a cavity.
- HCG secreted by the early embryo stimulates the corpus luteum to make progesterone, which helps maintain the pregnancy. During the second trimester, however, HCG production drops, the corpus luteum disintegrates, and the placenta completely takes over progesterone production.
- Vasectomy, females
- Because, in all cases where IVF is used, the embryo grows and develops in a woman's uterus

CHAPTER 47

Concept Check 47.1

- The increased Ca^{2+} would cause the cortical granules to fuse with the plasma membrane, releasing their contents and causing a fertilization envelope to form, even though no sperm had entered. This would prevent fertilization.
- During the cleavage stage in frogs and many other animals, the cell cycle is modified so that it lacks G_1 and G_2 , the growth phases. As a result, the early cleavage divisions divide the zygote's cytoplasm into many smaller cells; the embryo's size thus remains the same.
- Gastrulation organizes the embryo's cells into three tissue layers: ectoderm on the outside, endoderm on the inside, and mesoderm between them.
- Gastrulation involves global rearrangement of cells in the embryo, generating three tissue layers. Organogenesis involves local changes in cell position and cell shape.

Concept Check 47.2

- Microtubules elongate, lengthening the cell along one axis, while microfilaments oriented crosswise at one end of the cell contract, making that end smaller and the whole cell wedge-shaped.
- The cells of the notochord migrate toward the midline of the embryo, rearranging themselves so there are fewer cells across the notochord, which thus becomes longer overall (see Figure 47.20).

Concept Check 47.3

- Once the first two axes are specified, the third one is automatically determined. (Think of your own body: If you know where your head and tail are and where your left and right sides are, you automatically know which are your front and back.)
- A second embryo would probably not form, since the cells of a late gastrula, including the ventral cells, are already determined and can-

not change their fate, even if an organizer is present.

- A second embryo could develop because inhibiting BMP-4 activity would have the same effect as transplanting an organizer.

CHAPTER 48

Concept Check 48.1

- (a) Sensory neuron \rightarrow interneuron \rightarrow motor neuron (b) Interneuron
- Transmitting information, as the axon transmits away from the cell body
- The axons in the CNS would not have myelin sheaths.

Concept Check 48.2

- $E_h = 62 \text{ mV} \log(10/100) = -62 \text{ mV}$
- A decrease in permeability to K^+ , an increase in permeability to Na^+ , or both
- Ligand-gated ion channels open when a specific chemical binds to the channel, whereas voltage-gated ion channels open when the membrane potential changes.

Concept Check 48.3

- A graded potential has a magnitude that varies with stimulus strength, whereas an action potential has an all-or-none magnitude that is independent of stimulus strength.
- The maximum frequency would decrease.
- c, a, b

Concept Check 48.4

- Chemical synapses would be most affected because they require the influx of Ca^{2+} into the synaptic terminal for neurotransmitter release.
- These poisons would prolong the EPSPs that acetylcholine produces.
- It can bind to different types of receptors, each triggering a specific response in postsynaptic cells.

Concept Check 48.5

- The sympathetic division, which mediates the "fight-or-flight" response in stressful situations
- Functions include controlling breathing, heart and blood vessel activity, swallowing, vomiting, and digestion and coordinating large-scale body movements such as walking.
- Apart of the reticular formation, the reticular activating system, acts as a sensory filter, selecting which information reaches the cerebral cortex. The thalamus sorts information from all the senses and sends it to the appropriate cerebral centers for further processing.

Concept Check 48.6

- More sensory neurons innervate the hand than the neck. This conclusion is supported by the fact that the cortical surface area devoted to the hand is larger than that devoted to the neck.
- Each cerebral hemisphere is specialized for different parts of this task—the right for face recognition and the left for language. Without an intact corpus callosum, neither hemi-

sphere can take advantage of the other's processing abilities.

- Broca's area, which is active during the generation of speech, is located near the part of the primary motor cortex that controls muscles in the face. Wernicke's area, which is active when speech is heard, is located near the part of the temporal lobe that is involved in hearing.
- Direct: The receptor is part of an ion channel; when glutamate binds, Ca^{2+} diffuses through the channel. Indirect: Ca^{2+} influx through the channel activates signal transduction pathways that produce long-lasting changes.

Concept Check 48.7

- Without Netrin-1 receptors, the axons of interneurons would not be attracted toward the floor plate and might grow randomly through the spinal cord. Without Slit receptors, the axons would not be repelled by the floor plate and might grow back across the midline.
- In all three diseases, identical twins have about a 50% chance of sharing the disease, which implies that genetic and environmental components are of nearly equal importance. Also, there is evidence that stress may be an environmental factor in bipolar disorder and major depression.
- Both are progressive brain diseases whose risk increases with advancing age. Both result from the death of brain neurons and are associated with the accumulation of peptide or protein aggregates.

CHAPTER 49

Concept Check 49.1

- Such drugs block sensations transmitted by sensory neurons that synapse with receptors. Sensor- neurons that are receptors (such as stretch receptors) transmit sensations without a synapse, so they are unaffected by such drugs.
- Pain and light touch should be affected first because they involve receptors in the epidermis. Senses related to hair movement, strong pressure, and vibrations are affected last or not at all because they involve receptors deep in the dermis.

Concept Check 49.2

- Siatocysts detect the animal's orientation with respect to gravity, providing information that is essential in environments such as these, where light cues are absent.
- The stapes and the other middle ear bones transmit vibrations from the tympanic membrane to the oval window. Fusion of these bones blocks this transmission, resulting in hearing loss.
- As a sound that changes gradually from a very low to a very high pitch

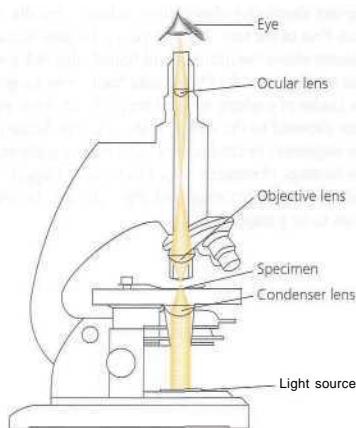

Concept Check 49.3

- As a fly walks on an object, gustatory sensilla on the feet determine whether the object contains food-related molecules, such as sugars. Sensilla on the mouthparts also detect these molecules when the fly begins to feed.

APPENDIX B The Metric System

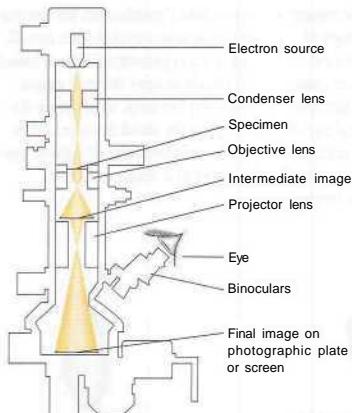

| Measurement | Unit and Abbreviation | Metric Equivalent | Metric-to-English Conversion Factor | English-to-Metric Conversion Factor |
|---|--|--|---|---|
| Length | | | | |
| 1 kilometer (km) | = 1000 (10^3) meters | I km = 0.62 mile | 1 mile = 1.61 km | |
| 1 meter (m) | = 100 (10^2) centimeters | 1 m = 1.09 yards | 1 yard = 0.914 m | |
| | = 1000 millimeters | 1 m = 3.28 feet | 1 foot = 0.305 m | |
| 1 centimeter (cm) | = 0.01 (10^{-2}) meter | I cm = 39.37 inches | | |
| | | 1 cm = 0.394 inch | 1 foot = 30.5 cm | |
| 1 millimeter (mm) | = 0.001 (10^{-3}) meter | 1 mm ≈ 0.039 inch | 1 inch = 2.54 cm | |
| 1 micrometer (μm) (formerly micron, μ) | = 10^{-6} meter (10^{-3} mm) | | | |
| 1 nanometer (nm) (formerly millimicron, μm) | = 10^{-9} meter (10^{-3} μm) | | | |
| 1 angstrom (Å) | = 10^{-10} meter (10^{-8} μm) | | | |
| Area | | | | |
| 1 hectare (ha) | = 10,000 square meters | 1 ha = 2.47 acres | 1 acre = 0.405 ha | |
| 1 square meter (m^2) | * 10,000 square centimeters | 1 $\text{H}\ddot{\text{a}}$ = 1.196 square yards | 1 square yard = 0.8361 m^2 | |
| | | 1 m^2 = 10.764 square feet | 1 square foot = 0.0929 m^2 | |
| 1 square centimeter (cm^2) | = 100 square millimeters | 1 cm^2 = 0.155 square inch | 1 square inch = 6.4516 cm^2 | |
| Mass | | | | |
| 1 metric ton (t) | = 1000 kilograms | 1 t = 1.103 tons | 1 ton = 0.907 t | |
| 1 kilogram (kg) | ≈ 1000 grams | 1 kg = 2.205 pounds | 1 pound = 0.4536 kg | |
| 1 gram (g) | ≈ 1000 milligrams | 1 g = 0.0353 ounce | 1 ounce = 28.35 g | |
| 1 milligram (mg) | = 10^{-3} gram | 1 g = 15.432 grains | | |
| 1 microgram (μg) | = 10^{-6} gram | 1 mg = approx. 0.015 grain | | |
| Volume (solids) | | | | |
| 1 cubic meter (m^3) | = 1,000,000 cubic centimeters | 1 m^3 = 1.308 cubic yards | 1 cubic yard = 0.7646 m^3 | |
| 1 cubic centimeter (cm^3 or cc) | ≈ 10^{-6} cubic meter | 1 m^3 = 35.315 cubic feet | 1 cubic foot = 0.0283 m^3 | |
| 1 cubic millimeter (mm^3) | = 10^{-9} cubic meter (10^{-3} cubic centimeter) | 1 cm^3 ≈ 0.061 cubic inch | 1 cubic inch = 16.387 cm^3 | |
| Volume (liquids and gases) | | | | |
| 1 kiloliter (kl or kL) | = 1000 liters | 1 kL = 264.17 gallons | 1 gallon = 3.785 L | |
| 1 liter (L) | = 1000 milliliters | 1 L = 0.264 gallons | 1 quart = 0.946 L | |
| | | 1 L = 1.057 quarts | | |
| 1 milliliter (mL) | ≈ 10^{-3} liter | 1 mL = 0.034 fluid ounce | 1 quart = 946 mL | |
| | = 1 cubic centimeter | 1 mL = approx. Y4 teaspoon | 1 pint = 473 mL | |
| | | 1 mL = approx. 15 - 16 drops (gtt.) | 1 fluid ounce = 29.57 mL | |
| 1 microliter (μL or uL) | = 10^{-6} liter (10^{-3} milliliters) | | 1 teaspoon = approx. 5 mL | |
| Time | | | | |
| 1 second (s) | * = 1/60 minute | | | |
| 1 millisecond (ms) | = 10^{-3} second | | | |
| Temperature | Oe'Lees Celsius (°C) (Absolute zero, when all molecular motion ceases, is -273°C . The Kelvin [K] scale, which has the same size degrees as Celsius, has its zero point at absolute zero. Thus, $0^\circ\text{K} = -273^\circ\text{C}$.) | | $^\circ\text{F} = \frac{9}{5}^\circ\text{C} + 32$ | $^\circ\text{C} = \frac{5}{9}(\text{F} - 32)$ |

A Comparison of the Light Microscope and the Electron Microscope

Light Microscope

In light microscopy, light is focused on a specimen by a glass condenser lens; the image is then magnified by an objective lens and an ocular lens, for projection on the eye or on photographic film.

Electron Microscope

In electron microscopy, a beam of electrons (top of the microscope) is used instead of light, and electromagnets are used instead of glass lenses. The electron beam is focused on the specimen by a condenser lens; the image is magnified by an objective lens and a projector lens for projection on a screen or on photographic film.

APPENDIX D Classification of Life

This appendix presents a taxonomic classification for the major extant groups of organisms discussed in this text; not all phyla are included. The classification presented here is based on the three-domain system, which assigns the two major groups of prokaryotes, archaea and bacteria, to separate domains (with eukaryotes making up the third domain). This classification contrasts with the traditional five-kingdom system, which groups all prokaryotes in a single kingdom, Monera (see Chapter 26).

DOMAIN ARCHAEA

- * **Kingdom Euryarchaeota**
- * **Kingdom Crenarchaeota**
- * **Kingdom Korarchaeota**
- * **Kingdom Nanoarchaeota**

DOMAIN BACTERIA

- * **Kingdom Proteobacteria**
- * **Kingdom Gram-Positive Bacteria**
- * **Kingdom Cyanobacteria**
- * **Kingdom Spirochetes**
- ^ **Kingdom Chlamydia**

Various alternative classification schemes are discussed in Unit Five of the text. The taxonomic turmoil includes debates about the number and boundaries of kingdoms. In this review, asterisks (*) indicate "candidate kingdoms," major clades of prokaryotes and protists that many systematists have elevated to the kingdom level. Other debates concern the alignment of the Linnaean classification hierarchy with the findings of modern cladistic analysis. Daggers (†) indicate currently recognized phyla thought by some systematists to be paraphyletic.

DOMAIN EUKARYA

The five-kingdom classification scheme unites all the eukaryotes generally called protists in a single kingdom, Protista. This book adopts the cladistic argument for dividing the protists into several "candidate kingdoms"¹ (*). This review also includes some protistan groups of less certain phylogeny (see Chapter 28).

* **Kingdom Parabasala** (parabasalids)

* **Kingdom Diplomonadida** (diplomonads)

* **Kingdom Euglenozoa**
Phylum Euglenophyta (euglenids)
Phylum Kinetoplastida (kinetoplastids)

* **Kingdom Alveolata**
Phylum Dinoflagellata (dinoflagellates)
Phylum Apicomplexa (apicomplexans)
Phylum Ciliophora (ciliates)

^ **Kingdom Stramenopila**

Phylum Phaeophyta (brown algae)
Phylum Oomycota (water molds)
Phylum Chrysophyta (golden algae)
Phylum Bacillariophyta (diatoms)

* **Kingdom Rhodophyta** (red algae)

* **Kingdom Chlorophyta** (green algae: chlorophytes and charophyceans, which some biologists now place with plants in the kingdom Viridiplantae)

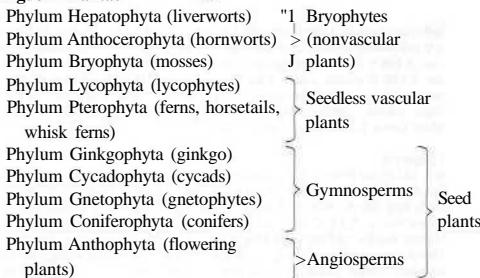

^ **Kingdom Amoebozoa**

Phylum Myxogastrida (plasmodial slime molds)
Phylum Dictyostelida (cellular slime molds)
Phylum Gymnamoeba (gymnamoebas)
Phylum Entamoeba (entamoebas)

Protists of less certain phylogenetic affinities;
Phylum Radiolaria (radiolarians)
Phylum Foraminifera (forams)

Kingdom Plantae

Kingdom Fungi

- ^fPhylum Chytridiomycota (chytrids)
- TPhylum Zygomycota (zygomycetes)
- Phylum Glomeromycota (glomeromycetes)
- Phylum Ascomycota (sac fungi)
- Phylum Basidiomycota (club fungi)

Kingdom Animalia

- tPhylum Porifera (sponges)
- Phylum Cnidaria (cnidarians)
 - Class Hydrozoa (hydrozoans)
 - Class Scyphozoa (jellies)
 - Class Cubozoa (box jellies and sea wasps)
 - Class Anthozoa (sea anemones and most corals)
- Phylum Placozoa (placozoans)
- Phylum Kinorhyncha (kinorhynchs)
- Phylum Platyhelminthes (flatworms)
 - Class Turbellaria (free-living flatworms)
 - Class Trematoda (flukes)
 - Class Monogenea (monogeneans)
 - Class Cestoda (tapeworms)

Phylum Nemertea (proboscis worms)

Phylum Ectoprocta (ectoprocts) "1

Phylum Phoronida (phoronids) > Lophophorates

Phylum Brachiopoda (brachiopods) J

Phylum Rotifera (rotifers)

Phylum Mollusca (molluscs)

Class Polyplacophora (chitons)

Class Gastropoda (gastropods)

Class Bivalvia (bivalves)

Class Cephalopoda (cephalopods)

Phylum Acanthocephala (spiny-headed worms)

Phylum Ctenophora (comb jellies)

Phylum Loricifera (loriciferans)

Phylum Pnlopula (priapulans)

Phylum Annelida (segmented worms)

Class Oligochaeta (oligochaetes)

Class Polychaeta (polychaetes)

Class Hirudinea (leeches)

Phylum Nematoda (roundworms)

Phylum Arthropoda (This survey groups arthropods into a single phylum, but some zoologists now split the arthropods into multiple phyla.)

Subphylum Cheliceriformes (horseshoe crabs, arachnids)

Subphylum Myriapoda (millipedes, centipedes)

Subphylum Hexapoda (insects, springtails)

Subphylum Crustacea (crustaceans)

Phylum Cyclopophora (cyclopophorans)

Phylum Tardigrada (tardigrades)

Phylum Onychophora (velvet worms)

Phylum Hemichordata (hemichordates)

Phylum Echinodermata (echinoderms)

Class Asteroidea (sea stars)

Class Ophiuroidea (brittle stars)

Class Echinoidea (sea urchins and sand dollars)

Class Crinoidea (sea lilies)

Class Concentricycloidea (sea daisies)

Class Holothuroidea (sea cucumbers)

Phylum Chordata (chordates)

Subphylum Urochordata (urochordates: tunicates)

Subphylum Cephalochordata (cephalochordates: lancelets)

Subphylum Craniata (craniates)

Class Myxini (hagfishes)

Class Cephalaspidomorphi (lampreys)

Class Chondrichthyes (sharks, rays, chimaeras)

Class Actinopterygii (ray-finned fishes)

Class Actinistia (coelacanths)

Class Dipnoi (lungfishes)

Class Amphibia (amphibians)

Class Reptilia (tuatara, lizards, snakes, turtles, crocodilians, birds)

Class Mammalia (mammals)

Vertebrates

Glossary

5' cap The 5' end of a pre-mRNA molecule modified by the addition of a cap of guanine nucleotide.

A band The broad region that corresponds to the length of the thick filaments of myofibrils.
A site One of a ribosome's three binding sites for tRNA during translation. The A site holds the tRNA carrying the next amino acid to be added to the polypeptide chain.
(A stands for aminoacetyl tRNA)

ABC model A model of flower formation identifying three classes of organ identity genes that direct formation of the four types of floral organs.

abdominal cavity The body cavity in mammals that primarily houses parts of the digestive, excretory, and reproductive systems. It is separated from the thoracic cavity by the diaphragm.

abiotic (uh-bi'-ot'-ik) Nonliving.

ABO blood groups Genetically determined classes of human blood that are based on the presence or absence of carbohydrates A and B on the surface of red blood cells. The ABO blood group phenotypes, also called blood types, are A, B, AB, and O.

abortion The termination of a pregnancy in progress.

abscisic acid (ABA) (ab-sis'-ik) A plant hormone that slows down growth; often antagonizing actions of growth hormones. Two of its many effects are to promote seed dormancy and facilitate drought tolerance.

absorption The uptake of small nutrient molecules by an organism's own body; the third main stage of food processing, following digestion.

absorption spectrum The range of a pigment's ability to absorb various wavelengths of light. Referring to the very deep benthic zone of the ocean.

acanthodian (ak'-an-tho'-de-un) Any of a group of ancient jawed fishes from the Devonian period.

acclimatization (uh-kli'-muh-tl-za'-shun)

Physiological adjustment to a change in an environmental factor.

accommodation The automatic adjustment of an eye to focus on near objects.

acetyl CoA Acetyl coenzyme A; the entry compound for the citric acid cycle in cellular respiration, formed from a fragment of pyruvate attached to a coenzyme.

acetylcholine (as'-uh-tih-koh'-len) One of the most common neurotransmitters; functions by binding to receptors and altering the permeability of the postsynaptic membrane to

specific ions, either depolarizing or hyperpolarizing the membrane.

acid A substance that increases the hydrogen ion concentration of a solution.

acid chyme (kim) A mixture of recently swallowed food and gastric juice.

acid precipitation Rain, snow, or fog that is more acidic than pH 5.6.

acoelomate (uh-se'-lo-mat) A solid-bodied animal lacking a cavity between the gut and outer body wall.

acquired immunity The kung of defense that is mediated by B lymphocytes (B cells) and T lymphocytes (T cells). It exhibits specificity, memory, and self-nonself recognition. Also called adaptive immunity.

acrosomal reaction The discharge of a sperm's acrosome when the sperm approaches an egg. Acrosome (ak'-ruh-som) A vesicle at the tip of a sperm cell that helps the sperm penetrate the egg.

actin (ah'-tih-n) A globular protein that links into chains, two of which twist helical-like about each other, forming microfilaments in muscle and other contractile elements in cells.

action potential A rapid change in the membrane potential of an excitable cell, caused by simultaneous opening, selective opening and closing of voltage-sensitive gates in sodium and potassium ion channels.

action spectrum A graph that depicts the relative effectiveness of different wavelengths of radiation in driving a particular process.

activation energy See free energy of activation.

activator A protein that binds to DNA and stimulates transcription of a specific gene.

active immunity Long-lasting immunity conferred by the action of a person's B cells and T cells and the resulting B and T memory cells specific for pathogen. Active immunity can develop as a result of natural infection or immunization.

active site The specific portion of an enzyme that attaches to the substrate by means of weak chemical bonds.

active transport The movement of a substance across a biological membrane against its concentration or electrochemical gradient with the help of energy input and specific transport proteins.

actual evapotranspiration The amount of water annually transpired by plants and evaporated from a landscape, usually measured in millimeters.

adaptive radiation The emergence of numerous species from a common ancestor introduced into an environment that presents a

diversity of new opportunities and problems.

adenohypophysis (uh'-uh-nö-hi-pof'-uh-sis)

See anterior pituitary.

adenylyl cyclase (ad'-en-uh-lil) An enzyme that converts ATP to cyclic AMP in response to a chemical signal.

adhesion The attraction between different kinds of molecules.

adipose tissue A connective tissue that insulates the body and serves as a fuel reserve; contains fat-storing cells called adipose cells.

adrenal gland (uh-dre-nul) One of two endocrine glands located adjacent to the kidneys in mammals. Endocrine cells in the outer portion (cortex) respond to ACTH by secreting steroid hormones that help maintain homeostasis during long-term stress. Neurosecretory cells in the central portion (medulla) secrete epinephrine and norepinephrine in response to nervous input triggered by short-term stress.

adrenocorticotrophic hormone (ACTH) A tropic hormone produced and secreted by the anterior pituitary that stimulates the production and secretion of steroid hormones by the adrenal cortex.

adventitious A term describing any plant organ that grows in an atypical location, such as roots growing from stems.

aerobic (ar'-oh-bik) Containing oxygen; referring to an organism, environment, or cellular process that requires oxygen.

afferent arteriole (af'-er-ent) The blood vessel supplying a nephron.

age structure The relative number of individuals of each age in a population.

aggregate fruit A fruit derived from a single flower that has more than one carpel.

agonistic behavior (ah'-go-nis'-tik) A type of behavior involving a contest of some kind that determines which competitor gains access to some resource, such as food or mates.

AIDS (acquired immunodeficiency syndrome) The name of the late stages of HIV infection, denoted by a specified reduction of T cells and the appearance of characteristic secondary infections.

alcohol fermentation The conversion of pyruvate to carbon dioxide and ethyl alcohol.

aldosterone (ah-dos'-uh-rön) An adrenal hormone that acts on the distal tubules of the kidney to stimulate the reabsorption of sodium (Na^+) and the passive flow of water from the filtrate.

Glossary

- alga (plural, algae) (al'-guh, al'-je) A photosynthetic, plant-like protist.
- alimentary canal (al'-uh-men'-tih-re) A digestive tract consisting of a tube running between a mouth and an anus.
- allantois (al'-an-to'-is) One of four extraembryonic membranes; serves as a repository for the embryo's nitrogenous waste.
- alleles (uh-le'-elz) Alternative versions of a gene that produce distinguishable phenotypic effects.
- allometric growth (al'-o-met'-rik) The variation in the relative rates of growth of various parts of the body, which helps shape the organism.
- allopatric speciation (al'-6-pat'-rik) A mode of speciation induced when an ancestral population becomes segregated by a geographic barrier or is itself divided into two or more geographically isolated subpopulations.
- I allopolyploid (al'-o-pol'-e-ploid) A common type of polyploid species resulting from two different species interbreeding and combining their chromosomes.
- allosteric regulation The binding of a molecule to a protein that affects the function of the protein at a different site.
- alpha (a) helix (al'-fuh he'-likz) A spiral shape constituting one form of the secondary structure of proteins, arising from a specific hydrogen-bonding structure.
- alternation of generations A life cycle in which there is both a multicellular diploid form, the sporophyte, and a multicellular haploid form, the gametophyte; characteristic of plants and some algae.
- alternative RNA splicing A type of regulation at the RNA-processing level in which different mRNA molecules are produced from the same primary transcript, depending on which RNA segments are treated as exons and which as introns.
- altruism (al'-tru-iz-um) Behavior that reduces an individual's fitness while increasing the fitness of another individual.
- alveolus (al'-ve-uh-lus) (plural, alveoli) One of the dead-end, multilobed air sacs that constitute the gas exchange surface of the lungs.
- Alzheimer's disease An age-related dementia (mental deterioration) characterized by confusion, memory loss, and other symptoms.
- amacrine cell (am'-uh-krihn) A neuron of the retina that helps integrate information before it is sent to the brain.
- amino acid (uh-nm'-n'oh) An organic molecule possessing both carboxyl and amino groups. Amino acids serve as the monomers of proteins.
- amino group A functional group that consists of a nitrogen atom bonded to two hydrogen atoms; can act as a base in solution, accepting a hydrogen ion and acquiring a charge of 1+.
- aminoacyl-tRNA synthetase An enzyme that joins each amino acid to the correct tRNA.
- ammonia A small, very toxic molecule made up of three hydrogen atoms and one nitrogen atom; produced by nitrogen fixation and as a metabolic waste product of protein and nucleic acid metabolism.
- ammonite A shelled cephalopod that was the dominant invertebrate predator for millions of years until the end of the Cretaceous period.
- amniocentesis (am'-ne-o-sen-te'-sis) A technique of prenatal diagnosis in which amniotic fluid, obtained by aspiration from a needle inserted into the uterus, is analyzed to detect certain genetic and congenital defects in the fetus.
- amnion (am'-ne-on) The innermost of four extraembryonic membranes; encloses a fluid-filled sac in which the embryo is suspended.
- amniote Member of a clade of tetrapods that have an amniotic egg containing specialized membranes that protect the embryo, including mammals and birds and other reptiles.
- amoeba (uh-me'-buh) A protist grade characterized by the presence of pseudopodia.
- amoebocyte (uh-me'-buh-sit) An amoeba-like cell that moves by pseudopodia, found in most animals; depending on the species, may digest and distribute food, dispose of wastes, form skeletal fibers, fight infections, and change into other cell types.
- amphibian Member of the tetrapod class Amphibia, including salamanders, frogs, and caecilians.
- amphiphatic molecule (am'-fe-path'-ik) A molecule that has both a hydrophile region and a hydrophobic region.
- amplification The strengthening of stimuli; energy that is otherwise too weak to be carried into the nervous system.
- anabolic pathway (an'-uh-bol'-ik) A metabolic pathway that synthesizes a complex molecule from simpler compounds.
- anaerobic (an'-ar-oh'-bik) Lacking oxygen; referring to an organism, environment, or cellular process that lacks oxygen and may be poisoned by it.
- anaerobic respiration The use of inorganic molecules other than oxygen in accept electrons at the "downhill" end of electron transport chains.
- analogy Similarity between two species that is due to convergent evolution rather than to descent from a common ancestor with the same trait.
- anaphase The fourth stage of mitosis, in which the chromatids of each chromosome have separated and the daughter chromosomes are moving to the poles of die cell.
- anaphylactic shock (an'-uh-fih-lak-tic) An acute, whole-body, life-threatening, allergic response.
- anatomy The study of the structure of an organism.
- anchorage dependence The requirement that to divide, a cell must be attached to the substratum.
- androgen (an'-drO-jsn) Any steroid hormone, such as testosterone, that stimulates the development and maintenance of the male reproductive system and secondary sex characteristics.
- aneuploidy (an'-yu-ploy-de) A chromosomal aberration in which one or more chromosomes are present in extra copies or are deficient in number.
- angiosperm (an'-je-o-sperm) A flowering plant, which forms seeds inside a protective chamber called an ovary.
- angiotensin II A hormone that stimulates constriction of precapillary arterioles and increases reabsorption of NaCl and water by the proximal tubules of the kidney, increasing blood pressure and volume.
- anhydrobiosis (an'-hi'-droh-be'-os-is) The ability to survive in a dormant state when an organism's habitat dries up.
- animal pole The portion of the egg where the least yolk is concentrated; opposite of vegetal pole.
- Animalia The kingdom that consists of multicellular eukaryotes that ingest their food.
- anion (an'-I-on) A negatively charged ion.
- annual A flowering plant that completes its entire life cycle in a single year or growing season.
- anterior Referring to the head end of a bilaterally symmetrical animal.
- anterior pituitary Also called the adenohypophysis; portion of the pituitary that develops from nonneuronal tissue; consists of endocrine cells that synthesize and secrete several tropic and nontropic hormones.
- anther (an'-ther) In an angiosperm, the terminal pollen sac of a stamen, where pollen grains with male gametes form.
- antheridium (an'-thuh-rid'-e-um) (plural, antheridia) In plants, the male gametangium, a moist chamber in which gametes develop.
- anthropoid (an'-thruh-poyd) A member of a primate group made up of the apes (gibbon, orangutan, gorilla, chimpanzee, and bonobo), monkeys, and humans.
- antibody A protein secreted by plasma cells (differentiated B cells) that binds to a particular antigen and marks it for elimination; also called immunoglobulin. All antibody molecules have the same Y-shaped structure and in their monomer form consist of two identical heavy chains and two identical light chains joined by disulfide bridges.
- anticodon (an'-ti-koh'-don) A specialized base triplet at one end of a tRNA molecule that recognizes a particular complementary codon on an mRNA molecule.
- antidiuretic hormone (ADH) A hormone produced in the hypothalamus and released from the posterior pituitary. It promotes

- water retention by the kidneys as part of an elaborate feedback scheme that helps regulate the osmolarity of the blood.
- antigen** (an'-tuh-jen) A macromolecule that elicits an immune response by lymphocytes.
- antigen presentation** The process by which an MHC molecule binds to a fragment of an intracellular protein antigen and carries it to the cell surface, where it is displayed and can be recognized by a T cell.
- antigen receptor** The general term for a surface protein, located on B cells and T cells, that binds to antigens, initiating acquired immune responses. The antigen receptors on B cells are called B cell receptors (or membrane immunoglobulins), and the antigen receptors on T cells are called T cell receptors.
- antigen-presenting cell** A cell that ingests bacteria and viruses and destroys them, generating peptide fragments that: are bound by class II MHC molecules and subsequently displayed on the cell surface to helper T cells. Macrophage, dendritic cells, and B cells are the primary antigen-presenting cells.
- antiparallel** The opposite arrangement of the sugar-phosphate backbones in a DNA double helix.
- aphotic zone** (a'-fō-tik) The part of the ocean beneath the photic zone, where light does not penetrate sufficiently for photosynthesis to occur.
- apical dominance** (a'-pik-ül) Concentration of growth at the tip of a plant shoot, where a terminal bud partially inhibits axillary bud growth.
- apical ectodermal ridge** A limb-bud organizer region consisting of a thickened area of ectoderm at the tip of a limb bud.
- apical meristem** (a'-pik-ül mar'-uh-stem) Embryonic plant tissue in the tips of roots and in the buds of shoots that supplies cells for the plant to grow in length.
- apicomplexan** (ap'-e-kom-plek's-un) A parasitic protozoan. Some apicomplexans cause human diseases.
- apomixis** (ap'-uh-mik'-sis) The asexual production of seeds.
- apoplast** (ap'-o-plast) In plants, the continuum of cell walls plus the extracellular spaces.
- apoptosis** The changes that occur within a cell as it undergoes programmed cell death, which is brought about by signals that trigger the activation of a cascade of suicide proteins in the cell destined to die.
- aposematic coloration** (ap'-o-so-mat'-ik) The bright coloration of animals with effective physical or chemical defenses that acts as a warning to predators.
- appendix** A small, fingerlike extension of the vertebrate cecum; contains a mass of white blood cells that contribute to immunity.
- aquaporin** A transport protein in the plasma membrane of a plant or animal cell that specifically facilitates the diffusion of water across the membrane (osmosis).
- aqueous humor** (ä'-kwe-us hyu'-mer) Plasma-like liquid in the space between the lens and the cornea in the vertebrate eye; helps maintain the shape of the eye, supplies nutrients and oxygen to its tissues, and disposes of its wastes.
- aqueous solution** (ä'-kwe-us) A solution in which water is the solvent.
- arbuscular mycorrhiza** A distinct type of endomycorrhiza formed by glomeromycete fungi, in which the tips of the fungal hyphae that invade the plant roots branch into tiny tree-like structures called arbuscules.
- Archaea** (är'-ke-uh) One of two prokaryotic domains, the other being Bacteria.
- archegonium** (är-ki-gō'-né-üm) (plural, archegonia) In plants, the female gametangium, a moist chamber in which gametes develop.
- archenteron** (är'-ken'-tuh-ron) The endoderm-lined cavity formed during the gastrulation process, that develops into the digestive tract of an animal.
- archosaur** Member of the reptilian group that includes crocodiles, alligators, dinosaurs, and birds.
- arteriole** (är-ter'-é-ööl) A vessel that conveys blood between an artery and a capillary.
- artery** A vessel that carries blood away from the heart to organs throughout the body.
- arthropod** A segmented coelomate with a chitinous exoskeleton, jointed appendages, and a body formed of distinct groups of segments.
- artificial selection** The selective breeding of domesticated plants and animals to encourage the occurrence of desirable traits.
- ascocarp** The fruiting body of a sac fungus (ascomycete).
- ascospore** See *sac fungus*.
- ascus** (plural, asci) A saclike spore capsule located at the tip of a dikaryotic hypha of a sac fungus.
- asexual reproduction** A type of reproduction involving only one parent that produces genetically identical offspring by budding or by the division of a single cell or the entire organism into two or more parts.
- aspartate** An amino acid that functions as a CNS neurotransmitter.
- assisted reproductive technology (ART)** Fertilization procedures that generally involve the surgical removal of eggs (secondary oocytes) from a woman's ovaries after hormonal stimulation, fertilizing the eggs, and returning them to the woman's body.
- associative learning** The acquired ability to associate one stimulus with another; also called classical conditioning.
- aster** A radial array of short microtubules that extends from each centrosome toward the plasma membrane in a cell undergoing mitosis.
- astrocyte** A glial cell that provides structural and metabolic support for neurons.
- atherosclerosis** A cardiovascular disease in which growths called plaques develop in the inner walls of the arteries, narrowing their inner diameters.
- atom** The smallest unit of matter that retains the properties of an element.
- atomic mass** The total mass of an atom, which is the mass in grams of one mole of the atom.
- atomic nucleus** An atom's central core, containing protons and neutrons.
- atomic number** The number of protons in the nucleus of an atom, unique for each element and designated by a subscript to the left of the elemental symbol.
- ATP (adenosine triphosphate)** (a-den'-uh-fos-fat') An adenine-containing nucleoside triphosphate that releases free energy when its phosphate bonds are hydrolyzed. This energy is used to drive endergonic reactions in cells.
- ATP synthase** A cluster of several membrane proteins found in the mitochondrial crista (and bacteria) plasma membrane that function in chemiosmosis with adjacent electron transport chains, using the energy of a hydrogen ion concentration gradient to make ATP. ATP synthases provide a port through which hydrogen ions diffuse into the matrix of a mitochondrion.
- atrial natriuretic factor (ANF)** (a'-tre-äl na'-tri-u-ret'ik) A peptide hormone that opposes the renin-angiotensin-aldosterone system (RAAS).
- atrioventricular (AV) node** A region of specialized muscle tissue between the right atrium and right ventricle where electrical impulses are delayed for about 0.1 second before spreading to the ventricles and causing them to contract.
- atrioventricular (AV) valve** A valve in the heart between each atrium and ventricle that prevents a backflow of blood when the ventricles contract.
- atrium** (ä'-trē-üm) (plural, atria) A chamber that receives blood returning to the vertebrate heart.
- autoimmune disease** An immunological disorder in which the immune system turns against self.
- autonomic nervous system (ot'-o-nom'-ik)** A subdivision of the motor nervous system of vertebrates that regulates the internal environment; consists of the sympathetic, parasympathetic, and enteric divisions.
- autopolyploid** (ot'-o-pol'-e-ploid) An individual that has more than two chromosome sets, all derived from a single species.
- autosome** (ot'-o-sōm) A chromosome that is not directly involved in determining sex, as opposed to a sex chromosome.
- autotroph** (ot'-ō-trof) An organism that obtains organic food molecules without eating other

Glossary

- organisms or substances derived from other organisms. Autotrophs use energy from the sun or from the oxidation of inorganic substances to make organic molecules from inorganic ones.
- auxin** (ók'-sin) A term that primarily refers to indoleacetic acid (IAA), a natural plant hormone that has a variety of effects, including cell elongation, root formation, secondary growth, and fruit growth.
- average heterozygosity** The percent, on average, of a population's loci that are heterozygous in members of the population.
- avirulent** A term describing a pathogen that can only mildly harm, but not kill, the host plant.
- axillary bud** (ak'-síl-ár-é) A structure that has the potential to form a lateral shoot, or branch. The bud appears in the angle formed between a leaf and a stem.
- axon** (ák'-son) A typically long extension, or process, from a neuron that carries nerve impulses away from the cell body toward target cells.
- axon hillock** The conical region of a neuron's axon where it joins the cell body; typically the region where nerve signals are generated.
- B cell receptor** The antigen receptor on B cells: a Y-shaped, membrane-bound molecule consisting of two identical heavy chains and two identical light chains linked by disulfide bridges and containing two antigen-binding sites; also called a membrane immunoglobulin or membrane antibody
- B lymphocyte (B cell)** A type of lymphocyte that develops to maturity in the bone marrow. After encountering antigen, B cells differentiate into antibody-secreting plasma cells, the effector cells of humoral immunity.
- Bacteria** One of two prokaryotic domains, the other being Archaea.
- bacterial artificial chromosome (BAC)** An artificial version of a bacterial chromosome that can carry inserts of 100,000 to 500,000 base pairs.
- bacteriophage (bak-tér'-é-6-faj)** A virus that infects bacteria; also called a phage.
- bacteroids** A form of *Rhizobium* contained within the vesicles formed by the root cells of a root nodule.
- baculum** (bak'-ú-lum) A bone that is contained in, and helps stiffen, the penis of rodents, raccoons, walruses, whales, and several other mammals.
- balanced polymorphism** The ability of natural selection to maintain diversity in a population.
- balancing selection** Natural selection that maintains stable frequencies of two or more phenotypic forms in a population (balanced polymorphism).
- barb** All tissues external to the vascular cambium, consisting mainly of the secondary phloem and layers of periderm.
- Barr body** A dense object lying along the inside of the nuclear envelope in female mammalian cells, representing an inactivated X chromosome.
- barrier method** Contraception that relies on a physical barrier to block the passage of sperm. Examples include condoms and diaphragms.
- Bartholin's glands** (bar'-to-linz) Glands near the vaginal opening in a human female that secrete lubricating fluid during sexual arousal.
- basal angiosperms** The most primitive lineages of flowering plants, including *Amborella*, water lilies, and star anise and relatives.
- basal body** (ba'-súl) A eukaryotic cell organelle consisting of a 9-4-0 arrangement of microtubule triplets; may organize the microtubule assembly of a cilium or flagellum; structurally identical to a centriole.
- basal metabolic rate (BMR)** The metabolic rate of a resting, fasting, and nonstressed endotherm.
- basal nuclei** A cluster of nuclei deep within the white matter of the cerebrum.
- base** A substance that reduces the hydrogen ion concentration of a solution.
- basement membrane** The floor of an epithelial membrane on which the basal cells rest.
- base-pair substitution** A type of point mutation; the replacement of one nucleotide and its partner in the complementary DNA strand by another pair of nucleotides.
- basidiocarp** Elaborate fruiting body of a dikaryotic mycelium of a club fungus.
- basidiomycete** See club fungus.
- basidium** (plural, basidia) A reproductive appendage that produces sexual spores on the gills of mushrooms (club fungi).
- Batesian mimicry** (bat'-ze-un mim'-uh-kre) A type of mimicry in which a harmless species looks like a species that is poisonous or otherwise harmful to predators.
- behavior** Everything an animal does and how it does it, including muscular activities such as chasing prey, certain nonmuscular processes such as secreting a hormone that attracts a mate, and learning.
- behavioral ecology** The scientific study of animal behavior, including how it is controlled and how it develops, evolves, and contributes to survival and reproductive success.
- benign tumor** A mass of abnormal cells that remains at the site of origin.
- benthic zone** The bottom surface of an aquatic environment.
- benthos** (ben'-thoz) The communities of organisms living in the benthic zone of an aquatic biome.
- beta oxidation** A metabolic sequence that breaks fatty acids down to two-carbon fragments that enter the citric acid cycle as acetyl CoA.
- beta (p)** pleated sheet One form of the secondary structure of proteins in which the polypeptide chain folds back and forth. Two regions of the chain lie parallel to each other and are held together by hydrogen bonds.
- biennial** (bi-en'-é-ul) A flowering plant that requires two years to complete its life cycle.
- big-bang reproduction** A life history in which adults have but a single reproductive opportunity to produce large numbers of offspring, such as the life history of the Pacific salmon; also known as semelparity.
- bilateral symmetry** Characterizing a body form with a central longitudinal plane that divides the body into two equal but opposite halves.
- bilaterian** (bi'-luh-ter'-é-uhn) Member of the clade Bilateria, animals with bilateral symmetry.
- bile** A mixture of substances that is produced in the liver, stored in the gallbladder, and acts as a detergent to aid in the digestion and absorption of fats.
- binary fission** The type of cell division by which prokaryotes reproduce. Each dividing daughter cell receives a copy of the single parental chromosome.
- binomial** The two-part latinized name of a species, consisting of genus and specific epithet.
- biodiversity hot spot** A relatively small area with an exceptional concentration of endemic species and a large number of endangered and threatened species.
- bioenergetics** The flow of energy through an animal, taking into account the energy stored in the food it consumes, the energy used for basic functions, activity, growth, reproduction, and regulation, and the energy lost to the environment as heat or in waste.
- biofilm** A surface-coating colony of prokaryotes that engage in metabolic cooperation.
- biogenic amine** A neurotransmitter derived from an amino acid,
- biogeochemical cycle** Any of the various nutrient circuits, which involve both biotic and abiotic components of ecosystems.
- biogeography** The study of the past and present distribution of species.
- bioinformatics** Using computing power, software, and mathematical models to process and integrate biological information from large data sets.
- biological augmentation** An approach to restoration ecology that uses organisms to add essential materials to a degraded ecosystem.
- biological clock** An internal timekeeper that controls an organism's biological rhythms. The biological clock marks time with or without environmental cues but often requires signals from the environment to remain tuned to an appropriate period. *See also circadian rhythm.*
- biological magnification** A trophic process in which retained substances become more concentrated with each link in the food chain.

biological species concept Definition of a species as a population or group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring, but are not able to produce viable, fertile offspring with members of other populations.

biology The scientific study of life.

biomanipulation A technique for restoring eutrophic lakes that reduces populations of algae by manipulating the higher-level consumers in the community rather than by changing nutrient levels or adding chemical treatments.

biomass The dry weight of organic matter comprising a group of organisms in a particular habitat.

biome (bi'-om) Any of the world's major ecosystems, classified according to the predominant vegetation and characterized by adaptations of organisms to that particular environment.

bioremediation The use of living organisms to detoxify and restore polluted and degraded ecosystems.

biosphere (bi'-sfer') The entire portion of Earth inhabited by life; the sum of all the planet's ecosystems.

biota All the organisms that are part of an ecosystem.

biotechnology The manipulation of living organisms or their components to produce useful products.

biotic (blōt'ik) Pertaining to the living organisms in the environment.

bipolar cell A neuron that synapses with the axon of a rod or cone in the retina of the eye.

bipolar disorder Depressive mental illness characterized by swings of mood from high to low; also called manic-depressive disorder.

birth control pills Chemical contraceptives that inhibit ovulation, retard follicular development, or alter a woman's cervical mucus to prevent sperm from entering the uterus.

blade (1) A leaflike structure of a seaweed that provides most of the surface area for photosynthesis. (2) The flattened portion of a typical leaf.

blastocoel (blas'-tuh-sel) The fluid-filled cavity that forms in the center of the blastula embryo.

blastocyst An embryonic stage in mammals; a hollow ball of cells produced one week after fertilization in humans.

blastoderm An embryonic cap of dividing cells resting on a large undivided yolk.

blastomere A small cell of an early embryo.

blastopore (blas'-to-por) The opening of the archenteron in the gastrula that develops into the mouth in protostomes and the anus in deuterostomes.

blastula (blas'-tyu-luh) The hollow ball of cells marking the end stage of cleavage during early embryonic development.

blood A type of connective tissue with a fluid matrix called plasma in which blood cells are suspended.

blood pressure The hydrostatic force that blood exerts against the wall of a vessel.

blood vessels A set of tubes through which the blood moves through the body.

blood-brain barrier A specialized capillary arrangement in the brain that restricts the passage of most substances into the brain, thereby preventing dramatic fluctuations in the brain's environment.

blue-light photoreceptors A class of light receptors in plants. Blue light initiates a variety of responses, such as phototropism and slowing of hypocotyl elongation.

body cavity A fluid-containing space between the digestive tract and the body wall.

body plan In animals, the set of morphological and developmental traits that define a grade (level of organizational complexity).

Bohr shift A lowering of the affinity of hemoglobin for oxygen, caused by a drop in pH; facilitates the release of oxygen from hemoglobin in the vicinity of active tissues.

bolus A lubricated ball of chewed food.

bone A type of connective tissue, consisting of living cells held in a rigid matrix of collagen fibers embedded in calcium salts.

book lung An organ of gas exchange in spiders, consisting of stacked plates contained in an internal chamber.

bottleneck effect Genetic drift resulting from the reduction of a population, typically by a natural disaster, such that the surviving population is no longer genetically representative of the original population.

bottom-up model A model of community organization in which mineral nutrients control community organization because nutrients control plant numbers, which in turn control herbivore numbers, which in turn control predator numbers.

Bowman's capsule (bo'-münz') A cup-shaped receptacle in the vertebrate kidney that is the initial, expanded segment of the nephron where filtrate enters from the blood.

brachiopod A marine lophophorate with a shell divided into dorsal and ventral halves. Brachiopods are also called lamp shells.

brain hormone A hormone, produced by neurosecretory cells in the insect brain, that promotes development by stimulating the prothoracic glands to secrete ecdysone.

brainstem Collection of structures in the adult brain, including the midbrain, the pons, and the medulla oblongata; functions in homeostasis, coordination of movement, and conduction of information to higher brain centers.

brassinosteroids Steroid hormones in plants that have a variety of effects, including cell elongation, retarding leaf abscission, and promoting xylem differentiation.

breathing The process involving alternate inhalation and exhalation of air that ventilates the lungs.

breathing control center A brain center that directs the activity of organs involved in breathing.

bronchiole One of the fine branches of the bronchus that transport air to alveoli.

bronchus (bron'-kus) (plural, bronchi) One of a pair of breathing tubes that branch from the trachea into the lungs.

brown alga A phaeophyte; a marine, multicellular, autotrophic protist that is the most common type of seaweed. Brown algae include the kelps.

brown fat A tissue in some mammals, located in the neck and between the shoulders, that is specialized for rapid heat production.

bryophyte (bri'-uh-fit) A moss, liverwort, or hornwort; a nonvascular plant that inhabits the land but lacks many of the terrestrial adaptations of vascular plants.

budding An asexual means of propagation in which outgrowths from the parent form and pinch off to live independently or else remain attached to eventually form extensive colonies.

buffer A substance that consists of acid and base forms in a solution and that minimizes changes in pH when extraneous acids or bases are added to the solution.

bulbourethral gland (bul'-bo-yu-re'-thrul) One of a pair of glands near the base of the penis in the human male that secretes fluid that lubricates and neutralizes acids in the urethra during sexual arousal.

bulk feeder An animal that eats relatively large pieces of food.

bulk flow The movement of water due to a difference in pressure between two locations.

bundle sheath cell A type of photosynthetic cell arranged into tightly packed sheaths around the veins of a leaf.

C₃ plant A plant that uses the Calvin cycle for the initial steps that incorporate CO₂ into organic material, forming a three-carbon compound as the first stable intermediate.

C₄ plant A plant that prefuses the Calvin cycle with reactions that incorporate CO₂ into a four-carbon compound, the end product of which supplies CO₂ for the Calvin cycle.

cadherins An important class of cell-to-cell adhesion molecules.

calcitonin (kal'-si-to'-riin) A hormone secreted by the thyroid gland that lowers blood calcium levels by promoting calcium deposition in bone and calcium excretion from the kidneys.

callus A mass of dividing, undifferentiated cells at the cut end of a shoot.

Glossary

- calorie (cal) The amount of heat energy required to raise the temperature of 1 g of water by 1°C ; also the amount of heat energy that 1 g of water releases when it cools by 1°C . The Calorie (with a capital C), usually used to indicate the energy content of food, is a kilocalorie.
- Calvin cycle The second of two major stages in photosynthesis (following the light reactions), involving atmospheric CO_2 fixation and reduction of the fixed carbon into carbohydrate.
- calyptra A protective cap of gametophyte tissue that wholly or partially covers an immature capsule in many mosses.
- CAM plant A plant that uses crassulacean acid metabolism, an adaptation for photosynthesis in arid conditions, first discovered in the family Crassulaceae. Carbon dioxide entering open stomata during the night is converted into organic acids, which release CO_2 for the Calvin cycle during the day when stomata are closed.
- Cambrian explosion A burst of evolutionary origins when most of the major body plans of animals appeared in a relatively brief time in geologic history; recorded in the fossil record about 542–525 million years ago.
- canopy The uppermost layer of vegetation in a terrestrial biome.
- capillary (kap'-il-är-e) A microscopic blood vessel that penetrates the tissues and consists of a single layer of endothelial cells that allows exchange between the blood and interstitial fluid.
- capillary bed A network of capillaries that infiltrate every organ and tissue in the body.
- capsid The protein shell that encloses a viral genome. It may be rod-shaped, polyhedral, or more complex in shape.
- capsule (1) A sticky layer that surrounds the cell walls of some prokaryotes, protecting the cell surface and sometimes helping to glue the cell to surfaces. (2) The sporangium of a bryophyte (moss, liverwort, or hornwort).
- carbohydrate (kar'-bo-här-dät) A sugar (monosaccharide) or one of its dimers (disaccharides) or polymers (polysaccharides).
- carbon fixation The incorporation of carbon from CO_2 into an organic compound by an autotrophic organism (a plant, another photosynthetic organism, or a chemolithoautotrophic prokaryote).
- carbonyl group (kar-buh-nel') A functional group present in aldehydes and ketones and consisting of a carbon atom double-bonded to an oxygen atom.
- carboxyl group (kar-bok'-sil) A functional group present in organic acids and consisting of a single carbon atom double-bonded to an oxygen atom and also bonded to a hydroxyl group.
- cardiac cycle (ikar'-cie-ak) The alternating contractions and relaxations of the heart.
- cardiac muscle A type of muscle that forms the contractile wall of the heart. Its cells are joined by intercalated disks that relay each heartbeat.
- cardiac output The volume of blood pumped per minute by the left ventricle of the heart. cardiovascular disease (kar'-deö-o-väs'-kyü-lär) Diseases of the heart and blood vessels.
- cardiovascular system A closed circulatory system with a heart and branching network of arteries, capillaries, and veins. The system is characteristic of vertebrates.
- carnivore An animal, such as a shark, hawk, or spider, that eats other animals.
- carotenoid (kuh-rof-th-noyd) An accessory pigment, either yellow or orange, in the chloroplasts of plants. By absorbing wavelengths of light that chlorophyll cannot, carotenoids broaden the spectrum of colors that can drive photosynthesis.
- carpel (kar'-pul) The ovule-producing reproductive organ of a flower, consisting of the stigma, style, and ovary.
- carrier In genetics, an individual who is heterozygous at a given genetic locus, with one normal allele and one potentially harmful recessive allele. The heterozygote is phenotypically normal for the character determined by the gene but can pass on the harmful allele to offspring.
- carrying capacity The maximum population size that can be supported by the available resources, symbolized as K .
- cartilage (kaf-til-ip) A type of flexible connective tissue with an abundance of collagenous fibers embedded in chondroitin sulfate.
- Caspian strip (kas-pär'-e-Lui) A wafer-impermeable ring of wax in the endodermal cells of plants that blocks the passive flow of water and solutes into the stele by way of cell walls.
- catabolic pathway (kat'-uh-bol'-ik) A metabolic pathway that releases energy by breaking down complex molecules to simpler compounds.
- catalyst A chemical agent that changes the rate of a reaction without being consumed by the reaction.
- catastrophism The hypothesis by Georges Cuvier that each boundary between strata corresponded in time to a catastrophe, such as a flood or drought, that had destroyed many of the species living there at that time.
- catecholamine Any of a class of compounds, including the hormones epinephrine and norepinephrine, that are synthesized from the amino acid tyrosine.
- cation (kat'ē-on) An ion with a positive charge, produced by the loss of one or more electrons.
- cation exchange A process in which positively charged minerals are made available to a plant when hydrogen ions in the soil displace mineral ions from the clay particles.
- CD4 A surface protein, present on most helper T cells, that binds to class II MHC molecules on antigen-presenting cells, enhancing the interaction between the T cell and the antigen-presenting cell.
- CD8 A surface protein, present on most cytotoxic cells, that binds to class I MHC molecules on target cells, enhancing the interaction between the T cell and the target cell.
- cDNA library A limited gene library using complementary DNA. The library includes only the genes that were transcribed in the cells examined.
- cecum (se'-küm) (plural, ceca) A blind outpocket of a hollow organ such as an intestine.
- cell Life's fundamental unit of structure and function.
- cell adhesion molecules (CAMs) Glycoproteins that contribute to cell migration and stable tissue structure.
- cell body The part, of a neuron that houses the nucleus and other organelles.
- cell cycle An ordered sequence of events in the life of a eukaryotic cell, from its origin in the division of a parent cell until its own division into two; composed of the M, G₁, S, and G₂ phases.
- cell cycle control system A cyclically operating set of molecules in the cell that triggers and coordinates key events in the cell cycle.
- cell differentiation The structural and functional divergence of cells as they become specialized during a multicellular organism's development; dependent on the control of gene expression.
- cell division The reproduction of cells.
- cell fractionation The disruption of a cell and separation of its organelles by centrifugation.
- cell lineage The ancestry of a cell.
- cell-mediated immune response The branch of acquired immunity that involves the activation of cytotoxic T cells, which defend against infected cells, cancer cells, and transplanted cells.
- cell plate A double membrane across the midline of a dividing plant cell, between which the new cell wall forms during cytokinesis.
- cellular respiration The most prevalent and efficient catabolic pathway for the production of ATP, in which oxygen is consumed as a reactant along with the organic fuel.
- cellular slime mold A type of protist that has unicellular amoeboid cells and aggregated reproductive bodies in its life cycle.
- cellulose (sel'-yü-lös) A structural polysaccharide of cell walls, consisting of glucose monomers joined by (3-1,4-glycosidic linkages.
- cell wall A protective layer external to the plasma membrane in plant cells, prokaryotes, fungi, and some protists. In plant cells, the wall is formed of cellulose fibers embedded in a polysaccharide-protein

matrix. The primary cell wall is thin and flexible, whereas the secondary cell wall is stronger and more rigid and is the primary constituent of wood.

Celsius scale (*sel'-e-süs*) A temperature scale (°C) equal to 5/9 (°F — 32) that measures the freezing point of water at 0°C and the boiling point of water at 100°C.

central canal The narrow cavity in the center of the spinal cord that is continuous with the fluid-filled ventricles of the brain.

central nervous system (CNS) In vertebrate animals, the brain and spinal cord.

central vacuole A membranous sac in a mature plant cell with diverse roles in reproduction, growth, and development.

centriole (*sen'-tri-ööl*) A structure in an animal cell composed of cylinders of microtubule triplets arranged in a 9 + 0 pattern. An animal cell usually has a pair of centrioles involved in cell division.

centromere (*sen'-köö-mär*) The centralized region joining two sister chromatids.

centrosome (*sen'-trö-söm*) Material present in the cytoplasm of all eukaryotic cells, important during cell division; the microtubule-organizing center.

cephalization (*sef'-uh-luh-zä'-shün*) An evolutionary trend toward the concentration of sensor' equipment on the anterior end of the body.

cerbellum (*sar-ruh-bel'-üm*) Part of the vertebrate hindbrain located dorsally; functions in unconscious coordination of movement and balance.

cerebral cortex (*suh-re'-brüł*) The surface of the cerebrum; the largest and most complex part of the mammalian brain, containing sensory and motor nerve cell bodies of the cerebrum; the part of the vertebrate brain most changed through evolution.

cerebral hemisphere The right or left side of the vertebrate brain.

cerebrospinal fluid (*suh-re'-brö-sp'l-nüł*)

Blood-derived fluid that surrounds, protects against infection, nourishes, and cushions the brain and spinal cord.

cerebrum, (*suh-re'-brüm*) The dorsal portion of the vertebrate forebrain, composed of right and left hemispheres; the integrating center for memory, learning, emotions, and other highly complex functions of the central nervous system.

cervix (*ser'-viks*) The neck of the uterus, which opens into the vagina.

chaparral (*shap'-uh-räl*) A **scrubland** biome of dense, spiny evergreen shrubs found at mid-latitudes along coasts where cold ocean currents circulate offshore; characterized by mild, rainy winters and long, hot, dry summers.

chaperonin A protein molecule that assists the proper folding of other proteins.

character An observable heritable feature.

character displacement The tendency for characteristics to be more divergent in sympatric populations of two species than in allopatric populations of the same two species.

checkpoint A critical control point in the cell cycle where stop and go-ahead signals can regulate the cycle.

chelicera One of a pair of clawlike feeding appendages characteristic of cheliceriforms.

cheliceriform An arthropod that has chelicerae and a body divided into a cephalothorax and an abdomen. Living cheliceriforms include sea spiders, horseshoe crabs, scorpions, ticks, and spiders.

chemical bond An attraction between two atoms, resulting from a sharing of outer-shell electrons or the presence of opposite charges on the atoms. The bonded atoms gain complete outer electron shells.

chemical energy Energy stored in the chemical bonds of molecules; a form of potential energy.

chemical equilibrium In a reversible chemical reaction, the point at which the rate of the forward reaction equals the rate of the reverse reaction.

chemical reaction A process leading to chemical changes in matter; involves the making and/or breaking of chemical bonds.

chemiosmosis (*kem'-e-öz-mö'-sis*) An energy-coupling mechanism that uses energy stored in the form of a hydrogen ion gradient across a membrane to drive cellular work, such as the synthesis of ATP. Most ATP synthesis in cells occurs by chemiosmosis.

chemoautotroph (*ke'-mo-ö'-tö-rof*) An organism that needs only carbon dioxide as a carbon source but that obtains energy by oxidizing inorganic substances.

chemoheterotroph (*ke'-mö-het'-er-o-trof*) An organism that must obtain both energy and carbon by consuming organic molecules.

chemokine Any of about 50 different proteins, secreted by many cell types near a site of injury or infection, that help direct migration of white blood cells to an injury site and induces other changes central to inflammation. chemoreceptor A receptor that transmits information about the total solute concentration in a solution or about individual kinds of molecules.

chiasma (plural, **chiasmata**) (*ki-az'-muh, ki-az'-muh-tuh*) The X-shaped, microscopically visible region representing homologous chromatids that have exchanged genetic material through crossing over during meiosis.

chimera An organism with a mixture of genetically different cells.

chitin (*la-tin*) A structural polysaccharide of an amino sugar found in many fungi and in the exoskeletons of all arthropods.

chlorophyll (*klor'-ö-fil*) A green pigment located within the chloroplasts of plants. Chlorophyll *a* can participate directly in the

light reactions, which convert solar energy to chemical energy.

chlorophyll *a* A type of blue-green photosynthetic pigment that participates directly in the light reactions.

chlorophyll *b* A type of yellow-green accessory photosynthetic pigment that transfers energy to chlorophyll *a*.

chloroplast (*klor'-ö-plast*) An organelle found only in plants and photosynthetic protists that absorbs sunlight and uses it to drive the synthesis of organic compounds from carbon dioxide and water.

choanocyte (*ko-an'-uh-slt*) A flagellated feeding cell found in sponges. Also called a collar cell, it has a collar-like ring that traps food particles around the base of its flagellum.

cholesterol (*ko-les'-tuh-rol*) A steroid that forms an essential component of animal cell membranes and acts as a precursor molecule for the synthesis of other biologically important steroids.

chondrichthyan Member of the class Chondrichthyes, vertebrates with skeletons made mostly of cartilage, such as sharks and rays. **chondrocyte** Cartilage cell that secretes collagen and chondroitin sulfate.

chordate (*kör'-dat*) Member of the phylum Chordata, animals that at some point during their development have a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.

chorion (*kör'-é-on*) The outermost of four extraembryonic membranes; contributes to the formation of the mammalian placenta.

chorionic villus sampling (CVS) (*kör-e-on'-ik vil'-us*) A technique of prenatal diagnosis in which a small sample of the fetal portion of the placenta is removed and analyzed to detect certain genetic and congenital defects in the fetus.

choroid A thin, pigmented inner layer of the vertebrate eye.

chromatin (*kro'-muh-tin*) The complex of DNA and proteins that makes up a eukaryotic chromosome. When the cell is not dividing, chromatin exists as a mass of very long, thin fibers that are not visible with a light microscope.

chromosome (*kro'-muh-söm*) A threadlike, gene-carrying structure found in the nucleus. Each chromosome consists of one very long DNA molecule and associated proteins. See chromatin.

chromosome theory of inheritance A basic principle in biology stating that genes are located on chromosomes and that the behavior of chromosomes during meiosis accounts for inheritance patterns.

chylomicron (*ki'-lo-mi'-kron*) One of the small intracellular globules composed of fats that are mixed with cholesterol and coated with special proteins.

chytrid (*kí'-trid*) Member of the fungal phylum Chytridiomycota, mostly aquatic fungi with

Glossary

- flagellated zoospores that probably represent the most primitive fungal lineage.
- ciliary body A portion of the vertebrate eye associated with the lens. It produces the clear, watery aqueous humor that fills the anterior cavity of the eye.
- ciliate (sil'-e-it) A type of protozoan that moves by means of cilia.
- cilium (sil'-e-um) (plural, cilia) A short cellular appendage specialized for locomotion, formed from a core of nine outer doublet microtubules and two inner single microtubules ensheathed in an extension of plasma membrane.
- circadian rhythm (ser-kā'-dē-un) A physiological cycle of about 24 hours that is present in all eukaryotic organisms and that persists even in the absence of external cues.
- cis Arrangement of two noncarbon atoms, each bound to one of the carbons in a carbon-carbon double bond, where the two noncarbon atoms are on the same side relative to the double bond.
- citric acid cycle A chemical cycle involving eight steps that completes the metabolic breakdown of glucose molecules to carbon dioxide; occurs within the mitochondrion; the second major stage in cellular respiration.
- clade A group of species that includes an ancestral species and all its descendants.
- cladistics (kluh-dis'-tiks) The analysis of how species may be grouped into clades.
- cladogram A diagram depicting patterns of shared characteristics among species.
- class In classification, the taxonomic category above order.
- class I MHC molecules A collection of cell surface proteins encoded by a family of genes called the major histocompatibility complex. Class I MHC molecules are found on nearly all nucleated cells.
- class II MHC molecules A collection of cell surface proteins encoded by a family of genes called the major histocompatibility complex. Class II MHC molecules are restricted to a few specialized cell types, commonly called antigen-presenting cells (dendritic cells, macrophages, and B cells),
- classical conditioning A type of associative learning; the association of a normally irrelevant stimulus with a fixed behavioral response.
- cleavage The process of cytokinesis in animal cells, characterized by pinching of the plasma membrane. Also, the succession of rapid cell divisions without growth during early embryonic development that converts the zygote into a ball of cells.
- cleavage furrow The first sign of cleavage in an animal cell; a shallow groove in the cell surface near the old metaphase plate.
- climate The prevailing weather conditions at a locality
- climatograph A plot of the temperature and precipitation in a particular region.
- cline A graded variation in a trait that parallels a gradient in the environment.
- clitoris (klif-uh-ris) An organ in the female that engorges with blood and becomes erect during sexual arousal.
- cloaca (klo-ä'-kuh) A common opening for the digestive, urinary, and reproductive tracts found in many nonmammalian vertebrates but in few mammals.
- clonal selection The process by which an antigen selectively binds to and activates only those lymphocytes bearing receptors specific for the antigen. The selected lymphocytes proliferate and differentiate into a clone of effector cells and a clone of memory cells specific for the stimulating antigen. Clonal selection accounts for the specificity and memory of acquired immune responses.
- clone (1) A lineage of genetically identical individuals or cells. (2) In popular usage, a single individual organism that is genetically identical to another individual. (3) As a verb, to make one or more genetic replicas of an individual or cell. *See also gene cloning.*
- cloning Using a somatic cell from a multicellular organism to make one or more genetically identical individuals.
- cloning vector An agent used to transfer DNA in genetic engineering. A plasmid that moves recombinant DNA from a test tube back into a cell is an example of it; cloning vector, as is a virus that transfers recombinant DNA by infection.
- closed circulatory system A circulatory system in which blood is confined to vessels and is kept separate from the interstitial fluid.
- club fungus The common name for members of the phylum Basidiomycota. The name comes from the club-like shape of the basidium.
- cnidocyte (mī'-duh-sit) A specialized cell for which the phylum Cnidaria is named; contains a capsule containing a fine coiled thread, which, when discharged, functions in defense and prey capture.
- cochlea (kok'-le-uh) The complex, coiled organ of hearing that contains the organ of Corti.
- codominance The situation in which the phenotypes of both alleles are exhibited in the heterozygote.
- codon (kō'-don) A three-nucleotide sequence of DNA or mRNA that specifies a particular amino acid or termination signal; the basic unit of the genetic code.
- coefficient of relatedness The probability that a particular gene present in one individual will also be inherited from a common parent or ancestor in a second individual.
- coelom (sē'-lōm) A body cavity completely lined with mesoderm.
- coelomate (sē'-lōm'-māt) Animal that possesses a true coelom (fluid-filled body cavity lined by tissue completely derived from mesoderm).
- coenocytic (sē'-no-sit'-ik) Referring to a multinucleated condition resulting from the repeated division of nuclei without cytoplasmic division.
- coenzyme (ko-en'-zim) An organic molecule serving as a cofactor. Most vitamins function as coenzymes in important metabolic reactions.
- coevolution The mutual evolutionary influence between two different species interacting with each other and reciprocally influencing each other's adaptations.
- cofactor Any nonprotein molecule or ion that is required for the proper functioning of an enzyme. Cofactors can be permanently bound to the active site or may bind loosely with the substrate during catalysis.
- cognition The ability of an animal's nervous system to perceive, store, process, and use information obtained by its sensory receptors.
- cognitive ethology The scientific study of cognition; the study of the connection between data processing by nervous systems and animal behavior.
- cognitive map A representation within the nervous system of spatial relations between objects in an animal's environment.
- cohesion The binding together of like molecules, often by hydrogen bonds.
- cohort A group of individuals of the same age, from birth until all are dead.
- coitus (kō'-uh-tus) The insertion of a penis into a vagina, also called sexual intercourse.
- coleoptile (kō'-le-öp'-tul) The covering of the young shoot of the embryo of a grass seed.
- coleorhiza (kō'-lé-uh-n'-zuh) The covering of the young root of the embryo of a grass seed.
- collagen A glycoprotein in the extracellular matrix of animal cells that forms strong fibers, found extensively in connective tissue and bone; the most abundant protein in the animal kingdom.
- collagenous fiber A tough fiber of the extracellular matrix. Collagenous fibers are made of collagen, are nonelastic, and do not tear easily when pulled lengthwise.
- collecting duct The location in the kidney where filtrate from renal tubules is collected; the filtrate is now called urine.
- collenchyma cell (ko-lēn'-kim-uh) A flexible plant cell type that occurs in strands or cylinders that support young parts of the plant without restraining growth.
- colloid A mixture made up of a liquid and particles that (because of their large size) remain suspended in that liquid.
- colon *See* large intestine.
- colony A collection of autonomously replicating cells of the same species.
- columnar The column shape of a type of epithelial cell.
- commensalism (kuh-mēn'-suh-lizm) A symbiotic relationship in which one organism benefits but the other is neither helped nor harmed.

- communication** Animal behavior involving transmission of, reception of, and response to signals.
- community** All the organisms that inhabit a particular area; an assemblage of populations of different species living close enough together for potential interaction.
- community ecology** The study of interactions between species affect community structure and organization.
- companion cell** A type of plant cell that is connected to a sieve-tube member by many plasmodesmata and whose nucleus and ribosomes may serve one or more adjacent sieve-tube members.
- competitive exclusion** The concept that when populations of two similar species compete for the same limited resources, one population will use the resources more efficiently and have a reproductive advantage that will eventually lead to the elimination of the other population.
- competitive inhibitor** A substance that reduces the activity of an enzyme by entering the active site in place of the substrate whose structure it mimics.
- complement system** A group of about 30 blood proteins that may amplify the inflammatory response, enhance phagocytosis, or directly lyse pathogens. The complement system is activated in a cascade initiated by surface antigen? on microorganisms or by antigen-antibody complexes.
- complementary DNA (cDNA)** A DNA molecule made *in vitro* using mRNA as a template and the enzyme reverse transcriptase. A cDNA molecule therefore corresponds to a gene, but lacks the introns present in the DNA of the genome.
- complete digestive tract** A digestive tube that runs between a mouth and an anus; also called an alimentary canal. An incomplete digestive tract has only one opening.
- complete dominance** The situation in which, the phenotypes of the heterozygote and dominant homozygote are indistinguishable.
- complete flower** A flower that has all four basic floral organs: sepals, petals, stamens, and carpels.
- complete metamorphosis** The transformation of a larva into an adult that looks very different, and often functions very differently in its environment, than the larva.
- compound** A substance consisting of two or more elements in a fixed ratio.
- compound eye** A type of multifaceted eye in insects and crustaceans consisting of up to several thousand light-detecting, focusing ommatidia; especially good at detecting movement.
- concentration gradient** An increase or decrease in the density of a chemical substance in an area. Cells often maintain concentration gradients of ions across their membranes.
- When a gradient exists, the ions or other chemical substances involved tend to move from where they are more concentrated to where they are less concentrated,**
- conception** The fertilization of the egg by a sperm cell in humans.
- condensation reaction** A reaction in which two molecules become covalently bonded to each other through the loss of a small molecule, usually water; also called a dehydration reaction.
- condom** A thin, latex rubber or natural membrane sheath that fits over the penis to collect semen.
- condont** Ancient lineage of jawless vertebrates that arose during the Cambrian period.
- conduction** The direct transfer of thermal motion (heat) between molecules of objects in direct contact with each other.
- cone cell** One of two types of photoreceptors in the vertebrate eye; detects color during the day.
- conformer** A characterization of an animal in regard to environmental variables. A conformer allows some conditions within its body to vary with certain external changes.
- conidia** Naked, asexual spores produced at the ends of specialized hyphae in ascomycetes.
- conifer** A gymnosperm whose reproductive structure is the cone. Conifers include pines, firs, and redwoods.
- coniferous forest** A terrestrial biome characterized by long, cold winters and dominated by cone-bearing trees.
- conjugation** (kon'-jii-ga-shun) In prokaryotes, the direct transfer of DNA between two cells that are temporarily joined. In ciliates, a sexual process in which two cells exchange haploid micronuclei.
- conjunctiva** (kon'-junk-ti'-vuh) A mucous membrane that helps keep the eye moist; lines the inner surface of the eyelid and covers the front of the eyeball, except the cornea.
- connective tissue** Animal tissue, that functions mainly to bind and support other tissues, having a sparse population of cells scattered through an extracellular matrix.
- codonot** An early, soft-bodied vertebrate with prominent eyes and dental elements.
- conservation biology** The integrated study of ecology, evolutionary biology, physiology, molecular biology, genetics, and behavioral biology in an effort to sustain biological diversity at all levels.
- contraception** The prevention of pregnancy.
- contractile vacuole** A membranous sac that helps move excess water out of certain cells.
- control element** A segment of noncoding DNA that helps regulate transcription of a gene by binding proteins called transcription factors.
- controlled experiment** An experiment in which an experiment,!, group "s compared to a control group that varies only in the factor being tested.
- convection** The mass movement of warmed air or liquid to or from the surface of a body or object.
- convergent extension** A mechanism of cell crawling in which the cells of a tissue layer rearrange themselves in such a way that the sheet, of cells becomes narrower while it becomes longer.
- cooperativity** An interaction of the constituent subunits of a protein whereby a conformational change in one subunit is transmitted to all the others.
- copepod** (ko'-puh-pod) Any of a group of small crustaceans that are important members of marine and freshwater plankton communities.
- coral reef** A warm-water, tropical ecosystem dominated by the hard skeletal structures secreted primarily by the resident cnidarians.
- corepressor** A small molecule that cooperates with a repressor protein to switch an operon off.
- cork cambium** (kam'-be-um) A cylinder of meristematic tissue in woody plants that replaces the epidermis with thicker, tougher cork cells.
- cornea** (kor'-ne-uh) The transparent frontal portion of the sclera, which admits light into the vertebrate eye.
- corpus callosum** (kor'-puh-kal'-uh-sum) The thick band of nerve fibers that connect the right and left cerebral hemispheres in placental mammals, enabling the hemispheres to process information together.
- corpus luteum** (kor'-pus lu'-te-uhm) A secreting tissue in the ovary that forms from the collapsed follicle after ovulation and produces progesterone.
- ortex** Ground tissue that is between the vascular tissue and dermal tissue in a root or dicot stem.
- cortical granules** Vesicles located just under the plasma membrane of an egg cell that undergo exocytosis during the cortical reaction.
- cortical nephrons** Nephrons located almost entirely in the renal cortex. These nephrons have a reduced loop of Henle.
- cortical reaction** Exocytosis of enzymes from cortical granules in the egg cytoplasm during fertilization.
- corticosteroid** Any steroid hormone produced and secreted by the adrenal cortex.
- cotransport** The coupling of the "downhill" diffusion of one substance to the "uphill" transport of another against its own concentration gradient.
- cotyledon** (kot'-uh-le'-don) A seed leaf of an angiosperm embryo. Some species have one cotyledon, others two.
- countercurrent exchange** The opposite flow of adjacent fluids that maximizes transfer rates; for example, blood in the gills flows in the opposite direction in which water passes over the gills, maximizing oxygen uptake and carbon dioxide loss.

Glossary

- countercurrent heat exchanger An arrangement of blood vessels that helps trap heat in the body core and is important in reducing heat loss in many endotherms.
- irountercurrent multiplier system A countercurrent system in which energy is expended in active transport to facilitate exchange of materials and create concentration gradients. For example, the loop of Henle actively transports NaCl from the filtrate in the upper part of the ascending limb of the loop, making the urine-concentrating function of the kidney more effective.
- covalent bond (*ko-vä'-lent*) A type of strong chemical bond in which two atoms share one or more pairs of valence electrons.
- cranial nerve A nerve that leaves the brain and innervates an organ of the head or upper body. craniate A chordate with a head.
- cmissulacean acid metabolism (CAM) A type of metabolism in which carbon dioxide is taken in at night and incorporated into a variety of organic acids.
- crisla (plural, cristae) (*kris'-tuh, kris'-te*) An infolding of the inner membrane of a mitochondrion that houses the electron transport chain and the enzyme catalyzing the synthesis of ATP.
- critical load The amount of added nutrient, usually nitrogen or phosphorus, that can be absorbed by plants without damaging ecosystem integrity.
- crop rotation The alternation of planting a nonlegume one year and a legume the next year to restore concentration of fixed nitrogen in the soil.
- crossing over The reciprocal exchange of genetic material between nonsister chromatids during prophase I of meiosis.
- cross-pollination In angiosperms, the transfer of pollen from an anther of a flower on one plant to the stigma of a flower on another plant of the same species.
- crustacean A member of a subphylum of arthropods that includes lobsters, crayfish, crabs, shrimps, and barnacles.
- cryptic coloration Camouflage, making potential prey difficult to spot against its background.
- cuboidal The cubic shape of a type of epithelial cell.
- culture The ideas, customs, skills, rituals, and similar activities of a people or group that are passed along to succeeding generations.
- cuticle (*kyü'-tuh-kü'l*) (1) A waxy covering on the surface of stems and leaves that acts as an adaptation to prevent desiccation in terrestrial plants. (2) The exoskeleton of an arthropod, consisting of layers of protein and chitin that are variously modified for different functions. (3) A tough coat that covers the body of a nematode.
- cyclic AMP (cAMP) Cyclic adenosine monophosphate, a ring-shaped molecule made from ATP that is a common intracellular signaling molecule (second messenger) in eukaryotic cells (for example, in vertebrate endocrine cells). It is also a regulator of some bacterial operons.
- cyclic electron flow A route of electron flow during the light reactions of photosynthesis that involves only photosystem 1 and that produces ATP but not NADPH or oxygen.
- cyclin (*sí'-klin*) A regulatory protein whose concentration fluctuates cyclically.
- cyclin-dependent kinase (Cdk) A protein kinase that is active only when attached to a particular cyclin.
- cystic fibrosis A human genetic disorder caused by a recessive allele for a chloride channel protein; characterized by an excessive secretion of mucus and consequent vulnerability to infection; fatal if untreated.
- cytochrome (*si'-to-krom*) An iron-containing protein, a component of electron transport chains in mitochondria and chloroplasts.
- cytogenetic map Chart of a chromosome that locates genes with respect to chromosomal features.
- cytokine Any of a group of proteins secreted by a number of cell types, including macrophages and helper T cells, that regulate the function of lymphocytes and other cells of the immune system.
- cytokinesis (*si'-to-kuh-ne'-sis*) The division of the cytoplasm to form two separate daughter cells; immediately after mitosis.
- cytokinins (*si'-lo-kin'-tins*) A class of related plant hormones that retard aging and act in concert with auxin to stimulate cell division, influence the pathway of differentiation, and control apical dominance.
- cytoplasm (*si'-to-plaz'-üm*) The entire contents of the cell, exclusive of the nucleus, and bounded by the plasma membrane.
- cytoplasmic determinants The maternal substances in the egg that influence the course of early development by regulating the expression of genes that affect the developmental fate of cells.
- cytoplasmic streaming A circular flow of cytoplasm, involving myosin and actin filaments, that speeds the distribution of materials within cells.
- cytoskeleton A network of microtubules, microfilaments, and intermediate filaments in a branch through out the cytoplasm and serve a variety of mechanical and transport functions.
- cytosol (*si'-to-sol*) The semifluid portion of the cytoplasm.
- cytotoxic T cell A type of lymphocyte that, when activated, kills infected cells, cancer cells, and transplanted cells.
- daily torpor A daily decrease in metabolic activity and body temperature during times of inactivity for some small mammals and birds.
- dalton A measure of mass (or atoms and subatomic particles).
- data Recorded observations.
- day-neutral plant A plant whose flowering is not affected by photoperiod.
- decapod A member of the group of crustaceans that includes lobsters, crayfish, crabs, and shrimps.
- decomposer Any of the saprobic fungi and protists that absorb nutrients from non-living organic material such as corpses, fallen plant material, and the wastes of living organisms, and convert them into inorganic forms.
- deductive reasoning A type of logic in which specific results are predicted from a general premise.
- deep-sea hydrothermal vent A dark, hot, oxygen-deficient environment associated with volcanic activity. The food producers are chemoautotrophic prokaryotes.
- de-etiolation The changes a plant shoot undergoes in response to sunlight; also known informally; as greening.
- dehydration reaction A chemical reaction in which two molecules covalently bond to each other with the removal of a water molecule.
- deletion (1) A deficiency in a chromosome resulting from the loss of a fragment through breakage. (2) A mutational loss of one or more nucleotide pairs from a gene.
- demographic transition A shift from zero population growth in which birth rates and death rates are high to zero population growth characterized instead by high birth and death rates.
- demography The study of statistics relating to births and deaths in populations.
- denaturation (*de-nä'-chur'-ä-shun*) In proteins, a process in which a protein unravels and loses its native conformation, thereby becoming biological; inactive. In RNA, IVT separation of the two strands of the double helix. Denaturation occurs under extreme conditions of pH, salt concentration, and temperature.
- dendrite (*den'-drít*) One of usually numerous, short, highly branched processes of a neuron that convey nerve impulses toward the cell body.
- dendritic cell An antigen-presenting cell, located mainly in lymphatic tissues and skin, that is particularly efficient in presenting antigens to naïve helper T cells, thereby initiating a primary immune response.
- density The number of individuals per unit area or volume.
- density dependent Referring to any characteristic that varies according to an increase in population density.
- density-dependent inhibition The phenomenon observed in normal animal cells that causes them to stop dividing when they come into contact with one another.

density independent Referring to any characteristic that is not affected by population density.

deoxyribonucleic acid (DNA) (de-ōk'-se-ri-bo-nū-kla'-ik) A double-stranded, helical nucleic acid molecule capable of replicating and determining the inherited structure of a cell's proteins.

deoxyribose The sugar component of DNA, having one less hydroxyl group than ribose, the sugar component of RNA.

depolarization An electrical state in an excitable cell whereby the inside of the cell is made less negative relative to the outside than at the resting membrane potential. A neuron membrane is depolarized if a stimulus decreases its voltage from the resting potential of -70 mV in the direction of zero voltage.

derivatives New cells that are displaced from an apical meristem and continue to divide until the cells they produce become specialized.

dermal tissue system The outer protective covering of plants.

descent with modification Darwin's initial phrase for the general process of evolution.

desert A terrestrial biome characterized by very low precipitation.

desmosome (dez'-muh-som) A type of intercellular junction in animal cells that functions as an anchor.

determinate cleavage A type of embryonic development in protostomes that rigidly casts the developmental fate of each embryonic cell very early.

determinate growth A type of growth characteristic of most animals and some plant organs, in which growth stops after a certain size is reached.

determination The progressive restriction of developmental potential, causing the possible fate of each cell to become more limited as the embryo develops.

detrivore A consumer that derives its energy from nonliving organic material; a decomposer.

detritus (di-trī'-tus) Dead organic matter.

deuteromycete Traditional classification for a fungus with no known sexual stage. When a sexual stage for a so-called deuteromycete is discovered, the species is assigned to a phylum. Also called an imperfect fungus.

deuterostome development In animals, a developmental mode distinguished by the development of the anus from the blastopore; often also characterized by enterocoelous development of the body cavity and by radial cleavage.

diabetes mellitus An endocrine disorder marked by inability to maintain glucose homeostasis. The type I form results from autoimmune destruction of insulin-secreting cells; treatment usually requires insulin injections several times a day. The type II form most commonly results from reduced

responsiveness of target cells to insulin; obesity and lack of exercise are risk factors. diacylglycerol (DAG) A second messenger produced by the cleavage of a certain kind of phospholipid in the plasma membrane.

diaphragm (1) A sheet of muscle that forms the bottom wall of the thoracic cavity in mammals; active in ventilating the lungs. (2) A dome-shaped rubber cup fitted into the upper portion of the vagina before sexual intercourse. It serves as a physical barrier to block the passage of sperm.

diapsid Member of an amniote clade distinguished by a pair of holes on each side of the skull, including the lepidosaurs and archosaurs.

diastole (di-as'-to-le) The stage of the heart cycle in which the heart muscle is relaxed, allowing the chambers to fill with blood.

diastolic pressure Blood pressure that remains between heart contractions.

diatom (di'-uh-tom) A unicellular photosynthetic alga with a unique, glassy cell wall containing silica.

dicots A term traditionally used to refer to flowering plants that have two embryonic seed leaves, or cotyledons. Recent molecular evidence indicates that dicots do not form a clade (see eudicots).

differential gene expression The expression of different sets of genes by cells with the same genome.

diffusion The spontaneous tendency of a substance to move down its concentration gradient from a more concentrated to a less concentrated area.

digestion The process of breaking down food into molecules small enough for the body to absorb.

dihybrid (di'-hi'-brid) An organism that is heterozygous with respect to two genes of interest. All the offspring from a cross between parents doubly homozygous for different alleles are dihybrids. For example, parents of genotypes *AABB* and *aabb* produce a dihybrid of genotype *AaBb*.

dikaryotic Referring to a fungal mycelium with two haploid nuclei per cell, one from each parent.

dinoflagellate (di'-no-flaj'-uh-let) Member of a group of mostly unicellular photosynthetic algae with two flagella situated in perpendicular grooves in cellulose plates covering the cell.

dinosaur Member of an extremely diverse group of ancient reptiles varying in body shape, size, and habitat.

dioecious (di-e'-shus) A term typically used to describe an angiosperm species in which carpelate and staminate flowers are on separate plants.

diploblastic Having two germ layers.

diploid cell (dip'-loid) A cell containing two sets of chromosomes (2B), one set inherited from each parent.

dipomonad A protist that has modified mitochondria, two equal-sized nuclei, and multiple flagella.

directional selection Natural selection that favors individuals at one end of the phenotypic range.

disaccharide (di-sak'-uh-rid) A double sugar, consisting of two monosaccharides joined by dehydration synthesis.

discovery science The process of scientific inquiry that focuses on describing nature.

dispersal The distribution of individuals within geographic population boundaries.

dispersion The pattern of spacing among individuals within geographic population boundaries.

disruptive selection Natural selection that favors individuals on both extremes of a phenotypic range over intermediate phenotypes.

dissociation curve A chart showing the relative amounts of oxygen bound to hemoglobin when the pigment is exposed to solutions varying in their partial pressure of dissolved oxygen, pH, or other characteristics.

distal tubule In the vertebrate kidney, the portion of a nephron that helps refine nitrate and empties it into a collecting duct.

disturbance A force that changes a biological community and usually removes organisms from it. Disturbances, such as fire and storms, play pivotal roles in structuring many biological communities.

disulfide bridge A strong covalent bond formed when the sulfur of one cysteine monomer bonds to the sulfur of another cysteine monomer.

DNA fingerprint An individual's unique collection of DNA restriction fragments, detected by electrophoresis and nucleic acid probes.

DNA ligase (li'-gas) A linking enzyme essential for DNA replication; catalyzes the covalent bonding of the 3' end of a new DNA fragment to the 5' end of a growing chain.

DNA microarray assay A method to detect and measure the expression of thousands of genes at one time. Tiny amounts of a large number of single-stranded DNA fragments representing different genes are fixed to a glass slide. These fragments, ideally representing all the genes of an organism, are tested for hybridization with various samples of cDNA molecules.

DNA polymerase (puh-lim'-er-as) An enzyme that catalyzes the elongation of new DNA at a replication fork by the addition of nucleotides to the existing chain.

domain (1) A taxonomic category above the kingdom level. The three domains are Archaea, Bacteria, and Eukarya. (2) An independently folding part of a protein.

dominant allele An allele that is fully expressed in the phenotype of a heterozygote.

dominant species Those species in a community that have the highest abundance or

Glossary

- highest biomass. These species exert a powerful control over the occurrence and distribution of other species.
- dopamine A biogenic amine closely related to epinephrine and norepinephrine.
- dormancy A condition typified by extremely low metabolic rate and a suspension of growth and development.
- dorsal Pertaining to the back (top) of a bilaterally symmetrical animal.
- dorsal lip The dorsal side of the blastopore.
- double circulation A circulation scheme with separate pulmonary and systemic circuits, which ensures vigorous blood flow to all organs.
- double fertilization A mechanism of fertilization in angiosperms, in which two sperm cells unite with two cells in the embryo sac to form the zygote and endosperm.
- double helix The form of native DNA, referring to its two adjacent polynucleotide strands wound into a spiral shape.
- Down syndrome A human genetic disease caused by presence of an extra chromosome 21; characterized by mental retardation and heart and respiratory defects.
- Duchenne muscular dystrophy (duh-shen') A human genetic disease caused by a sex-linked recessive allele; characterized by progressive weakening and a loss of muscle tissue.
- duodenum (du-o-de'-num) The first section of the small intestine, where acid chyme from the stomach mixes with digestive juices from the pancreas, liver, gallbladder, and gland cells of the intestinal wall.
- duplication An aberration in chromosome structure due to fusion with a fragment from a homologous chromosome, such that a portion of a chromosome is duplicated.
- dynamic stability hypothesis The idea that long food chains are less stable than short chains.
- dynein (di'-nin) A large contractile protein forming the side-arms of microtubule doublets in cilia and flagella.
- E site One of a ribosome's three binding sites for tRNA during translation. The E site is the place where discharged RNAs leave the ribosome. (E stands for exit.)
- ecdysome (ek'-duh-sohm) A steroid hormone, secreted by the prothoracic glands, that triggers molting in arthropods.
- ecdsysozoan Member of a group of animal phyla with protostome development that some systematists hypothesize form a clade, including many molting animals.
- echinoderm (uh-ki'-no-derm) A slow-moving or sessile marine deuterostome with a water vascular system and, in adults, radial anatomy. Echinoderms include sea stars, brittle stars, sea urchins, feather stars, and sea cucumbers.
- ecological capacity The actual resource base of a country.
- ecological footprint A method of using multiple constraints to estimate the human carrying capacity of Earth by calculating the area land and water area in various ecosystem categories appropriated by a nation to produce all the resources it consumes and to absorb all the waste it generates.
- ecological niche (niche) The sum total of a species' use of the biotic and abiotic resources in its environment.
- ecological species concept Defining species in terms of ecological roles (niches).
- ecological succession Transition in the species composition of a biological community, often following ecological disturbance of the community; the establishment of a biological community in an area virtually barren of life.
- ecology The study of how organisms interact with their environment.
- ecosystem All the organisms in a given area as well as the abiotic factors with which they interact; a community and its physical environment.
- ecosystem ecology The study of energy flow and the cycling of chemicals among the various biotic and abiotic factors in an ecosystem.
- ecosystem services Functions performed by natural ecosystems that directly or indirectly benefit humans.
- ecotone The transition from one type of habitat or ecosystem to another, such as the transition from a forest to a grassland.
- ectoderm (ek'-to-derm) The outermost of the three primary germ layers in animal embryos; gives rise to the outer covering and, in some phyla, the nervous system, inner ear, and lens of the eye.
- ectomycorrhiza (ek'-to-my'-ko-rr-zuh) A type of mycorrhiza in which the mycelium forms a dense sheath, or mantle, over the surface of the root. Hyphae extend from the mantle into the soil, greatly increasing the surface area for water and mineral absorption.
- ectomycorrhizal fungus A fungus that forms ectomycorrhizae with plant roots.
- ectoparasite A parasite that feeds on the external surface of a host.
- ectoprotect A sessile, colonial lophophorate commonly called a bryozoan.
- ectotherm (ek'-to-therm) An animal, such as a reptile (other than birds), fish, or amphibian, that must use environmental energy and behavioral adaptations to regulate its body temperature.
- ectothermic Referring to organisms that do not produce enough metabolic heat to have much effect on body temperature.
- Ediacaran fauna Earliest generally accepted animal fossils, dating from about 575 million years ago.
- effective population size An estimate of the size of a population based on the numbers of females and males that successfully breed; generally smaller than the total population.
- effector cell A muscle cell or gland cell that performs the body's responses to stimuli; responds to signals from the brain or other processing center of the nervous system.
- efferent arteriole The blood vessel draining a nephron.
- egg-polarity gene Another name for a maternal effect gene, a gene that helps control the orientation (polarity) of the egg.
- ejaculation The propulsion of sperm from the epididymis through the muscular vas deferens, ejaculatory duct, and urethra.
- ejaculatory duct The short section of the ejaculatory route in mammals formed by the convergence of the vas deferens and a duct from the seminal vesicle. The ejaculatory duct transports sperm from the vas deferens to the urethra.
- elastic fiber A long thread made of the protein elastin. Elastic fibers provide a rubbery quality to the extracellular matrix that complements the nonelastic strength of collagenous fibers.
- electrocardiogram (ECG or EKG) A record of the electrical impulses that travel through cardiac muscle during the heart cycle.
- electrochemical gradient The diffusion gradient of an ion, representing a type of potential energy that accounts for both the concentration difference of the ion across a membrane and its tendency to move relative to the membrane potential.
- electrogenic pump An ion transport protein that generates voltage across a membrane, electromagnetic receptor A receptor of electromagnetic energy, such as visible light, electricity and magnetism.
- electromagnetic spectrum The entire spectrum of radiation ranging in wavelength from less than a nanometer to more than a kilometer.
- electron A subatomic particle with a single negative charge. One or more electrons move around the nucleus of an atom.
- electron microscope (EM) A microscope that focuses an electron beam through a specimen, resulting in resolving power a thousandfold greater than that of a light microscope. A transmission electron microscope (TEM) is used to study the internal structure of thin sections of cells. A scanning electron microscope (SEM) is used to study the fine details of cell surfaces.
- electron shell An energy level represented as the distance of an electron from the nucleus of an atom.
- electron transport chain A sequence of electron carrier molecules (membrane proteins) that shuttle electrons during the redox reactions that release energy used to make ATP.
- electronegativity The attraction of an atom for the electrons of a covalent bond.
- electroporation A technique to introduce recombinant DNA into cells by applying a brief electrical pulse to a solution containing

cells. The electricity creates temporary holes in the cells' plasma membranes, through which DNA can enter.

element Any substance that cannot be broken down to any other substance.

elicitor A molecule that induces a broad type of host defense response.

elimination The passing of undigested material out of the digestive compartment.

embryo New developing individual.

embryo sac (*em'-bre'-o*) The female

gametophyte of angiosperms, formed from the growth and division of the megasporangium into a multicellular structure with eight haploid nuclei.

embryonic lethal A mutation with a phenotype leading to death at the embryo or larval stage.

embryophyte Another name for land plants, recognizing that land plants share the common derived trait of multicellular, dependent embryos.

emergent properties New properties that emerge with each step upward in the hierarchy of life, owing to the arrangement and interactions of parts as complexity increases.

emigration The movement of individuals out of a population.

enantiomer (*en-art'-te-6-mer*) One of two molecules that are mirror images of each other, endangered species A species that is in danger of extinction throughout all or a significant portion of its range.

endemic species (*en-dem'-ik*) Species that are confined to a specific, relatively small geographic area.

endergonic reaction (*en-der-gon'-ik*) A non-spontaneous chemical reaction, in which free energy is absorbed from the surroundings.

endocrine gland (*en'-do-krin*) A ductless gland that secretes hormones directly into the interstitial fluid, from which they diffuse into the bloodstream.

endocrine system The internal system of chemical communication involving hormones, the ductless glands that secrete hormones, and the molecular receptors on or in target cells that respond to hormones; functions in concert with the nervous system to effect internal regulation and maintain homeostasis.

endocytosis (*en'-do-si-to'-sis*) The cellular uptake of macromolecules and particulate substances by localized regions of the plasma membrane that surround the substance and pinch off to form an intracellular vesicle.

endoderm (*en'-do-derrn*) The innermost of the three primary germ layers in animal embryos; lines the archenteron and gives rise to the liver, pancreas, lungs, and the lining of the digestive tract.

endodermis The innermost layer of the cortex in plant roots; a cylinder one cell thick that forms the boundary between the cortex and the vascular cylinder.

endomembrane system The collection of membranes inside and around a eukaryotic cell, related either through direct physical contact or by the transfer of membranous vesicles.

endometrium (*en'-do-me'-tre-um*) The inner lining of the uterus, which is richly supplied with blood vessels.

endomycorrhiza (*en'-do-my'-ko-ri'-zuh*) A type of mycorrhiza that, unlike ectomycorrhizae, does not have a dense mantle ensheathing the root. Instead, microscopic fungal hyphae extend from the root into the soil.

endomycorrhizal fungus A fungus that forms endomycorrhizae with plant roots.

endoparasite A parasite that lives within a host. **endoplasmic reticulum** (ER) (*en'-d6-plaz'-mik ruh-tik'-yu-lum*) An extensive membranous network in eukaryotic cells, continuous with the outer nuclear membrane and composed of ribosome-studded (rough) and ribosome-free (smooth) regions.

endorphin (*en-d6r'-fin*) Any of several hormones produced in the brain and anterior pituitary that inhibits pain perception.

endoskeleton A hard skeleton buried within the soft tissues of an animal, such as the spicules of sponges, the plates of echinoderms, and the bony skeletons of vertebrates.

endosperm A nutrient-rich tissue formed by the union of a sperm cell with two polar nuclei during double fertilization, which provides nourishment to the developing embryo in angiosperm seeds.

endospore A thick-coated, resistant cell produced within a bacterial cell exposed to harsh conditions.

endothelium (*en'-do-the'-le-um*) The innermost, simple squamous layer of cells lining the blood vessels; the only constituent structure of capillaries.

endotherm An animal, such as a bird or mammal, that uses metabolic heat to regulate body temperature.

endothermic Referring to organisms with bodies that are warmed by heat generated by metabolism. This heat is usually used to maintain a relatively stable body temperature higher than that of the external environment.

endotoxin A toxic component of the outer membrane of certain gram-negative bacteria that is released only when the bacteria die.

energetic hypothesis The concept that the length of a food chain is limited by the inefficiency of energy transfer along the chain.

energy The capacity to do work (to move matter against an opposing force).

energy coupling In cellular metabolism, the use of energy released from an exergonic reaction to drive an endergonic reaction.

energy level Any of several different states of potential energy for electrons in an atom.

enhancer A DNA segment containing multiple control elements that may be located far away from the gene it regulates.

enteric division Complex networks of neurons in the digestive tract, pancreas, and gallbladder, normally regulated by the sympathetic and parasympathetic divisions of the autonomic nervous system.

enterocoelous (*en'-ter-o-se'-lus*) Pattern of formation of the body cavity common in deuterostomes, development, in which the mesoderm buds from the wall of the archenteron and hollows, forming the body cavity.

entropy (*en'-truh-pe*) A quantitative measure of disorder or randomness, symbolized by *S*.

enzymatic hydrolysis The process in digestion that splits macromolecules from food by the enzymatic addition of water.

enzyme (*en'-zim*) A protein serving as a catalyst, a chemical agent that changes the rate of a reaction without being consumed by the reaction.

enzyme-substrate complex A temporary complex formed when an enzyme binds to its substrate molecule(s).

eosinophil A type of white blood cell with low phagocytic activity that is thought to play a role in defense against parasitic worms by releasing enzymes toxic to these invaders.

epicotyl (*ep'-uh-cot'-ul*) In an angiosperm embryo, the embryonic axis above the point of attachment of the cotyledon(s).

epidermis (1) The dermal tissue system of non-woody plants, usually consisting of a single layer of tightly packed cells. (2) The outer covering of animals.

epididymis (*ep'-uh-did'-uh-mus*) A coiled tube located adjacent to the testes where sperm are stored.

epigenetic inheritance Inheritance of traits transmitted by mechanisms not directly involving the nucleotide sequence.

epiglottis A cartilaginous flap that blocks the top of the windpipe, the glottis, during swallowing, which prevents the entry of food or fluid into the respiratory system.

epinephrine A catecholamine hormone secreted from the adrenal medulla that mediates "fight-or-flight" responses to short-term stress; also functions as a neurotransmitter.

epiphyte (*ep'-uh-fit*) A plant that nourishes itself but grows on the surface of another plant for support, usually on the branches or trunks of tropical trees.

episome (*ep'-uh-som*) A genetic element that can exist either as a plasmid or as part of the bacterial chromosome.

epistasis A type of gene interaction in which one gene alters the phenotypic effects of another gene that is independently inherited, **epithalamus** A brain region, derived from the diencephalon, that contains several clusters of capillaries that produce cerebrospinal fluid.

epithelial tissue (*ep'-uh-the'-le-ul*) Sheets of tightly packed cells that line organs and body cavities.

Glossary

- epitope A small, accessible region of an antigen to which an antigen receptor or antibody binds; also called an antigenic determinant, equilibrium potential (E_{ion}) The magnitude of a cell's membrane voltage at equilibrium; calculated using the Nernst equation.
- erythrocyte (eh-rith'ro-sit) A red blood cell; contains hemoglobin, which functions in transporting oxygen in the circulatory system.
- erythropoietin (EPO) (eh-rith'rō-poy'uh-tin) A hormone produced in the kidney when tissues of the body do not receive enough oxygen. This hormone stimulates the production of erythrocytes.
- esophagus (eh-sof'uh-gus) A channel that conducts food, by peristalsis, from the pharynx to the stomach.
- essential amino acid An amino acid that an animal cannot synthesize itself and must be obtained from food. Eight amino acids are essential in the human adult.
- essential element In plants, a chemical element that is required for the plant to grow from a seed and complete the life cycle, producing another generation of seeds.
- essential fatty acids Certain unsaturated fatty acids that animals cannot make.
- essential nutrient A substance that an organism must absorb in preassembled form because it cannot be synthesized from any other material. In humans, there are essential vitamins, minerals, amino acids, and fatty acids.
- estivation (es'-tuh-vā'-shun) Summer torpor; a physiological state that is characterized by slow metabolism and inactivity and that permits survival during long periods of elevated temperature and diminished water supplies.
- estrogen (es'-tro-jen) Any steroid hormone, such as estradiol, that stimulates the development and maintenance of the female reproductive system and secondary sex characteristics.
- estrous cycle (es'-trüs) A type of reproductive cycle in all female mammals except higher primates, in which the nonpregnant endometrium is reabsorbed rather than shed, and sexual response occurs only during mid-cycle at estrus.
- estrus A period of sexual activity associated with ovulation.
- estuary The area where a freshwater stream or river merges with the ocean.
- ethology The study of animal behavior in natural conditions.
- ethylene (eth'-uh-leh) The only gaseous plant hormone. Among its many effects are response to mechanical stress, programmed cell death, leaf abscission, and fruit ripening.
- etiolation Plant morphological adaptations for growing in darkness.
- euchromatin (ū-kro'-muh-tin) The more open, unraveled form of eukaryotic chromatin that is available for transcription,
- eudicots (ū-di-kots) A clade consisting of the vast majority of flowering plants that have two embryonic seed leaves, or cotyledons.
- euglenid A protist, such as Euglena or its relatives, characterized by an anterior pocket, or chamber, from which one or two flagella emerge.
- Eukarya The domain that includes all eukaryotic organisms.
- eukaryotic cell (ū-kar-e-ōt'ik) A type of cell with a membrane-enclosed nucleus and membrane-enclosed organelles, present in protists, plants, fungi, and animals; also called eukaryote.
- eumetazoa (ū'-met-uh-zo'-uh-n) Member of the clade Eumetazoa, animals with true tissues (all animals except sponges).
- euryhaline Referring to organisms that can tolerate substantial changes in external osmolarity.
- eurypterid An extinct carnivorous cheliceriform also called a water scorpion.
- Eustachian tube The tube that connects the middle ear to the pharynx.
- etherian (u-thēr-e-un) Placental mammal; mammal whose young complete their embryonic development within the uterus, joined to the mother by the placenta.
- eutrophic lake A nutrient-rich and oxygen-poor lake, having a high rate of biological productivity.
- eutrophication A process by which nutrients, particularly phosphorus and nitrogen, become highly concentrated in a body of water, leading to increased growth of organisms such as algae. Cultural eutrophication refers to situations where the nutrients added to the water body originate mainly from human sources, such as agricultural drainage or sewage.
- evaporation The removal of heat energy from the surface of a liquid that is losing some of its molecules.
- evaporative cooling The property of a liquid whereby the surface becomes cooler during evaporation, owing to a loss of highly kinetic molecules to the gaseous state.
- evapotranspiration The evaporation of water from soil plus the transpiration of water from plants.
- evolution All the changes that have transformed life on Earth from its earliest beginnings to the diversity that characterizes it today.
- evolutionary adaptation An accumulation of inherited characteristics that enhance organisms' ability to survive and reproduce in specific environments.
- excitatory postsynaptic potential (EPSP) An electrical change (depolarization) in the membrane of a postsynaptic neuron caused by the binding of an excitatory neurotransmitter from a presynaptic cell to a postsynaptic receptor; makes it more likely for a postsynaptic neuron to generate an action potential.
- excretion The disposal of nitrogen-containing waste products of metabolism.
- exergonic reaction (ek'-ser-gon-ik) A spontaneous chemical reaction, in which there is a net release of free energy.
- exocytosis (ek'-so-si-tō-sis) The cellular secretion of macromolecules by the fusion of vesicles with the plasma membrane.
- exoenzyme A powerful hydrolytic enzyme secreted by a fungus outside its body to digest food.
- exon A coding region of a eukaryotic gene. Exons, which are expressed, are separated from each other by introns.
- exoskeleton A hard encasement on the surface of an animal, such as the shell of a mollusc or the cuticle of an arthropod, that provides protection and points of attachment for muscles.
- exotoxin (ek'-so-tok'-sin) A toxic protein that is secreted by a prokaryote and that produces specific symptoms even in the absence of the prokaryote.
- expansins Plant enzymes that break the cross-links (hydrogen bonds) between cellulose microfibrils and other cell wall constituents, loosening the wall's fabric.
- exponential population growth The geometric increase of a population as it grows in an ideal, unlimited environment.
- expression vector A cloning vector that contains the requisite prokaryotic promoter just upstream of a restriction site where a eukaryotic gene can be inserted.
- external fertilization The fusion of gametes that parents have discharged into the environment.
- exteroceptor A sensory receptor that detects stimuli outside the body, such as heat, light, pressure, and chemicals.
- extinction vortex A downward population spiral in which positive-feedback loops of inbreeding and genetic drift cause a small population to shrink and, unless reversed, become extinct.
- extracellular digestion The breakdown of food outside cells.
- extracellular matrix (ECM) The substance in which animal tissue cells are embedded, consisting of protein and polysaccharides.
- extraembryonic membranes Four membranes (yolk sac, amnion, chorion, allantois) that support the developing embryo in mammals and birds and other reptiles.
- extreme halophile A prokaryote that lives in a highly saline environment, such as the Great Salt Lake or the Dead Sea.
- extreme thermophile A prokaryote that thrives in hot environments (often 60–80°C or hotter).
- extremophile A prokaryote that lives in an extreme environment. Extremophiles include methanogens, extreme halophiles, and extreme thermophiles.
- F factor A fertility factor in bacteria; a DNA segment that confers the ability to form pili for conjugation and associated functions.

- required for the transfer of DNA from donor to recipient. It may exist as a plasmid or be integrated into the bacterial chromosome.
- F plasmid** The plasmid form of the F factor.
- F₁ generation** The first filial, or hybrid, offspring in a series of genetic crosses.
- F₂ generation** Offspring resulting from interbreeding of the hybrid F₁ generation.
- facilitator A** species that has a positive effect on the survival and reproduction of other species in a community and that contributes to community structure.
- facilitated diffusion** The spontaneous passage of molecules and ions, bound to specific carrier proteins, across a biological membrane down their concentration gradients.
- facultative anaerobe** (fak'-ü-tä-tiv an'-uh-roh) An organism that makes ATP by aerobic respiration if oxygen is present but that switches to fermentation under anaerobic conditions.
- family** In classification, the taxonomic category above genus.
- fast block to polyspermy** The depolarization of the egg membrane within 1–3 seconds after sperm binding to the vitelline layer. The reaction prevents additional sperm from fusing with the egg's plasma membrane.
- fast muscle fibers** Muscle cells used for rapid, powerful contractions.
- fat (triacylglycerol)** (tri-as'-ül-glis'-uh-rol) A biological compound consisting of three fatty acids linked to one glycerol molecule.
- fat map** Territorial diagram of embryonic development that reveals the future development of individual cells and tissues.
- fatty acid A** long carbon cKun (carboxylic acid). Fatty acids vary in length and in the number and location of double bonds; three fatty acids linked to a glycerol molecule form fat.
- feces** The wastes of the digestive tract.
- feedback inhibition** A method of metabolic control in which the end product of a metabolic pathway acts as an inhibitor of an enzyme within that pathway.
- fermentation** A catabolic process that makes a limited amount of ATP from glucose without an electron transport chain and that produces a characteristic end product, such as ethyl alcohol or lactic acid.
- fertilization** The union of haploid gametes to produce a diploid zygote.
- fertilization envelope** The swelling of the vitelline layer away from the plasma membrane.
- fetus** (fë'-tus) A developing human from the ninth week of gestation until birth; has all the major structures of an adult.
- fiber** A lignified cell type that reinforces the xylem of angiosperms and functions in mechanical support; a slender, tapered sclerenchyma cell that usually occurs in bundles.
- fibrin** (fibrin) The activated form of the blood-clotting protein fibrinogen, which aggregates into threads that form the fabric of the clot.
- fibrinogen** The inactive form of the plasma protein that is converted to the active form fibrin, which aggregates into threads that torn the framework of a blood clot.
- fibroblast** (fi'-bro-blast) A type of cell in loose connective tissue that secretes the protein ingredients of the extracellular fibers.
- fibronectin** A glycoprotein that binds cell? attach to the extracellular matrix.
- fibrous connective tissue** A dense tissue with large numbers of collagenous fibers organized into parallel bundles. This is the dominant tissue in tendons and ligaments.
- fibrous root system** A root system common to monocots consisting of a mat of thin roots spreading out below the soil surface.
- filament** The stalk of a stamen.
- filtrate** Fluid extracted by the excretory system from the body fluid. The excretory system produces urine from the filtrate after extracting valuable solutes from it and concentrating it.
- filtration** The extraction of water and small solutes, including metabolic wastes, from the body fluid into the excretory system.
- fimbria** (plural, fimbriae) A short, hairlike prokaryotic appendage that functions in adherence to the substrate or to other cells.
- first law of thermodynamics** The principle of conservation of energy. Energy can be transferred and transformed, but it cannot be created or destroyed.
- fission** The separation of a parent into two or more individuals of approximately equal size.
- fitness** The contribution an individual makes to the gene pool of the next generation, relative to the contributions of other individuals.
- fixed action pattern (FAP)** A sequence of behavioral acts that is "essent," "unchangeable and usually carried to completion once initiated.
- flaccid (Has"-ü-a)** Limp. A walled cell is flaccid in surroundings where there is no tendency for water to enter.
- flagellum** (fluh-jel'-üm") (plural, flagella) A long cellular appendage specialized for locomotion. The flagella of prokaryotes and eukaryotes differ in both structure and function.
- florigen** A flowering signal, not yet chemically identified, that may be a hormone or may be a change in relative concentrations of multiple hormones.
- flower** In an angiosperm, a short stem with up to four sets of modified leaves, bearing structures that function in sexual reproduction.
- fluid feeder** An animal that lives by sucking nutrient-rich fluids from another living organism.
- fluid mosaic model** The currently accepted model of cell membrane structure, which envisions the membrane as a mosaic of individual protein molecules drifting laterally in a fluid bilayer of phospholipids.
- follicle** (fö'l-uh-kü'l) A microscopic structure in the ovary that contains the developing ovum and secretes estrogens.
- follicle-stimulating hormone (FSH)** A trophic hormone produced and secreted by the anterior pituitary that stimulates the production of eggs by the ovaries and sperm by the testes.
- follicular phase** That part of the ovarian cycle during which follicles are growing and oocytes maturing.
- food chain** The pathway along which food is transferred from trophic level to trophic level, beginning with producers.
- food vacuole** A membranous sac formed by phagocytosis.
- food web** The elaborate, interconnected feeding relationships in an ecosystem.
- foot** (1) The portion of a bryophyte sporophyte that gathers sugars, amino acids, water, and minerals from the parent gametophyte via transfer cells. (2) One of the three main parts of a mollusc; a muscular structure usually used for movement.
- foraging** Behavior necessary to recognize, search for, capture, and consume food.
- foraminiferan (foram)** An aquatic protist that secretes a hardened shell containing calcium carbonate and extends pseudopodia through pores in the shell.
- forebrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into the rhalamus, hypothalamus, and cerebrum.
- fossil** (1) A preserved remnant or impression of an organism that lived in the past.
- fossil record** The chronicle of evolution over millions of years of geologic time engraved in the order in which fossils appear in rock strata.
- founder effect** Genetic drift that occurs when a few individuals become isolated from a larger population, with the result that the new population's gene pool is not reflect*i* of the original population.
- fovea** (fo've-uh) An eye center of focus and the place on the retina where photoreceptors are highly concentrated.
- fragmentation** A means of asexual reproduction whereby a single parent breaks into parts that regenerate into whole new individuals.
- frameshift mutation** A mutation occurring when the number of nucleotides inserted or deleted is not a multiple of three, resulting in the improper grouping of the following nucleotides into codons.
- free energy** The portion of a system's energy that can perform work when temperature and pressure are uniform throughout the system. The change in free energy of a system is calculated by the equation $\Delta G = \Delta H - \Delta S \cdot T$, where T is absolute temperature.

Glossary

- free energy of activation The amount of energy that reactants must absorb before a chemical reaction will start; also called activation energy.
- frequency-dependent selection A decline in the reproductive success of a morph resulting from the morphs phenotype becoming LOO common in a population; a cause of balanced polymorphism in populations.
- fruit A mature ovary of a flower that protects dormant seeds and aids in their dispersal.
- functional group A specific configuration of atoms commonly attached to the carbon skeletons of organic molecules and usually involved in chemical reactions.
- Fungi (fūn'jē) The eukaryotic kingdom that include^a organisms that absorb nutrients after decomposing organic material.
- fusiform initials Cells within the vascular cambium that produce elongated cells such as tracheids, vessel elements, fibers, and sieve-tube members.
- G protein A GTP-binding protein that relays signals from a plasma membrane signal receptor, known as a G-protein-Kinase receptor, to other signal transduction proteins inside the cell. When such a receptor is activated, it in turn activates the G protein, causing it to bind a molecule of GTP in place of GDP. Hydrolysis of the bound GTP to GDP inactivates the G protein.
- G₀ phase A nondividing state in which a cell has left the cell cycle.
- G₁ phase The first growth phase of the cell cycle, consisting of the portion of interphase before DNA synthesis begins.
- G₂ phase The second growth phase of the cell cycle, consisting of the portion of interphase after DNA synthesis occurs.
- gallbladder An organ that stores bile and releases it as needed into the small intestine.
- gametangium (gam'-uh-tan'-jē-um) (plural, gametangia) Multicellular plant structures in which gametes are formed. Female gametangia are called archegonia, and male gametangia are called antheridia.
- gamete (gam'-ēt) A haploid cell, such as an egg or sperm. Gametes unite during sexual reproduction to produce a diploid zygote.
- game theory An approach to evaluating alternative strategies in situations where the outcome depends not only on each individual's strategy but also on the strategies of other individuals; a way of thinking about behavioral evolution in situations where the fitness of a particular behavioral phenotype is influenced by other behavioral phenotypes in the population.
- gametogenesis The process by which gametes are produced in the mammalian body.
- gametophore The mature gamete-producing structure of a gametophyte body of a moss.
- gametophyte (guh-mē'-tō-fit) In organisms undergoing alternation of generations, the multicellular haploid form that mitotically produce? ;i:ploid gametes that unite and grow into the sporophyte generatior.
- gamma aminobutyric acid (GABA) An amino acid that functions as a CNS neurotransmitter ganglion (gāl'-jōn) (singular, ganglion) A cluster (functional group) of nerve cell bodies in a centralized nervous system.
- ganglion cell A type of neuron in the retina that synapses with bipolar cells and transmits action potentials to the brain via axons in the optic nerve.
- gap junction A type of intercellular junction in animal cells that allow? the passage of maleial or current between cells.
- gas exchange The uptake of molecular oxygen from the environment and the discharge of carbon dioxide to the environment.
- gastric juice A digestive fluid seemed by the stomach.
- gas trovascular cavity An extensive pouch that serves as the site of extracellular digestion and a pasageway to disperse materials throughout most of an animal? bod.
- gasimila (gas'-trū-hib) The three-la-ered, cup-shaped embryonic stage.
- gastrulation vgas'-iru-la-shurō the formation of a gastrula from a blastula.
- gated channel A protein channel in a cell membrane that opens or closes in response to a particular stimulus.
- gated ion channel A gated channel fo" a specific ion. When ion channels are opened or c/oied, the membrane potential of the cell is altered.
- gel electrophoresis (e-lek'-tro-for-e-sis) The separation of nucleic acids or proteins, on the basis of their size and electrical charge, by measuring their rate of movement through an electrical field in a gel.
- gene A discrete unit of hereditary information Consisting of a specific nucleotide sequence in DNA (or RNA, in some viruses).
- gene cloning The production of multiple copies of a gene.
- gene flow Genetic additions to or subtractions from a population resulting from the movement of fertile individuals or gametes.
- gene-for-gene recognition A widespread form of plant disease resistance involving recognition of pathogen-derived molecules by the protein products of specific plant disease resistance genes.
- gene pool The total aggregate of genes in a population at any one time.
- gene therapy The alteration of the genes of a person afflicted with a genetic disease.
- genetic annealing The production of a new genome through the transfer of part of the genome of one organism 'anoihé' organism.
- genetic drift Unpredictable fluctuations in allele frequencies from one generation to the next because of a populations finite size.
- genetic engineering The direct manipulation of genes for practical purposes.
- genetic map An ordered list of genetic loci (genes or other genetic markers)^a along a chromosome.
- genetic polymorphism The existence of two or more distinct alleles at a given locus in a population's gene pool.
- genetic recombination General term for the production of offspring that combine traits of the two parents.
- genetically modified (GM) organism An organism that has acquired one or more genes by artificial means; also known as a transgenic organism.
- genetics The scientific study of heredity and hereditary variation.
- genome (je'-nōm) The complete complement of an organism's genes; an organism's genetic material.
- genomic imprinting Phenomenon in which expression of an allele in offspring depends on whether the allele is inherited from the male or female parent.
- genomic library A set of thousand? of DNA segments from a genome, each carried by a plasmid, phage, or other cloning vector.
- genomics (jeh-no'-miks) The study of whoie sets of genes and their interactions.
- genotype (je-no-tip) The genetic makeup, or set of alleles, of an organism.
- genus (jē-nus) (plural, genera) A taxonomic category above the species level, designated by the first word of a species' two-part scientific name.
- geographic variation Differences between the gene pools of separate populations or population subgroups.
- geologic record The division of Earths history into time periods, grouped into three eras: Archaean, Proterozoic, and Phanerozoic, and further subdivided into eras and epochs.
- geometric isomer One of several organic compounds that have the same molecular formula but differ in the spatial arrangements of their atoms.
- germ layers Three main layers that form the various tissues and organs of an animal body.
- gestation (jes-tā'-shun) Pregnancy; the state of carrying developing young within the female reproductive tract.
- giberellins (jib'-uh-rell'-inz) A class of related plant hormones that stimulate growth in the stem and leaves, trigger the germination of seeds and breaking of bud dormancy and stimulate fruit development with auxin.
- gill A localized extension of the body surface of many aquatic animals, specialized for gas exchange.
- gill circulation The flow of blood through gills.
- glandular epithelium An epithelium that absorbs or secretes chemical solutions.
- glans penis The head end of the penis.
- glia Supporting cells that are essential for the structural integrity of the nervous system and for the normal functioning of neurons.

glomeromycete Member of the fungal phylum GLomeromycota, characterized by forming a distinct branching form of ectomycorrhizae (symbiotic relationships with plant roots) called arbuscular mycorrhizae.

glomerulus (glo-mar'-u-lus) A ball of capillaries surrounded by Bowman's capsule in the nephron and serving as the site of filtration in the vertebrate kidney.

glucagon (glü'-kuh-gon) A hormone secreted by pancreatic alpha cells that raises blood glucose levels. It promotes glycogen breakdown and release of glucose by the liver.

glucocorticoid A steroid hormone secreted by the adrenal cortex that influences glucose metabolism and immune function.

glutamate An amino acid that functions as a CNS neurotransmitter.

glyceraldehyde-3-phosphate (G3P) (gli'-er-al'-de-hid) The carbohydrate produced directly from the Calvin cycle.

glycine (gli'-sen) An amino acid that functions as a CNS neurotransmitter.

glycogen (gt'-kō-jen) An extensively branched α -D-glucose storage polysaccharide found in the liver and muscle of animals; the animal equivalent of starch.

glycolipid A lipid covalently attached to a carbohydrate.

glycolysis (gli'-kol'-uh-sis) The splitting of glucose into pyruvate. Glycolysis is the one metabolic pathway that occurs in all living cells, serving as the starting point for Fermentation or aerobic respiration.

glycoprotein A protein covalently attached to a carbohydrate.

glycosidic linkage A covalent bond formed between two monosaccharides by a dehydration reaction.

gnathostome (nāl'-lhū-stom) Member of the vertebrate subgroup possessing jaws.

golden algae A chrysophyte; a typically unicellular, briaryletted alga with yellow and brown carotenoid pigments.

Golgi apparatus (gōl'-je) An organelle in eukaryotic cells consisting of stacks of flat membranous sacs that modify, store, and route products of the endoplasmic reticulum.

gonadotropin (go-nah-dō-tro'-pin) A hormone that stimulates the activities of the testes and ovaries. Follicle-stimulating hormone and luteinizing hormone are gonadotropins.

gonads (go'-nādz) The male and female sex organs; the gamete-producing organs in most animals.

G-protein-linked receptor A signal receptor protein in the plasma membrane that responds to the binding signal molecule by activating a G protein.

grade Group of animal species that share the π_{crit} level of organizational complexity.

graded potential A local voltage change in a neuron membrane induced by stimulation of a neuron, with strength proportional to the

strength of the stimulus and lasting about a millisecond.

gradualism A view of Earth's history that attributes profound change to the cumulative product of slow but continuous processes.

graft versus host reaction An attack against a patient's body cells by lymphocytes received in a bone marrow transplant.

gram-negative Describing the group of bacteria with a cell wall that is structurally more complex and contains less peptidoglycan than that of gram-positive bacteria. Gram-negative bacteria are often more toxic than gram-positive bacteria.

gram-positive Describing the group of bacteria with a cell wall that is structurally less complex and contains more peptidoglycan than that of gram-negative bacteria. Gram-positive bacteria are usually less toxic than gram-negative bacteria.

Gram stain A staining method that distinguishes between two different kinds of bacterial cell walls.

grana (gran'-urn) (plural, grana) A stacked portion of the thylakoid membrane in the chloroplast. Grana function in the light reactions of photosynthesis.

gravitropism (grav'-uh-tro'-pīsm¹): A response of a plant or animal to gravity.

gray crescent A ikru-gray region of cytoplasm located near the equator of line egg on the side opposite the sperm entry

gray matter Regions of dendrites and clusters of neuron cell bodies within the CNS.

green alga A unicellular, colonial, or multicellular photosynthetic protist that has grass-green chloroplasts. Green algae are closely related to true plants.

greenhouse effect The warming of planet Earth due to the atmospheric accumulation of carbon dioxide, which absorbs reflected infrared radiation and re-reflects some of it back toward Earth.

green world hypothesis The conjecture that terrestrial herbivores consume relatively little plant biomass because they are held in check by a variety⁷ of factors, including predators, parasites, and disease.

gross primary production (GPP) The total primary production of an ecosystem.

ground tissue system Plant tissues that are neither vascular nor dermal, fulfilling a variety of functions, such as storage, photosynthesis, and support.

growth cone Responsive region at the leading edge of a growing axon.

growth factor A protein that must be present in the extracellular environment (culture medium or animal body) for the growth and normal development of certain types of cells; a local regulator that acts on stem cells to stimulate cell proliferation and differentiation.

growth hormone (GH) A hormone produced and secreted by the anterior pituitary that

has both direct (nontropic) effects and tropic effects on a wide variety of tissues.

guard cells The two cells that flank the stomatal pore and regulate the opening and closing of the pore.

gustatory receptor Taste receptor.

guttation The exudation of water droplets, caused by root pressure in certain plants.

gymnosperm (jim'-no-sperm) A vascular plant that bears naked seeds—seeds not enclosed in specialized chambers.

habituation A very simple type of learning that involves a loss of responsiveness to stimuli that convey little or no information.

hair cell A type of mechanoreceptor that detects sound waves and other forms of movement in air or water.

half-life The number of years it takes for 50% of a sample of an isotope to decay.

Hamilton's rule The principle that for natural selection to favor an altruistic act, the benefit to the recipient, devalued by the coefficient of relatedness, must exceed the cost to the altruist.

haploid cell (hap'-loyd) A cell containing only one set of chromosomes (*n*).

Hardy-Weinberg equilibrium The condition describing a non-evolving population (one that is in genetic equilibrium).

Hardy-Weinberg theorem The principle that frequencies of alleles and genotypes in a population remain constant from generation to generation, provided that only Mendelian segregation and recombination of alleles are at work.

haustorium (plural, haustoria) In certain symbiotic fungi, specialized hyphae that can penetrate the tissues of host organisms.

heart A muscular pump that uses metabolic energy to elevate hydrostatic pressure of the blood. Blood then flows down a pressure gradient through blood vessels that eventually return blood to the heart.

heart attack The death of cardiac muscle tissue resulting from prolonged blockage of one or more coronary arteries.

heart murmur A hissing sound that occurs when blood squirts backward through a leaky valve in the heart.

heart rate The rate of heart contraction.

heartwood Older layers of secondary xylem, closer to the center of a stem or root, that no longer transport xylem sap.

heat The total amount of kinetic energy due to molecular motion in a body of matter. Heat is energy in its most random form.

heat of vaporization The quantity of heat a liquid must absorb for 1 g of it to be converted from the liquid to the gaseous state.

heat-shock protein A protein that helps protect other proteins during heat stress. Heat-shock proteins are found in plants, animals, and microorganisms.

- heavy chain** One of the two types of polypeptide chains that make up an antibody molecule and B cell receptor; consists of a variable region, which contributes to the antigen-binding site, and a constant region.
- helicase** An enzyme that untwists the double helix of DNA at the replication forks.
- helper T cell** A type of T cell that, when activated, secretes cytokines that promote the response of B cells (humoral response) and cytotoxic T cells (cell-mediated response) to antigens.
- hemocyanin** (he'-muhn-sT-uh-nin) A type of respiratory pigment that uses copper as its oxygen-binding component. Hemocyanin is found in the hemolymph of arthropods and many molluscs.
- hemoglobin** (he'-mo-glo-bin) An iron-containing protein in red blood cells that reversibly binds oxygen.
- hemolymph** In invertebrates with an open circulatory system, the body fluid that bathes tissues.
- hemophilia** A human genetic disease caused by a sex-linked recessive allele; characterized by excessive bleeding following injury.
- hepatic portal vein** A large circulatory channel that conveys nutrient-laden blood from the small intestine to the liver, which regulates the blood's nutrient content.
- herbaceous** Referring to nonwoody plants.
- herbivore** A heterotrophic animal that eats plants.
- herbivory** An interaction, in which an herbivore eats parts of a plant or afga.
- heredity** The transmission of traits from one generation to the next.
- hermaphrodite** (her-maf-ro-dit) An individual that functions as both male and female in sexual reproduction by producing both sperm and eggs.
- hermaphroditism** (her-maf-ro-di-tizm) A condition in which an individual has both female and male gonads and functions as both a male and female in sexual reproduction by producing both sperm and eggs.
- heterochromatin** (het'-er-o-kro'-muh-tin) Nontranscribed eukaryotic chromatin that is so highly compacted that it is visible with a light microscope during interphase.
- heterochrony** (het'-uh-rok'-ruh-ne) Evolutionary change in the timing or rate of an organism's development.
- heterocyst** (het'-er-o-sis) A specialized cell that engages in nitrogen fixation in some filamentous cyanobacteria.
- heterokaryon** A fungal mycelium formed by the fusion of two hyphae that have genetically different nuclei.
- heteromorphic** (het'-er-o-mor-fik) Referring to a condition in the life cycle of all living plants and certain algae in which the sporophyte and gametophyte generations differ in morphology.
- heteroporous** (het'-er-o'-por-us) A term referring to a plant species that has two kinds of spores: microspores that develop into male gametophytes and megasporangia that develop into female gametophytes.
- heterotroph** (het'-er-o-trof) An organism that obtains organic food molecules by eating other organisms or their by-products.
- heterozygote advantage** Greater reproductive success of heterozygous individuals compared to homozygotes; tends to preserve variation in gene pools.
- heterozygous** (het'-er-o-zf-gus) Having two different alleles for a given gene.
- hexapod** An insect or closely related wingless, six-legged arthropod.
- hibernation** A physiological state that allows survival during long periods of cold temperatures and reduced food supplies, in which metabolism decreases, the heart and respiration slow down, and body temperature is maintained at a lower level than normal.
- high-density lipoprotein (HDL)** A cholesterol-carrying particle in the blood, made tip of cholesterol and other lipids surrounded by a single layer of phospholipids in which proteins are embedded. An HDL particle carries less cholesterol than a related lipoprotein, LDL, and may be correlated with a decreased risk of blood vessel blockage.
- hindbrain** One of three ancestral and embryonic regions of the vertebrate brain, develops into the medulla oblongata, pons, and cerebellum.
- bistamine** (bis'-tuh-men) A substance released by mast cells that causes blood vessels to dilate and become more permeable during an inflammatory response.
- histone** (his'-ton) A small protein (\-tēn) that binds to the negatively charged DNA and plays a key role in its chromatin structure.
- histone acetylation** The attachment of acetyl groups to certain amino acids of histone proteins.
- HIV** (human immunodeficiency virus) The infectious agent that causes AIDS. HIV is a retrovirus.
- holdfast** A rootlike structure that anchors a seaweed.
- holoblastic cleavage** (ho'-lo-blas'-ik) A type of cleavage in which there is complete division of the egg, as in eggs having little yolk (sea urchin) or a moderate amount of yolk (frog).
- homeobox** ('ho'-le-o-hoks') A 180-nucleotide sequence within homeotic genes and some other developmental genes that is widely conserved in animals. Related sequences occur in plants and prokaryotes.
- homeostasis** (ho'-me-o'-sta'-sis) The steady-state physiological condition of the body.
- homeotic gene** (ho'-me-of-ik) Any of the genes that control the overall body plan of animals and plants by controlling the developmental fate of groups of cells.
- hominid** (hah'-mi-nid) A species on the human branch of the evolutionary tree; a member of the family Hominidae, including *homo sapiens* and our ancestors.
- hominoid** A term that refers to great apes and humans.
- homologous chromosomes** (ho-mol'-uh-gus) Chromosome pairs of the same length, centromere position, and staining pattern that possess genes for the same characters at corresponding loci. One homologous chromosome is inherited from the organism's father, the other from the mother.
- homologous structures** Structures in different species that are similar because of common ancestry.
- homology** (ho-mol'-uh-je) Similarity in characteristics resulting from a shared ancestry.
- homoplasy** Similar (analogous) structure or molecular sequence that has evolved independently in two species.
- homosporous** (ho-mos-por-us) A term referring to a plant species that has a single kind of spore, which typically develops into a bisexual gametophyte.
- homozygous** (ho'-mōz'-joo-sis) Having two identical alleles for a given gene.
- horizon** A distinct layer of soil, such as topsoil.
- horizontal cell** A neuron of the retina that helps integrate information before it is sent to the brain.
- hormone** In multicellular organisms, one of many types of circulating chemical signals that are formed in specialized cells, enter the body fluids, and act on specific target cells to change their functioning.
- hornwort** A small, herbaceous nonvascular plant that is a member of the phylum Anthocerophyta.
- host** The larger participant in a symbiotic relationship, serving as home and feeding ground to the symbiont.
- host range** The limited range of host cells that each type of virus can infect and parasitize.
- hutnan chorionic gonadotropin (HCG)** (kor'-e-on'-ik go-nab'-do-iro'-pin^ A hormone secreted by the chorion that maintains the corpus luteum of the ovary during the first three months of pregnancy.
- Human Genome Project** An international collaborative effort to map and sequence the DNA of the entire human genome.
- humoral immune response** (hyü'-mer-al) The branch of acquired immunity that involves the activation of B cells and that leads to the production of antibodies, which defend against bacteria and viruses in body fluids.
- humus** (hyü'-mus) Decomposing organic material found in topsoil.
- Huntington's disease** A human genetic disease caused by a dominant allele; characterized by uncontrolled body movements and degeneration of the nervous system; usually fatal 10 to 20 years after the onset of symptoms.

hybridization In genetics, the mating, or crossing, of two true-breeding varieties.

hydration shell The sphere of water molecules around each dissolved ion.

hydrocarbon An organic molecule consisting only of carbon and hydrogen.

hydrogen bond A type of weak chemical bond. Formed when the slightly positive hydrogen atom of a polar covalent bond in one molecule is attracted to the slightly negative atom of a polar covalent bond in another molecule.

hydrogen ion A single proton with a charge of +1. I. The dissociation of a water molecule (H_2O) leads to the generation of a hydroxide ion (OH^-) and a hydrogen ion (H^+).

hydrolysis (hl -drol'-uh-sis) A chemical process that lyzes, or splits, molecules by the addition of water.

hydrophilic (hT' -dro-fil'-ik) Having an affinity for water.

hydrophobic (hl -dro-fö'-bik) Having an aversion to water; tending to coalesce and form droplets in water.

hydrophobic interaction A type of weak chemical bond formed when molecules that do not mix with water coalesce to exclude the water.

hydroponic culture A method in which plants are grown without soil by using mineral solutions.

hydrostatic skeleton (hi '-dro-staf-ik) A skeletal system composed of fluid held under pressure in a closed body compartment; the main skeleton of most cnidarians, flatworms, nematodes, and annelids.

hydroxide ion A water molecule that has lost a proton; OH^- .

hydroxyl group (hl -drok'-sil) A functional group consisting of a hydrogen atom joined to an oxygen atom by a polar covalent bond. Molecules possessing this group are soluble in water and are called alcohols.

hymen A thin membrane that partly covers the vaginal opening in the human female. The hymen is ruptured by sexual intercourse or other vigorous activity.

hyperpolarization An electrical state in which the inside of the cell is more negative relative to the outside than at the resting membrane potential. A neuron membrane is hyperpolarized if a stimulus increases its voltage from the resting potential of -70 mV reducing the chance that the neuron will transmit a nerve impulse.

hypersensitive response (HR) A plants localized defense response to a pathogen.

hypertension Chronically high blood pressure within the arteries.

hypertonic In comparing two solutions, referring to the one with a greater solute concentration.

hypha (plural, **hyphae**) (hl '-fuh, hl '-fe) A filament that collectively makes up the body of a fungus.

hypocotyl (hl '-puh-cot'-ul) In an angiosperm embryo, the embryonic axis below the point of attachment of the cotyledon(s) and above the radicle.

hypothalamus (hi '-po-thal'-uh-mus) The ventral part of the vertebrate forebrain; functions in maintaining homeostasis, especially in coordinating the endocrine and nervous systems; secretes hormones of the posterior pituitary and releasing factors that regulate the anterior pituitary.

hypothesis A tentative answer to a well-framed question.

hypotonic In comparing two solutions, referring to the one with a lower solute concentration.

I band The area near the edge of the sarcomere where there are only thin filaments.

immigration The influx of new individuals from other areas.

immunization The process of generating a state of immunity by artificial means. In active immunization, a nonpathogenic version of a normally pathogenic microbe is administered, inducing B and T cell responses and immunological memory. In passive immunization, antibodies specific for a particular microbe are administered, conferring immediate but temporary protection. Also called vaccination.

immunoglobulin (Ig) (im '-u-no-glob'-u-lin)

Any of the class of proteins that function as antibodies. Immunoglobulins are divided into five major classes that differ in their distribution in the body and antigen disposal activities.

imperfect fungus See deuteromycete.

imprinting A type of learned behavior with a significant innate component, acquired during a limited critical period.

in vitro fertilization (ve '-tro) Fertilization of ova in laboratory containers followed by artificial implantation of the early embryo in the mother's uterus.

in vitro mutagenesis A technique to discover the function of a gene by introducing specific changes into the sequence of a cloned gene, reinserting the mutated gene into a cell, and studying the phenotype of the mutant-inclusive fitness The total effect an individual has on proliferating its genes by producing its own offspring and by providing aid that enables other close relatives to increase the production of their offspring.

incomplete dominance The situation in which the phenotype of heterozygotes is intermediate between the phenotypes of individuals homozygous for either allele.

incomplete flower A flower in which one or more of the four basic floral organs (sepals, petals, stamens, or carpels) are either absent or nonfunctional.

incomplete metamorphosis A type of development in certain insects, such as grasshoppers, in which the young (called

nymphs) resemble adults but are smaller and have different body proportions. The nymph goes through a series of molts, each time looking more like an adult, until it reaches full size.

incus The second of the three middle ear bones. indeterminate cleavage A type of embryonic development in deuterostomes, in which each cell produced by early cleavage divisions retains the capacity to develop into a complete embryo.

indeterminate growth A type of growth characteristic of plants, in which the organism continues to grow as long as it lives.

individualistic hypothesis The concept, put forth by H. A. Gleason, that a plant community is a chance assemblage of species found in the same area simply because they happen to have similar biotic requirements. induced fit The change in shape of the active site of an enzyme so that it binds more snugly to the substrate, induced by entry of the substrate.

inducer A specific small molecule that inactivates the repressor in an operon.

induction The ability of one group of embryonic cells to influence the development of another.

inductive reasoning A type of logic in which generalizations are based on a large number of specific observations.

infant mortality The number of infant deaths per 1,000 live births.

inflammatory response A localized innate immune defense triggered by physical injury or infection of tissue in which changes to nearby small blood vessels enhance the infiltration of white blood cells, antimicrobial proteins, and clotting elements that aid in tissue repair and destruction of invading pathogens; may also involve systemic effects such as fever and increased production of white blood cells.

inflorescence A group of flowers tightly clustered together.

ingestion A heterotrophic mode of nutrition in which other organisms or detritus are eaten whole or in pieces.

ingroup In a cladistic study of evolutionary relationships among taxa of organisms, the group of taxa that is actually being analyzed.

inhibitory postsynaptic potential (IPSP)

(post'-sin-ap'-tik) An electrical charge (hyperpolarization) in the membrane of a postsynaptic neuron caused by the binding of an inhibitory neurotransmitter from a presynaptic cell to a postsynaptic receptor; makes it more difficult for a postsynaptic neuron to generate an action potential.

initials Cells that remain within an apical meristem as sources of new cells.

innate behavior Behavior that is developmentally fixed and under strong genetic control. Innate behavior is exhibited in **virtually** the

- same form by all individuals in a population despite internal and external environmental differences during development and throughout their lifetimes.
- innate immunity** The kind of defense that is mediated by phagocytic cells, antimicrobial proteins, the inflammatory response, and natural killer (NK) cells. It is present before exposure to pathogens and is effective from the time of birth.
- inner cell mass** A cluster of cells in a mammalian blastocyst that protrudes into one end of the cavity and subsequently develops into the embryo proper and some of the extraembryonic membranes.
- inner ear** One of three main regions of the vertebrate ear; includes the cochlea, organ of Corti, and semicircular canals.
- inositol trisphosphate (IP₃)** (m-o'-suh-tol) A second messenger that functions as an intermediate between certain nonsteroid hormones and a third messenger, a rise in cytoplasmic Ca²⁺ concentration.
- inquiry** The search for information and explanation, often focused by specific questions.
- insertion A mutation** involving the addition of one or more nucleotide pairs to a gene.
- insertion sequence** The simplest kind of transposable element, consisting of inverted repeats of DNA flanking a gene for transposase, the enzyme that catalyzes transposition.
- insulin** (in'-su-lin) A hormone secreted by pancreatic beta cells that lowers blood glucose levels. It promotes the uptake of glucose by most body cells and the synthesis and storage of glycogen in the liver and also stimulates protein and fat synthesis.
- insulin-like growth factor A** hormone produced by the liver whose secretion is stimulated by growth hormone. It directly stimulates bone and cartilage growth.
- integral protein** Typically a transmembrane protein with hydrophobic regions that completely spans the hydrophobic interior of the membrane.
- integrated hypothesis** The concept, put forth by E. E. Clements, that a community is an assemblage of closely linked species, locked into association by mandatory biotic interactions that cause the community to function as an integrated unit, a sort of superorganism.
- integration** The interpretation of sensory signals within neural processing centers of the central nervous system.
- integrin** A receptor protein built into the plasma membrane that interconnects the extracellular matrix and the cytoskeleton.
- integument (in-teg'-u-ment)** Layer of sporophyte tissue that contributes to the structure of an ovule of a seed plant.
- integumentary system** The outer covering of a mammal's body, including skin, hair, and nails.
- intercalated disk** A specialized junction between cardiac muscle cells that provides direct electrical coupling between cells.
- imsriwwi Ga'-ttriB'-flli)** A protist that has antiviral or immune regulatory functions.
- interferon-a and interferon-p**, secreted by virus-infected cells, help nearby cells resist viral infection; interferon-y, secreted by T cells, helps activate macrophages.
- intermediate disturbance hypothesis** The concept that moderate levels of disturbance can foster greater species diversity than low or high levels of disturbance.
- intermediate filament** A component of the cytoskeleton that includes all filaments intermediate in size between microtubules and microfilaments.
- internal fertilization** Reproduction in which sperm are typically deposited in or near the female reproductive tract and fertilization occurs within the tract.
- interneuron (in'-ter-nur'-on)** An association neuron; a nerve cell within the central nervous system that forms synapses with sensory and motor neurons and integrates sensory input and motor output.
- internode** A segment of a plant stem between the points where leaves are attached.
- interparity** A life history in which adults produce large numbers of offspring over many years; also known as repeated reproduction.
- interreceptor** A sensory receptor that detects stimuli within the body, such as blood pressure and body position.
- interphase** The period in the cell cycle when the cell is not dividing. During interphase, cellular metabolic activity is high, chromosomes and organelles are duplicated, and cell size may increase. Interphase accounts for 90% of the cell cycle.
- intersexual selection** Selection whereby individuals of one sex (usually females) are choosy in selecting their mates from individuals of the other sex; also called mate choice.
- interspecific competition** Competition for resources between plants, between animals, or between decomposers when resources are in short supply.
- interspecific interaction** Relationships between species of a community.
- interstitial fluid** The internal environment of vertebrates, consisting of the fluid filling the spaces between cells.
- intertidal zone** The shallow zone of the ocean where land meets water.
- intracellular digestion** The joining of food vacuoles and lysosomes to allow chemical digestion to occur within the cytoplasm of a cell.
- intrasexual selection** A direct competition among individuals of one sex (usually the males in vertebrates) for mates of the opposite sex.
- introduced species** A species moved by humans, either intentionally or accidentally, from its native location to a new geographic region; also called an exotic species.
- intron (in'-tron)** A noncoding, intervening sequence within a eukaryotic gene.
- invagination** The infolding of cells.
- invasive species** A species that takes hold outside of its native range; usually introduced by humans.
- inversion** An aberration in chromosome structure resulting from reattachment in a reverse orientation of a chromosomal fragment to the chromosome from which the fragment originated.
- invertebrate** An animal without a backbone. Invertebrates make up 95% of animal species.
- involution** Cells rolling over the edge of the lip of the blastopore into the interior of the embryo during gastrulation.
- ion (i'-on)** An atom that has gained or lost electrons, thus acquiring a charge.
- ion channel** Protein channel in a cell membrane that allows passage of a specific ion down its concentration gradient.
- ionic bond (i-on'-ik)** A chemical bond resulting from the attraction between oppositely charged ions.
- ionic compound** A compound resulting from the formation of an ionic bond; also called a salt.
- islets of Langerhans** Clusters of endocrine cells within the pancreas that produce and secrete the hormones glucagon (alpha cells) and insulin (beta cells).
- isomer (i'-so-mer)** One of several organic compounds with the same molecular formula but different structures and therefore different properties. The three types of isomers are structural isomers, geometric isomers, and enantiomers.
- isomorphic** Referring to alternating generations in plants and certain algae in which the sporophytes and gametophytes look alike, although they differ in chromosome number.
- isopod** A member of one of the largest groups of crustaceans, which includes terrestrial, freshwater, and marine species. Among the terrestrial isopods are the pill bugs, or wood lice.
- isotonic (I'-so-ton'-ik)** Having the same solute concentration as another solution.
- isotope (r-so-top)** One of several atomic forms of an element, each containing a different number of neutrons and thus differing in atomic mass.
- jasmionic acid** An important molecule in plant defense against herbivores.
- joule (J)** A unit of energy: $1 \text{ J} = 0.239 \text{ cal}$; $1 \text{ cal} = 4.184 \text{ J}$.
- juvenile hormone** A hormone in arthropods, secreted by the corpora allata glands, that promotes the retention of larval characteristics.

- juxtaglomerular apparatus (JGA)** (juks'-uh-gluh-mar-u-lər) A specialized tissue that releases the enzyme renin when blood pressure or blood volume drops in the afferent arterioles that supplies blood to the glomerulus.
- juxtamedullary nephrons** Nephrons with well-developed loops of Henle that extend deeply into the renal medulla.
- karyogamy** (kar'-e-ōg'-uh-mē) The fusion of nuclei of two cells, as part of syngamy.
- karyotype** (kar'-e-o-tüp) A display of the chromosome pairs of a cell arranged by size and shape.
- keystone species** A species that is not necessarily abundant in a community yet exerts strong control on community structure by the nature of its ecological role or niche.
- kilocalorie (kcal)** A thousand calories; the amount of heat energy required to raise the temperature of 1 kg of water by PC.
- kin selection** A phenomenon of inclusive fitness, used to explain altruistic behavior between related individuals.
- kinesis** (kuh-ne'-sis) A change in activity or turning rate in response to a stimulus.
- kinetic energy** (kuh-net'-ik) The energy of motion, which is directly related to the speed of that motion. Moving matter does work by imparting motion to other matter.
- kinetochore** (kuh-net'-uh-kor) A specialized region on the centromere that links each sister chromatid to the mitotic spindle.
- kinetoplastid** A protist, such as *Trypanosoma*, which has a single large mitochondrion that houses extranuclear DNA.
- kingdom** A taxonomic category, the second broadest after domain.
- K-selection** The concept that in certain (K-selected) populations, life history is centered around producing relatively few offspring that have a good chance of survival.
- labia majora** A pair of thick, fatty ridges that enclose and protect the labia minora and vestibule.
- labia minora** A pair of slender skin folds that enclose and protect the vestibule.
- labor** A series of strong, rhythmic contractions of the uterus that expel a baby out of the uterus and vagina during childbirth.
- lactation** The continued production of milk.
- lacteal** (lak'-te-al) A tiny lymph vessel extending into the core of an intestinal villus and serving as the destination for absorbed chylomicrons.
- lactic acid fermentation** The conversion of pyruvate to lactate with no release of carbon dioxide.
- lagging strand** A discontinuously synthesized DNA strand that elongates in a direction away from the replication fork.
- lancelet** Member of the subphylum Cephalochordata, small blade-shaped marine chordates that lack a backbone.
- landmark** A point of reference for orientation during navigation.
- landscape** Several different, primarily terrestrial ecosystems linked by exchanges of energy, materials and organisms.
- landscape ecology** The study of past, present, and future patterns of landscape use, as well as ecosystem management and the biodiversity of interacting ecosystems.
- large intestine (colon)** (ko'-len) The tubular portion of the vertebrate alimentary tract between the small intestine and the anus; functions mainly in water absorption and the formation of feces.
- larva** (lar'-vuh) (plural, larvae) A free-living, sexually immature form in some animal life cycles that may differ from the adult in morphology, nutrition, and habitat.
- larynx** (lar'-inks) The voice box, containing the vocal cords.
- lateral geniculate nuclei** The destination in the thalamus for most of the ganglion cell axons that form the optic nerves.
- lateral inhibition** A process that sharpens the edges and enhances the contrast of a perceived image by inhibiting receptors lateral to those that have responded to light.
- lateralization** Segregation of functions in the cortex of the left and right hemispheres of the brain.
- lateral line system** A mechanoreceptor system consisting of a series of pores and receptor units (neuromasts) along the sides of the body in fishes and aquatic amphibians; detects water movements made by the animal itself and by other moving objects.
- lateral meristem** (mər'-uh-stəm) A meristem that thickens the roots and shoots of woody plants. The vascular cambium and cork cambium are lateral meristems.
- lateral root** A root that arises from the outermost layer of the pericycle of an established root.
- law of independent assortment** Mendel's second law, stating that each pair of alleles segregates independently during gamete formation; applies when genes for two characters are located on different pairs of homologous chromosomes.
- law of segregation** Mendel's first law, stating that each allele in a pair separates into a different gamete during gamete formation.
- leading strand** The new continuous complementary DNA strand synthesized along the template strand in the mandatory 5' → 3' direction.
- leaf** The main photosynthetic organ of vascular plants.
- leaf primordia** Fingerlike projections along the flanks of a shoot apical meristem, from which leaves arise.
- leaf trace** A small vascular bundle that extends from the vascular tissue of the stem through the petiole and into a leaf,
- learning** A behavioral change resulting from experience.
- lens** The structure in an eye that focuses light rays onto the retina.
- lenticels** Small raised areas in the bark of stems and roots that enable gas exchange between living cells and the outside air.
- lepidosaur** Member of the reptilian group that includes lizards, snakes, and two species of New Zealand animals called tuatara.
- leukocyte** (lu'-ko-sit) A white blood cell; typically functions in immunity, such as phagocytosis or antibody production.
- Leydig cell** A cell that produces testosterone and other androgens and is located between the seminiferous tubules of the testes.
- lichen** (li'-ken) The symbiotic collective formed by the mutualistic association between a fungus and a photosynthetic alga or cyanobacterium.
- life cycle** The generation-to-generation sequence of stages in the reproductive history of an organism.
- life expectancy at birth** The predicted average length of life at birth.
- life history** The series of events from birth through reproduction and death.
- life table** A table of data summarizing mortality in a population.
- ligament** A type of fibrous connective tissue that joins bones together at joints.
- ligand** (lig'-uhnd) A molecule that binds specifically to a receptor site of another molecule.
- ligand-gated ion channel** A protein pore in the plasma membrane that opens or closes in response to a chemical signal, allowing or blocking the flow of specific ions.
- light chain** One of the two types of polypeptide chains that make up an antibody molecule and B cell receptor; consists of a variable region, which contributes to the antigen-binding site, and a constant region.
- light-harvesting complex** Complex of proteins associated with pigment molecules (including chlorophyll *a*, chlorophyll *b*, and carotenoids) that captures light energy and transfers it to reaction-center pigments in a photosystem.
- light microscope (LM)** An optical instrument with lenses that refract (bend) visible light to magnify images of specimens.
- light reactions** The steps in photosynthesis that occur on the thylakoid membranes of the chloroplast and that convert solar energy to the chemical energy of ATP and NADPH, evolving oxygen in the process.
- lignin** (lig'-nīn) A hard material embedded in the cellulose matrix of vascular plant cell walls that functions as an important adaptation for support in terrestrial species.
- limbic system** (lim'-bik) A group of nuclei (clusters of nerve cell bodies) in the lower part of the mammalian forebrain that interact with the cerebral cortex in determining

Glossary

- emotions; includes the hippocampus and the amygdala.
- limiting nutrient** An element that must be added for production to increase in a particular area.
- limnetic zone** In a lake, the well-lit, open surface waters farther from shore.
- linkage map** A genetic map based on the frequencies of recombination between markers during crossing over of homologous chromosomes.
- linked genes** Genes located close enough together on a chromosome to be usually inherited together.
- lipid** (lip'īd) One of a family of compounds, including fats, phospholipids, and steroids, that are insoluble in water.
- littoral zone** In a lake, the shallow, well-lit waters close to shore.
- liver** The largest organ in the vertebrate body. The liver performs diverse functions, such as producing bile, preparing nitrogenous wastes for disposal, and detoxifying poisonous chemicals in the blood.
- liverwort** A small, herbaceous nonvascular plant that is a member of the phylum Hepatophyta.
- loam** The most fertile of all soils, made up of roughly equal amounts of sand, silt, and clay.
- lobe-fin** Member of the vertebrate subgroup Sarcopterygii, osteichthys with rod-shaped muscular fins, including coelacanths and lungfishes, as well as the lineage that gave rise to tetrapods.
- local regulator** A chemical messenger that influences cells in the vicinity.
- locomotion** Active movement from place to place.
- locus** (lo'kus) (plural, loci) A specific place along the length of a chromosome where a given gene is located.
- logistic population growth** A model describing population growth that levels off as population size approaches carrying capacity.
- long-day plant** A plant that flowers (usually in late spring or early summer) only when the light period is longer than a critical length.
- long-term memory** The ability to hold, associate, and recall information over one's life.
- long-term potentiation (LTP)** An enhanced responsiveness to an action potential (nerve signal) by a receiving neuron.
- loop of Henle** The long hairpin turn, with a descending and ascending limb, of the renal tubule in the vertebrate kidney; functions in water and salt reabsorption.
- loose connective tissue** The most widespread connective tissue in the vertebrate body. It binds epithelia to underlying tissues and functions as packing material, holding organs in place.
- lophophore** (lof'uh-for) A horseshoe-shaped or circular fold of the body wall bearing ciliated tentacles that surround the mouth.
- lophotrochozoan** Member of a group of animal phyla with protostome development that some systematists hypothesize form a clade, characterized by lophophores or trophophore larvae.
- low-density lipoprotein (LDL)** A cholesterol-carrying particle in the blood, made up of cholesterol and other lipids surrounded by a single layer of phospholipids in which proteins are embedded. An LDL particle carries more cholesterol than a related lipoprotein, HDL, and high LDL levels in the blood correlate with a tendency to develop blocked blood vessels and heart disease.
- lung** An invaginated respiratory surface of terrestrial vertebrates, land snails, and spiders that connect to the atmosphere by narrow tubes.
- luteal phase** That portion of the ovarian cycle during which endocrine cells of the corpus luteum secrete female hormones.
- luteinizing hormone (LH)** (lu'tē-uh-mī'zing) A tropic hormone produced and secreted by the anterior pituitary that stimulates ovulation in females and androgen production in males.
- lycophyte** An informal name for any member of the phylum Lycophyta, which includes club mosses, spike mosses, and quillworts.
- lymph** The colorless fluid, derived from interstitial fluid, in the lymphatic system of vertebrate animals.
- lymph node** Organ located along a lymph vessel. Lymph nodes filter lymph and help attack viruses and bacteria.
- lymphatic system** A system of vessels and lymph nodes, separate from the circulatory system, that returns fluid, proteins, and cells to the blood.
- lymphocyte** A type of white blood cell that mediates acquired immunity. Lymphocytes that complete their development in the bone marrow are called B cells, and those that mature in the thymus are called T cells.
- lysogenic cycle** (lī'sō-jen'ik) A phage replication cycle in which the viral genome becomes incorporated into the bacterial host chromosome as a prophage and does not kill the host.
- lysosome** (lī'sō-sōm) A membrane-enclosed organelle of hydrolytic enzymes found in the cytoplasm of eukaryotic cells.
- lysozyme** (lī'sō-zim') An enzyme in sweat, tears, and saliva that attacks bacterial cell walls.
- lytic cycle** (lit'ik) A type of viral (phage) replication cycle resulting in the release of new phages by lysis (and death) of the host cell.
- M phase** See mitotic (M) phase.
- macrochromate** Large-scale variations in climate; the climate of an entire region.
- macroevolution** Evolutionary change above the species level, including the appearance of major evolutionary developments, such as flight, that we use to define higher **taxa**.
- macromolecule** A giant molecule formed by the joining of smaller molecules, usually by a condensation reaction. Polysaccharides,
- proteins, and nucleic acids are macromolecules.
- macronutrient** A chemical substance that an organism must obtain in relatively large amounts. *See also micronutrient.*
- macrophage** (mak'-ro-fāj) A phagocytic cell present in many tissues that functions in innate immunity by **destroying** microbes and in acquired immunity as an antigen-presenting cell.
- magnetic reversal** A reversal of the polarity of Earth's magnetic field.
- magnoliids** A flowering plant clade that evolved later than basal angiosperms but before monocots and eudicots. Extant examples are magnolias, laurels, and black pepper plants.
- major depression** Depressive mental illness characterized by experiencing a low mood most of the time.
- major histocompatibility complex (MHC)** A family of genes that encode a large set of cell surface proteins called MHC molecules. Class I and class II MHC molecules function in antigen presentation to T cells. Foreign MHC molecules on transplanted tissue can trigger T cell responses that may lead to rejection of the transplant.
- malignant tumor** A cancerous tumor that is invasive enough to impair the functions of one or more organs.
- malleus** The first of the three middle ear bones.
- malnourished** Referring to an animal whose diet is missing one or more essential nutrients.
- Malpighian tubule** (mal-pig'ē-un) A unique excretory organ of insects that empties into the digestive tract, removes nitrogenous wastes from the hemolymph, and functions in osmoregulation.
- mammal** Member of the class Mammalia, amniotes with mammary glands that produce milk.
- mammary glands** Exocrine glands that secrete milk to nourish the young. These glands are characteristic of mammals.
- mandible** One of a pair of jaw-like feeding appendages found in myriapods, hexapods, and crustaceans.
- mantle** A fold of tissue in molluscs that drapes over the visceral mass and may secrete a shell.
- mantle cavity** A water-filled chamber that houses the gills, anus, and excretory pores of a mollusc.
- map unit** A unit of measurement of the distance between genes. One map unit is equivalent to a 1% recombination frequency.
- marine benthic zone** The ocean floor.
- mark-recapture method** A sampling technique used to estimate wildlife populations.
- marsupial** (mar-su'-pe-ul) A mammal, such as a koala, kangaroo, or opossum, whose young complete their embryonic development inside a maternal pouch called the marsupium.

mass number The sum of the number of protons and neutrons in an atom's nucleus.

mast cell A vertebrate body cell that produces histamine and other molecules that trigger the inflammatory response.

mate choice copying Behavior in which individuals in a population copy the mate choice of others, apparently as a result of social learning.

maternal effect gene A gene that, when mutant in the mother, results in a mutant phenotype in the offspring, regardless of the genotype.

matter Anything that takes up space and has mass.

maximum likelihood A principle that states that when considering multiple phylogenetic hypotheses, one should take into account the one that reflects the most likely sequence of evolutionary events, given certain rules about how DNA changes over time.

maximum parsimony A principle that states that when considering multiple explanations for an observation, one should first investigate the simplest explanation that is consistent with the facts.

mechanoreceptor A sensor that detects physical deformations in the body's environment associated with pressure, touch, stretch, motion, and sound.

medulla oblongata The lowest part of the vertebrate brain, commonly called the medulla; a swelling of the hindbrain dorsal to the anterior spinal cord that controls autonomic, homeostatic functions, including breathing, heart and blood vessel activity, swallowing, digestion, and vomiting.

medusa (muh-doo'-suh) The floating, flattened, mouth-down version of the cnidarian body plan. The alternate form is the polyp.

megapascal (MPa) (mehg'-uh-pas-kuhF) A unit of pressure equivalent to 10 atmospheres of pressure.

megaphyll A leaf with a highly branched vascular system, characteristic of the vast majority of vascular plants.

megaspore A spore from a heterosporous plant species that develops into a female gametophyte.

meiosis (mi'-oh-sis) A two-stage type of cell division in sexually reproducing organisms that results in cells with half the chromosome number of the original cell.

meiosis I The first division of a two-stage process of cell division in sexually reproducing organisms that results in cells with half the chromosome number of the original cell.

meiosis II The second division of a two-stage process of cell division in sexually reproducing organisms that results in cells with half the chromosome number of the original cell.

melanocyte-stimulating hormone (MSH) A hormone produced and secreted by the anterior pituitary that regulates the activity of pigment-containing cells in the skin of some vertebrates.

melatonin A hormone secreted by the pineal gland that regulates body functions related to seasonal day length.

membrane attack complex (MAC) A molecular complex consisting of a set of complement proteins that forms a pore in the membrane of bacterial and transplanted cells, causing the cells to die by lysis.

membrane potential The charge difference between a cell's cytoplasm and the extracellular fluid, due to the differential distribution of ions. Membrane potential affects the activity of excitable cells and the transmembrane movement of all charged substances.

memory cell One of a clone of long-lived lymphocytes, formed during the primary immune response, that remains in a lymphoid organ until activated by exposure to the same antigen that triggered our formation. Activated memory cells mount the secondary immune response.

menopause The cessation of ovulation and menstruation.

menstrual cycle (men'-strü-üü) A type of reproductive cycle in higher female primates, in which the nonpregnant endometrium is shed as a bloody discharge through the cervix into the vagina.

menstrual flow phase That portion of the uterine (menstrual) cycle when menstrual bleeding occurs.

menstruation The shedding of portions of the endometrium during a uterine (menstrual) cycle.

meristem (mehr'-uh-stem) Plant tissue that remains embryonic as long as the plant lives, allowing for indeterminate growth.

meristem identity gene A plant gene that promotes the switch from vegetative growth to lowering.

meroblastic cleavage (mär'-ö-bäs-tik) A type of cleavage in which there is incomplete division of yolk-rich egg, characteristic of avian development.

mesentery (mez'-en-tär-é*) A membrane that suspends many of the organs of vertebrates inside fluid-filled body cavities.

mesoderm (mehz'-uh-dér'm) The middle primary germ layer of an early embryo that develops into the notochord, the lining of the coelom, muscles, skeleton, glands, kidneys, and most of the circulatory system.

mesohyl (mehs'-uh-hil) A gelatinous region between the two layers of cells of a sponge.

mesophyll (mehz'-uh-fil) The ground tissue of a leaf, sandwiched between the upper and lower epidermis and specialized for photosynthesis.

mesophyll cell A loosely arranged photosynthetic cell located between the bundle sheath and the leaf surface.

messenger RNA (mRNA) A type of RNA, synthesized from DNA, that attaches to ribosomes in the cytoplasm and specifies the primary structure of a protein.

metabolic pathway A series of chemical reactions that either builds a complex molecule (anabolic pathway) or breaks down a complex molecule into simpler compounds (catabolic pathway).

metabolic rate The total amount of energy an animal uses in a unit of time.

metabolism (mehb'-uh-lizm) The totality of an organism's chemical reactions, consisting of catabolic and anabolic pathways.

metamorphosis (met'-uh-mor'-fuh-sis) The resurgence of development in an animal larva that transforms it into a sexually mature adult.

metanephridium (met'-uh-nuh-frid'-ü-üm) (plural, **metanephridia**) In annelid worms, a type of excretory tubule with internal openings called nephrostomes that collect body fluids and external openings called nephriopores.

metaphase The third stage of mitosis, in which the spindle is complete and the chromosomes, attached to microtubules at their kinetochores, are all aligned at the metaphase plate.

metaphase plate An imaginary plane during metaphase in which the centromeres of all the duplicated chromosomes are located midway between the two poles.

metapopulation A subdivided population of a single species.

metastasis (muh'-tas'-uh-sis) The spread of cancer cells to locations distant from their original site.

methanogen A microorganism that obtains energy by using carbon dioxide to oxidize hydrogen, producing methane as a waste product.

microclimate Very fine scale variations of climate, such as the specific climatic conditions underneath a log.

microevolution Evolutionary change below the species level; change in the genetic makeup of a population from generation to generation.

microfilament A solid rod of actin protein in the cytoplasm of almost all eukaryotic cells, making up part of the cytoskeleton and acting alone or with myosin to cause cell contraction.

micronutrient An element that an organism needs in very small amounts and that functions as a component or cofactor of enzymes. *See also macronutrient.*

microphyll In lycophytes, a small leaf with a single unbranched vein.

micropyle A pore in the integument(s) of an ovule.

micro-RNA (miRNA) A small, single-stranded RNA molecule that binds to a complementary sequence in mRNA molecules and directs associated proteins to degrade or prevent translation of the target mRNA.

microspore A spore from a heterosporous plant species that develops into a male gametophyte.

- microsporidia** Unicellular parasites of animals and protists that molecular comparisons suggest may be most closely related to zygomycete fungi.
- microtubule** A hollow rod of tubulin protein in the cytoplasm of all eukaryotic cells and in cilia, flagella, and the cytoskeleton.
- microvillus** (plural, microvilli) One of many fine, fingerlike projections of the epithelial cells in the lumen of the small intestine that increase its surface area.
- midbrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into sensory integrating and relay centers that send sensory information to the cerebrum.
- middle ear** One of three main regions of the vertebrate ear; a chamber containing three small bones (the hammer, anvil, and stirrup) that convey vibrations from the eardrum to the oval window.
- middle lamella** (luh-mel'-uh) A thin layer of adhesive extracellular material, primarily pectins, found between the primary walls of adjacent young plant cells.
- mineral** In nutrition, a chemical element other than hydrogen, oxygen, or nitrogen that an organism requires for proper body functioning.
- mineral nutrient** An essential chemical element absorbed from the soil in the form of inorganic ions.
- mineralocorticoid** A steroid hormone secreted by the adrenal cortex that regulates salt and water homeostasis.
- minimum viable population (MVP)** The smallest population size at which a species is able to sustain its numbers and survive.
- mismatch repair** The cellular process that uses special enzymes to fix incorrectly paired nucleotides.
- missense mutation** The most common type of mutation, a base-pair substitution in which the new codon makes sense in that it still codes for an amino acid.
- mitochondrial matrix** The compartment of the mitochondrion enclosed by the inner membrane and containing enzymes and substrates for the Krebs cycle.
- mitochondrion** (mih'-to-kon'-dre-on) (plural, mitochondria) An organelle in eukaryotic cells that serves as the site of cellular respiration.
- mitosis** (mi-to'-sis) A process of nuclear division in eukaryotic cells conventionally divided into five stages: prophase, prometaphase, metaphase, anaphase, and telophase. Mitosis conserves chromosome number by equally allocating replicated chromosomes to each of the daughter nuclei.
- mitotic (M) phase** The phase of the cell cycle that includes mitosis and cytokinesis.
- mitotic spindle** An assemblage of microtubules and associated proteins that is involved in the movements of chromosomes during mitosis.
- mixotroph** An organism that is capable of both photosynthesis and heterotrophy.
- model** A representation of a theory or process.
- model organism** An organism chosen to study broad biological principles.
- modern synthesis** A comprehensive theory of evolution emphasizing populations as units of evolution and integrating ideas from many fields, including genetics, statistics, paleontology, taxonomy, and biogeography.
- molarity** A common measure of solute concentration, referring to the number of moles of solute per liter of solution.
- mold** A rapidly growing fungus that reproduces asexually by producing spores.
- mole (mol)** The number of grams of a substance that equals its molecular weight in daltons and contains Avogadro's number of molecules.
- molecular clock** An evolutionary timing method based on the observation that at least some regions of genomes evolve at constant rates.
- molecular formula** A type of molecular notation indicating only the quantity of the constituent atoms.
- molecular mass** The sum of the masses of all the atoms in a molecule; sometimes called molecular weight.
- molecular systematic[†]** The comparison of nucleic acids or other molecules in different species to infer relatedness.
- molecule** Two or more atoms held together by covalent bonds.
- molting** A process in arthropods in which the exoskeleton is shed at intervals, allowing growth by the production of a larger exoskeleton.
- monoclonal antibody** (mon'-o-klon-ul) Any of a preparation of antibodies that have been produced by a single clone of cultured cells and thus are all specific for the same epitope.
- monocots** A clade consisting of flowering plants that have one embryonic seed leaf, or cotyledon.
- monocyte** A type of white blood cell that migrates into tissues and develops into a macrophage.
- monoecious** (muh-ne'-shus) A term typically used to describe an angiosperm species in which carpelate and staminate flowers are on the same plant.
- monogamous** A type of relationship in which one mate has just one female.
- monohybrid** An organism that is heterozygous with respect to a single gene of interest. All the offspring from a cross between parents homozygous for different alleles are monohybrids. For example, parents of genotypes AA and aa produce a monohybrid with genotype Aa.
- monomer** (mon'-uh-mer) The subunit that serves as the building block of a polymer.
- monophyletic** (mon'-uh-fil-ik') Pertaining to a grouping of species consisting of an ancestral species and all its descendants; a clade.
- monosaccharide** (mon'-uh-sak'-uh-rid) The simplest carbohydrate, active alone or serving as a monomer for disaccharides and polysaccharides. Also known as simple sugars, i.e., molecular formulas of monosaccharides are generally some multiple of CH₂O.
- monosomic** Referring to a cell that has only one copy of a particular chromosome, instead of the normal two.
- monoLreme** (mon'-uh-tren) An egg-laying mammal, represented by the platypus and echidna.
- morphogen** A substance, such as Bicoid protein, that provides positional information in the form of a concentration gradient along an embryonic axis.
- morphogenesis** (mor'-fö-jen'-uh-sis) The development of body shape and organization, morphological species concept Defining species by measurable anatomical criteria.
- morula** (mör'-yuh-luh) A solid ball of blastomeres formed by early cleavage.
- mosaic evolution** The evolution of different Features of organisms at different rates.
- mosss** A small, herbaceous nonvascular plant that is a member of the phylum Bryophyta.
- motor neuron** A nerve cell that transmits signals from the brain or spinal cord to muscles or glands.
- motor unit** A single motor neuron and all the muscle fibers it controls.
- movement corridor** A series of small clumps or a narrow strip of quality habitat (disjunct by organisms) that connects otherwise isolated patches of quality habitat.
- MPF** Maturation-promoting factor (M-phase-promoting factor); a protein complex required for a cell to progress from late interphase to mitosis. The active form consists of cyclin and a protein kinase.
- mucous membrane** (myü'-küs) Smooth moist epithelium that lines the digestive tract and air tubes leading to the lungs.
- Müllerian mimicry** (myü'-lar'-e-üñ) A mutual mimicry by two unpalatable species.
- multifactorial** Referring to a phenotypic character that is influenced by multiple genes and environmental factors.
- multigene family** A collection of genes with similar or identical sequences, presumably of common origin.
- multiple fruit** A fruit derived from an inflorescence, a group of flowers tightly clustered together.
- muscle spindle** A mechanoreceptor stimulated by mechanical distortion.
- muscle tissue** Tissue consisting of long muscle cells that are capable of contracting when stimulated by nerve impulses.
- mutagen** (myü'-tuh-jen) A chemical or physical agent that interacts with DNA and causes a mutation.
- mutation** (myü'-tshün) A change in the DNA of a gene. *uStimtek* creating genetic diversity

mutualism (myoo'-chu-ul-izm) A symbiotic relationship in which both participants benefit.

mycelium (mee'-seel-ee-uhm) The densely branched network of hyphae in a fungus.

mycorrhizae (mi'-ko-ri'-ze) Mutualistic associations of plant roots and fungi.

mycosis The general term for a fungal infection.

myelin sheath (mi'-uh-lin) In a neuron, an insulating coat of cell membrane from Schwann cells that is interrupted by nodes of Ranvier, where saltatory conduction occurs.

myofibril (mi'-o-frib'-uhf) A fibril collectively arranged in longitudinal bundles in muscle cells (fibers); composed of thin filaments of actin and a regulatory protein and thick filaments of myosin.

myofilaments The thick and thin filaments that form the myofibrils.

myogenic heart A type of heart, such as in vertebrate animals, in which the pacemaker is made up of specialized muscle tissues and located within the heart itself.

myoglobin (mi'-uh-glo'-bin) An oxygen-storing, pigmented protein in muscle cells.

myosin (mi'-uh-sin) A type of protein filament that interacts with actin filaments to cause cell contraction.

myotonia Increased muscle tension.

myriapod A terrestrial arthropod with many body segments and one or two pairs of legs per segment. Millipedes and centipedes comprise the two classes of living myriapods.

NAD⁺ Nicotinamide adenine dinucleotide, a coenzyme present in all cells that helps enzymes transfer electrons during the redox reactions of metabolism.

NADP⁺ Nicotinamide adenine dinucleotide phosphate, an acceptor that temporarily stores energized electrons produced during die light reactions.

natural family planning A form of contraception that relies on refraining from sexual intercourse when conception is most likely to occur; also called the rhythm method.

natural killer (NK) cell A type of white blood cell that can kill tumor cells and virus-infected cells; an important component of innate immunity.

natural selection Differential success in the reproduction of different phenotypes resulting from the interaction of organisms with their environment. Evolution occurs when natural selection causes changes in relative frequencies of alleles in the gene pool.

negative feedback A primary mechanism of homeostasis, whereby a change in a physiological variable that is being monitored triggers a response that counteracts the initial fluctuation.

negative pressure breathing A breathing system in which air is pulled into the lungs.

nematocyst (nem'-uh-tuh-sist) A stinging, capsule-like organelle in a cnidocyte.

neocortex In the mammalian brain, the outermost region of the cerebral cortex.

nephon (nef'-ron) The tubular excretory unit of the *venerbrae* (kidney).

neritic zone (neh-rit'-ik') The shallow region of the ocean overlying the continental shelf.

nerve A ropelike bundle of neuron fibers (axons and dendrites) tightly wrapped in connective tissue.

nerve cord A ropelike arrangement of neurons characteristic of animals with bilateral symmetry and cephalization.

nerve net A weblike system of neurons, characteristic of radially symmetrical animals, such as hydra.

nervous tissue Tissue made up of neurons and supportive cells.

net primary production (NPP) The gross primary production of an ecosystem minus the energy used by the producers for respiration.

neural crest A band of cells along the border where the neural tube pinches off from the ectoderm. The cells migrate to various parts of the embryo and form the pigment cells in the skin, bones of the skull, the teeth, the adrenergic glands, and parts of the peripheral nervous system.

neural tube A tube of cells running along the dorsal axis of the body, just dorsal to the notochord. It will give rise to the central nervous system.

neurogenic heart A type of heart, such as in insects, in which lie *pacemakers* originate in motor nerves arising from outside the heart.

neurohypophysis (ner'-o-hi-pof-uh-sis) *See posterior pituitary*

neuron (ner'-on) A nerve cell; the fundamental unit of the nervous system, having structure and properties that allow it to conduct signals by taking advantage of the electrical charge across its cell membrane.

neuropeptide A relatively short chain of amino acids that serves as a neurotransmitter.

neurosecretory cell A specialized nerve cell that releases a hormone into the blood stream: i.e., response to signals from other nerve cells; located in the hypothalamus and adrenal medulla.

neurotransmitter A chemical messenger released from the synaptic terminal of a neuron at a chemical synapse that diffuses across the synaptic cleft and binds to and stimulates the postsynaptic cell.

neutral theory The hypothesis that much evolutionary change in genes and proteins has no effect on fitness and therefore is not influenced by Darwinian natural selection.

neutral variation Genetic diversity that confers no apparent selective advantage.

neutron An electrically neutral particle (a particle having no electrical charge), found in the nucleus of an atom.

neutrophil The most abundant type of white blood cell. Neutrophils are phagocytic.

tend to self-destruct as they destroy foreign invaders, limiting their life span to a few days.

niche *See ecological niche.*

nitric oxide (NO) A gas produced by many types of cells that functions as a local regulator, a neurotransmitter, and an antibacterial agent.

nitrogen fixation The assimilation of atmospheric nitrogen by certain prokaryotes into nitrogenous compounds that can be directly used by plants.

nitrogenase (ni-troj'-uh-naz) An enzyme complex, unique to certain prokaryotes, that reduces N₂ to NH₃.

nitrogen-fixing bacteria Microorganisms that restock nitrogenous minerals in the soil by converting nitrogen to ammonia.

nociceptor A class of naked dendrites in the epidermis of the skin.

node A point along the stem of a plant at which leaves are attached.

node A swelling on the root of a legume. Nodules are composed of plant cells that contain nitrogen-fixing bacteria of the genus *Rhizobium*.

noncompetitive inhibitor A substance that reduces the activity of an enzyme by binding to a location remote from the active site, changing its conformation so that it no longer binds to the substrate.

noncyclic electron flow A route of electron flow during the light reactions of photosynthesis that involves both photosystems and produces ATP, NADPH, and oxygen. The net electron flow is from water to NADP⁺.

nondisjunction An error in meiosis or mitosis, in which both members of a pair of homologous chromosomes or both sister chromatids fail to move apart properly.

nonequilibrium model The model of communities that emphasizes that they are not stable in time but constantly changing after being buffeted by disturbances.

nonpolar covalent bond A type of covalent bond in which electrons are shared equally between two atoms of similar electronegativity.

nonsense mutation A mutation that changes an amino acid codon to one of the three stop codons, resulting in a shorter and usually nonfunctional protein.

nonshivering thermogenesis (NST) The increased production of heat in some mammals by the action of certain hormones that cause mitochondria to increase their metabolic activity and produce heat instead of ATP.

norepinephrine A hormone that is chemically and functionally similar to epinephrine.

norm of reaction The range of phenotypes produced by a single genotype, due to environmental influences.

notochord A longitudinal, flexible rod that runs along the dorsal axis of an animal's body in the future position of the vertebral column.

- nuclear envelope** The membrane in eukaryotes that encloses the nucleus, separating it from the cytoplasm.
- nuclear lamina** A netlike array of protein filaments that maintains the shape of the nucleus.
- nuclease** An enzyme that hydrolyzes DNA and RNA into their component nucleotides.
- nucleic acid** A polymer (polynucleotide) consisting of many nucleotide monomers; serves as a blueprint for proteins and, through the actions of proteins, for all cellular activities. The two types are DNA and RNA.
- nucleic acid hybridization** Base pairing between a gene and a complementary sequence on another nucleic acid molecule.
- nucleic acid probe** (nu-kla'-ik) In DNA technology, a labeled single-stranded nucleic acid molecule used to tag a specific nucleotide sequence in a nucleic acid sample. Molecules of the probe hydrogen-bond to the complementary sequence wherever it occurs; radioactive or other labeling of the probe allows its location to be detected.
- nucleoid** (nu'-kle-oid) A dense region of DNA in a prokaryotic cell.
- nucleoid region** The region in a prokaryotic cell consisting of a concentrated mass of DNA.
- nucleolus** (nu'-kle'-üs) (plural, **nucleoli**) A specialized structure in the nucleus, formed from various chromosomes and active in the synthesis of ribosomes.
- nucleosome** (nu'-kle-o-som) The basic, bead-like unit of DNA packaging in eukaryotes, consisting of a segment of DNA wound around a protein core composed of two copies of each of four types of histone.
- nucleotide** (nu'-kle-o-tid) The building block of a nucleic acid, consisting of a five-carbon sugar covalently bonded to a nitrogenous base and a phosphate group.
- nucleotide excision repair** The process of removing and then correctly replacing a damaged segment of DNA using the undamaged strand as a guide.
- nucleus** (1) An atom's central core, containing protons and neutrons. (2) The chromosome-containing organelle of a eukaryotic cell. (3) A cluster of neurons.
- obligate aerobe** (ob'-ig-et ar'-ob) An organism that requires oxygen for cellular respiration and cannot live without it.
- obligate anaerobe** (ob'-ig-et an'-uh-roh) An organism that cannot use oxygen and is poisoned by it.
- oceanic pelagic biome** Most of the ocean's waters far from shore, constantly mixed by ocean currents.
- oceanic zone** The region of water lying over deep areas beyond the continental shelf.
- Okazaki fragment** A short segment of DNA synthesized on a template strand during DNA replication. Many Okazaki fragments make up the lagging strand of newly synthesized DNA.
- olfactory receptor** Smell receptor.
- oligodendrocyte** (ol'-ig-ō-den'-druh-sit) A type of glial cell that forms insulating myelin sheaths around the axons of neurons in the central nervous system.
- oligosaccharin** A type of elicitor (molecule that induces a broad defense response in plants) that is derived from cellulose fragments released by cell wall damage.
- oligotrophic lake** A nutrient-poor, oxygen-rich clear, deep lake with few phytoplankton.
- ommatidium** (plural, **ommatidia**) (om'-uh-tid'-ē-uhm) One of the facets of the compound eye of arthropods and some polychaete worms.
- omnivore** A heterotrophic animal that consumes both meat and plant material.
- oncogene** (on'-ko-jen) A gene found in viruses or as part of the normal genome that is involved in triggering cancerous characteristics.
- one gene-one polypeptide hypothesis** The premise that a gene is a segment of DNA that codes for one polypeptide.
- oogenesis** (ō'-uh-jen'-uh-sis) The process in the ovary that results in the production of female gametes.
- oogonia** Ovary-specific stem cells.
- oomycete** A protist with flagellated cells, such as a water mold, white rust, or downy mildew, that acquires nutrition mainly as a decomposer or plant parasite.
- open circulatory system** A circulatory system in which fluid called hemolymph bathes the tissues and organs directly and there is no distinction between the circulating fluid and the interstitial fluid.
- operant conditioning** (op'er-ent) A type of associative learning in which an animal learns to associate one of its own behaviors with a reward or punishment and then tends to repeat or avoid that behavior; also called trial-and-error learning.
- operator** In prokaryotic DNA, a sequence of nucleotides near the start of an operon to which an active repressor can attach. The binding of the repressor prevents RNA polymerase from attaching to the promoter and transcribing the gene(s) of the operon.
- operculum** In aquatic osteichthyans, a protective bony flap that covers and protects the gills.
- operon** (op'er-on) A unit of genetic function common in bacteria and phages, consisting of coordinate; regulated clusters of genes with related functions.
- opisthokont** Member of the clade Opisthokonta, organisms that descended from an ancestor with a posterior flagellum, including fungi, animals, and certain protists.
- opposable thumb** An arrangement of the fingers such that the thumb can touch the ventral surface of the fingertips of all four fingers.
- opsin** A membrane protein bonded to a light-absorbing pigment molecule.
- optic chiasm** The arrangement of the nerve tracts of the eye such that the visual sensations from the left visual field of both eyes are transmitted to the right side of the brain and the sensations from the right visual field of both eyes are transmitted to the left side of the brain.
- optimal foraging theory** The basis for analyzing behavior as a compromise of feeding costs versus feeding benefits.
- oral cavity** The mouth of an animal.
- orbital** The three-dimensional space where an electron is found 90% of the time.
- order** In classification, the taxonomic category above family.
- organ** A specialized center of body function composed of several different types of tissues.
- organ identity genes** Plant homeotic genes that use positional information to determine which emerging leaves develop into which types of floral organs.
- organ of Corti** The actual hearing organ of the vertebrate ear, located in the floor of the cochlear canal in the inner ear; contains the receptor cells (hair cells) of the ear.
- organ system** A group of organs that work together in performing vital body functions.
- organelle** (or-guh-nel') One of several formed bodies within, specialized functions, suspended in the cytoplasm of eukaryotic cells.
- organic chemistry** The study of carbon compounds (organic compounds).
- organism** An individual living thing.
- organismal ecology** The branch of ecology concerned with the morphological, physiological, and behavioral ways in which individual organisms meet the challenges posed by their biotic and abiotic environments.
- organogenesis** (or-gan'-ō-jen-uh-sis) The development of organ rudiments from the three germ layers.
- orgasm** Rhythmic, involuntary contractions of certain reproductive structures in both sexes during the human sexual response cycle.
- origin of replication** Site where the replication of a DNA molecule begins.
- orthologous genes** I homologous genes that are passed in a straight line from one generation to the next, but have ended up in different gene pools because of speciation.
- osculum** A large opening in a sponge that connects the spongocoel to the environment.
- osmoconformer** An animal that does not actively adjust its internal osmolarity because it is isoosmotic with its environment.
- osmolarity** (oz'-mo-lar'-uh-ih) Solute concentration expressed as molarity.
- osmoregulation** M_w organisms regulate solute concentrations and balance the gain and loss of water.
- osmoregulator** An animal whose body fluids have a different osmolarity than the environment and that must either discharge excess water if it lives in a hypoosmotic environment

or take in water if it inhabits a hyperosmotic environment.

osmosis (o^z-mo^s-sis) The diffusion of water across a selectively permeable membrane.

osmotic potential A component of water potential that is proportional to the number of dissolved solute molecules in a solution and measures the effect of solutes on the direction of water movement; also called solute potential, it can be either zero or negative.

osteichthyan Member of a vertebrate subgroup with jaws and mostly bony skeletons.

osteoblast A bone-forming cell that deposits collagen.

osteon The repeating organizational unit forming the microscopic structure of hard mammalian bone.

outer ear One of three main regions of the ear in reptiles, birds, and mammals; made up of the auditory canal and, in many birds and mammals, the pinna.

outgroup A species or group of species that is closely related to the group of species being studied, but clearly not as closely related as any study-group members are to each other.

oval window In the vertebrate ear, a membrane-covered gap in the skull bone, through which sound waves pass from the middle ear to the inner ear.

ovarian cycle (o-var^e-e-un) The cyclic recurrence of the follicular phase, ovulation, and the luteal phase in the mammalian ovary, regulated by hormones.

ovary (o'-vuh-re) (1) In flowers, the portion of a carpel in which the egg-containing ovules develop. (2) In animals, the structure that produces female gametes and reproductive hormones.

overexploitation Harvesting by humans of wild plants or animals at rates exceeding the ability of populations of those species to rebound.

overnourishment A diet that is chronically excessive in calories.

oviduct (o'-vuh-duct) A tube passing from the ovary to the vagina in invertebrates or to the uterus in vertebrates.

oviparous (o-vip'-uh-rus) Referring to a type of development in which young hatch from eggs laid outside the mother's body

ovoviparous (o'-vo-vi-vip'-uh-rus) Referring to a type of development in which young hatch from eggs that are retained in the mother's uterus.

ovulation The release of an egg from ovaries. In humans, an ovarian follicle releases an egg during each uterine (menstrual) cycle.

ovule (o'-vuyl) A structure that develops within the ovary of a seed plant and contains the female gametophyte.

ovum (o'-vum) The female gamete; the haploid, unfertilized egg, which is usually a relatively large, nonmotile cell.

oxidation The loss of electrons from a substance involved in a redox reaction.

oxidative phosphorylation (fos'-i-or-uh-lā-shun) The production of ATP using energy derived from the redox reactions of an electron transport chain.

oxidizing agent The electron acceptor in a redox reaction.

oxytocin A hormone produced by the hypothalamus and released from the posterior pituitary. It induces contractions of the uterine muscles and causes the mammary glands to eject milk during nursing.

P generation The parent individuals from which offspring are derived in studies of inheritance; P stands for "parental."

P site One of a ribosome's three binding sites for tRNA during translation. The P site holds the tRNA carrying the growing polypeptide chain. (P stands for peptidyl tRNA.)

p53 gene The "guardian angel of the genome," a gene that is expressed when a cell's DNA is damaged. Its product, p53 protein, functions as a transcription factor for several genes.

pacemaker A specialized region of the right atrium of the mammalian heart that sets the rate of contraction; also called the sinoatrial (SA) node.

paedomorphosis (pe'-duh-mor'-fuh-sis) The retention in an adult organism of the juvenile features of its evolutionary ancestors.

pain receptor A kind of interceptor that detects pain; also called a nociceptor.

paleoanthropology The study of human origins and evolution.

paleontological species concept Definition of species based on morphological differences known only from the fossil record.

paleontology (pal'-euhn-tol'-oh-je) The scientific study of fossils.

palisade mesophyll One or more layers of elongated photosynthetic cells on the upper part of a leaf; also called palisade parenchyma.

pancreas (pan'-kree-us) A gland with dual functions: The nonendocrine portion secretes digestive enzymes and an alkaline solution into the small intestine via a duct; the endocrine portion secretes the hormones insulin and glucagon into the blood.

Pangaea (pan-jé'-uh) The supercontinent formed near the end of the Paleozoic era when plate movements brought all the land masses of Earth together.

parabasalid A protist such as a trichomonad, with modified mitochondria.

parabronchus (plural, parabronchi) A site of gas exchange in bird lungs. Parabronchi allow air to flow past the respiratory surface in just one direction.

paralogous genes Homologous genes that are found in the same genome due to gene duplication.

paraphyletic (par'-uh-fi-let'-ik) Pertaining to a grouping of species that consists of an ancestral species and some, but not all, of its descendants.

parareptile First major group of reptiles to emerge, mostly large, stocky quadrupedal herbivores; died out in the late Triassic period.

parasite (par'-uh-sit) An organism that benefits by living in or on another organism at the expense of the host.

parasitism (pär'-uh-sit-izm) A symbiotic relationship in which the symbiont (parasite) benefits at the expense of the host by living either within the host (an endoparasite) or outside the host (as an ectoparasite).

parasitoidism A type of parasitism in which an insect lays eggs on or in a living host; the larvae then feed on the body of the host, eventually killing it.

parasympathetic division One of three

divisions of the autonomic nervous system; generally enhances body activities that gain and conserve energy, such as digestion and reduced heart rate.

parathyroid gland Any of four small endocrine glands, embedded in the surface of the thyroid gland, that secrete parathyroid hormone.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that raises blood calcium level by promoting calcium release from bone and calcium retenion by the kidneys.

parazoan Animal belonging to a grade of organization lacking true tissues (collections of specialized cells isolated from other tissues by membranes); a sponge (**phylum Porifera**).

parenchyma cell (puh-ren'-kim-uh) A

relatively unspecialized plant cell type that carries out most of the metabolism, synthesizes and stores organic products, and develops into a more differentiated cell type.

parental type An offspring with a phenotype that matches one of the parental phenotypes.

Parkinson's disease A motor disorder caused by a progressive brain disease and characterized by difficulty in initiating movements, slowness of movement, and rigidity.

parthenogenesis (par'-thuh-no'-jen'-uh-sis) A type of reproduction in which females produce offspring from unfertilized eggs.

partial pressure A measure of the concentration of one gas in a mixture of gases; the pressure exerted by a particular gas in a mixture of gases (for instance, the pressure exerted by oxygen in air).

parturition The expulsion of a baby from the mother; also called birth.

passive immunity Short-term immunity conferred by the administration of ready-made antibodies or the transfer of maternal antibodies to a fetus or nursing infant; lasts only a few weeks or months because the immune system has not been stimulated by antigens.

passive transport The diffusion of a substance across a biological membrane.

- patchiness** Localized variation, in environmental conditions within an ecosystem, arranged spatially into a complex of discrete areas that may be characterized by distinctive groups of species or ecosystem processes.
- pathogen** A disease-causing agent.
- pattern formation** The ordering of cells into specific three-dimensional structures, an essential part of shaping an organism and its individual parts during development.
- peat** Extensive deposits of undecayed organic material formed primarily from the wetland moss *Sphagnum*.
- pedigree** A diagram of a family tree showing the occurrence of heritable characters in parents and offspring over multiple generations.
- pelagic zone** (puh-laj'-ik) The area of the ocean past the continental shelf, with areas of open water often reaching to very great depths.
- penis** The copulatory structure of male mammals.
- PEP carboxylase** An enzyme that adds carbon dioxide to phosphoenolpyruvate (PEP) to form oxaloacetate.
- pepsin** An enzyme present in gastric juice that begins the hydrolysis of proteins.
- pepsinogen** The inactive form of pepsin that is first secreted by specialized (chief) cells located in gastric pits of the stomach.
- peptide bond** The covalent bond between two amino acid units, formed by a dehydration reaction.
- peptidoglycan** (pep'-tid-o-gli'-kun) A type of polymer in bacterial cell walls consisting of modified sugars cross-linked by short polypeptides.
- perception** The interpretation of sensations by the brain.
- perennial** (puh-ren'-e-ul) A flowering plant that lives for many years.
- pericarp** The thickened wall of a fruit.
- pericycle** (par'-uh-sl-kul) The outermost layer of the vascular cylinder of a root, where lateral roots originate.
- periderm** (par-uh-derm) The protective coat that replaces the epidermis in plants during secondary growth, formed of the cork and cork cambium.
- periodic table of the elements** A chart of the chemical elements, arranged in three rows, corresponding to the number of electron shells in their atoms.
- peripheral nervous system (PNS)** The sensory and motor neurons that connect to the central nervous system.
- peripheral protein** A protein appendage loosely bound to the surface of a membrane and not embedded in the lipid bilayer.
- peripheral resistance** The impedance of blood flow by the arterioles.
- peristalsis** (par'-uh-stal'-sis) (1) Rhythmic waves of contraction of smooth muscle that push food along the digestive tract. (2) A type of movement on land produced by rhythmic waves of muscle contractions passing from front to back, as in many annelids.
- peristome** The upper part of the moss capsule (sporangium) often specialized for gradual spore discharge.
- peritubular capillaries** The network of tiny blood vessels that surrounds the proximal and distal tubules in the kidney
- permafrost** A permanently frozen stratum below the arctic tundra.
- peroxisome** (puh-rok'-suh-som) A microbody containing enzymes that transfer hydrogen from various substrates to oxygen, producing and then degrading hydrogen peroxide.
- petal** A modified leaf of a flowering plant. Petals are the often colorful parts of a flower that advertise it to insects and other pollinators.
- petiole** (pet'e-ol) The stalk of a leaf, which joins the leaf to a node of the stem.
- pH** A measure of hydrogen ion concentration equal to $-\log [H^+]$ and ranging in value from 0 to 14.
- phage** (faj') A virus that infects bacteria; also called a bacteriophage.
- phagocytosis** (fag'-suh-sis) A type of endocytosis involving large, particulate substances, accomplished mainly by macrophages, neutrophils, and dendritic cells.
- pharyngeal clefts** In chordate embryos, grooves that separate a series of pouches along the sides of the pharynx and may develop into pharyngeal slits.
- pharyngeal slits** In chordate embryos, slits that form from the pharyngeal clefts and communicate to the outside, later developing into gill slits in many vertebrates.
- pharynx** (far'-inks) An area in the vertebrate throat where air and food passages cross; in flatworms, the muscular tube that protrudes from the ventral side of the worm and ends in the mouth.
- phase change** A shift from one developmental phase to another.
- phenotype** (fe'-no-tip) The physical and physiological traits of an organism, which are determined by its genetic makeup.
- phenotypic polymorphism** The existence of two or more distinct morphs (discrete forms), each represented in a population in high enough frequencies to be readily noticeable.
- pheromone** (far'-uh-mon) In animals and fungi, a small, volatile chemical that functions in communication and that in animals acts much like a hormone in influencing physiology and behavior.
- phloem** (floid'-um) Vascular plant tissue consisting of living cells arranged into elongated tubes that transport sugar and other organic nutrients throughout the plant.
- phoronids** A tube-dwelling marine lophophorate.
- phosphate group** (fos'-fat) A functional group important in energy transfer.
- phospholipid** (fos'-fo-lip'-id) A molecule that is a constituent of the inner bilayer of biological membranes, having a polar, hydrophilic head and a nonpolar, hydrophobic tail.
- phosphorylated** Referring to a molecule that has been the recipient of a phosphate group.
- photic zone** (fis'-tic) The narrow top slice of the ocean, where light permeates sufficiently for photosynthesis to occur.
- photoautotroph** (fö-to-ö-trof') An organism that harnesses light energy to drive the synthesis of organic compounds from carbon dioxide.
- photoheterotroph** (fö'-to-het'-uh-rö-tröf') An organism that uses light to generate ATP but that must obtain carbon in organic form.
- photomorphogenesis** Effects of light on plant morphology.
- photon** (fö-ton') A quantum, or discrete amount, of light energy.
- photoperiodism** (fö'-to-per'-e-ö-düm) A physiological response to photoperiod, the relative lengths of night and day. An example of photoperiodism is flowering.
- photophosphorylation** (fö'-to-fos'-fö-uh-la'-shun) The process of generating ATP from ADP and phosphate by means of a proton-motive force generated by the thylakoid membrane of the chloroplast during the light reactions of photosynthesis.
- photopsin** (fö-top'-sin) One of a family of visual pigments in the cones of the vertebrate eye that absorb bright, colored light.
- photoreceptor** An electromagnetic receptor that detects the radiation known as visible light.
- photorespiration** A metabolic pathway that consumes oxygen, releases carbon dioxide, generates no ATP, and decreases photosynthetic output; generally occurs on hot, dry, bright days, when stomata close and the oxygen concentration in the leaf exceeds that of carbon dioxide.
- photosynthesis** The conversion of light energy to chemical energy that is stored in glucose or other organic compounds; occurs in plants, algae, and certain prokaryotes.
- photosystem** Light-capturing unit located in the thylakoid membrane of the chloroplast, consisting of a reaction center surrounded by numerous light-harvesting complexes. There are two types of photosystems, I and II; they absorb light best at different wavelengths.
- photosystem I** One of two light-capturing units in a chloroplast's thylakoid membrane; it has two molecules of P700 chlorophyll *a* at its reaction center.
- photosystem II** One of two light-capturing units in a chloroplast's thylakoid membrane; it has two molecules of P680 chlorophyll *a* at its reaction center.
- phototropism** (fö'-to-tröf'-pizm) Growth of a plant shoot toward or away from light.

- phragmoplast** An alignment of cytoskeletal elements and Golgi-derived vesicles across the midline of a dividing plant cell.
- phylogenetic tree** A branching diagram that represents a hypothesis about evolutionary relationships.
- phylogeny** (fī-lōj'ē-uh-nē) The evolutionary history of a species or group of related species.
- phylogram** A phylogenetic tree in which the lengths of the branches reflect the number of genetic changes that have taken place in a particular DNA or RNA sequence in the various lineages.
- phylum** (fī'lūm) In classification, the taxonomic category above class.
- physical map** A genetic map in which the actual physical distances between genes or other genetic markers are expressed, usually as the number of base pairs along the DNA.
- physiology** The study of the functions of an organism.
- phytoalexin** (fī-to-uh-lek'sin) An antibiotic, produced by plants, that destroys microorganisms or inhibits their growth.
- phytochromes** (fī-tūh-krohm's) A class of light receptors in plants. Mostly absorbing red light, these photoreceptors regulate many plant responses, including seed germination and shade avoidance.
- phytoplankton** (fīl'-to-plank'ton) Algae and photosynthetic bacteria that drift passively in the pelagic zone of an aquatic environment.
- phytoremediation** An emerging nondestructive technology that seeks to cheaply reclaim contaminated areas by taking advantage of the remarkable ability of some plant species to extract heavy metals and other pollutants from the soil and to concentrate them in easily harvested portions of the plant.
- pillar** (plural, **pili**) (pi'lūs, pi'lī) A long, hair-like prokaryotic appendage that functions in adherence or in the transfer of DNA during conjugation.
- pineal gland** (pin'e-əl) A small gland on the dorsal surface of the vertebrate forebrain that secretes the hormone melatonin.
- pinocytosis** (pi'nō-si-tō'sis) A type of endocytosis in which the cell ingests extracellular fluid and its dissolved solutes.
- pistil** A single carpel or a group of fused carpels.
- pitch** A function of a sound wave's frequency, or number of vibrations per second, expressed in hertz.
- pith** Ground tissue that is internal to the vascular tissue in a stem; in many monocot roots, parenchyma cells that form the central core of the vascular cylinder.
- pit** A thinner region in the walls of tracheids and vessels where only primary wall is present.
- pituitary gland** (puh-mī'uh-tärē) An endocrine gland at the base of the hypothalamus; consists of a posterior lobe (neurohypophysis), which stores and releases two hormones produced by the hypothalamus, and an anterior lobe (adenohypophysis), which produces and secretes many hormones that regulate diverse body functions.
- placenta** (pluh-sen-tuh) A structure in the pregnant uterus for nourishing a viviparous fetus with the mother's blood supply; formed from the uterine lining and embryonic membranes.
- placental transfer cell** A plant cell that enhances the transfer of nutrients from parent to embryo.
- placoderm** (plak'dē-derm) A member of an extinct class of **fishlike** vertebrates that had jaws and were enclosed in a tough, outer armor.
- planarian** A free-living flatworm found in unpolluted ponds and streams.
- plankton** Mostly microscopic organisms that drift passively or swim weakly near the surface of oceans, ponds, and lakes.
- Plantae** (plan'-tā) The kingdom that consists of multicellular eukaryotes that carry out photosynthesis.
- plasma** (plaz'muh) The liquid matrix of blood in which the cells are suspended.
- plasma cell** The antibody-secreting effector cell of humoral immunity; arises from antigen-stimulated B cells.
- plasma membrane** The membrane at the boundary of every cell that acts as a selective barrier, thereby regulating the cell's chemical composition.
- plasmid** (plaz'mid) A small ring of DNA that carries accessory genes separate from those of a bacterial chromosome; also found in some eukaryotes, such as yeast.
- plasmodesma** (plaz'mō-dez'muh) (plural, **plasmodesmata**) An open channel in the cell wall of a plant through which strands of cytosol connect from an adjacent cell.
- plasmodial slime mold** (plaz'mō-de'ul) A type of protist that has amoeboid cells, flagellated cells, and a plasmodial feeding stage in its life cycle.
- plasmodium** A single mass of cytoplasm containing many diploid nuclei that forms during the life cycle of some slime molds.
- plasmogamy** The fusion of the cytoplasm of cells from two individuals; occurs as one stage of syngamy.
- plasmolysis** (plaz'mō-lēs'is) A phenomenon in walled cells in which the cytoplasm shrivels and the plasma membrane pulls away from the cell wall when the cell loses water to a hypertonic environment.
- plasmolyze** To shrink and pull away from a cell wall, or when a plant cell protoplast pulls away from the cell wall as a result of water loss.
- plasticity** An organism's ability to alter or "mold" itself in response to local environmental conditions.
- plastid** One of a family of closely related plant organelles that includes chloroplasts, chromoplasts, and amyloplasts (leucoplasts).
- platelet** A small enucleated blood cell important in blood clotting; derived from large cells in the bone marrow.
- pleiotropy** (pīl'-uh-troh-pe) The ability of a single gene to have multiple effects.
- pluripotent** Describing a stem cell, from an embryo or adult organism, that can give rise to multiple but not all differentiated cell types.
- point mutation** A change in a gene at a single nucleotide pair.
- polar covalent bond** A covalent bond between atoms that differ in electronegativity. The shared electrons are pulled closer to the more electronegative atom, making it slightly negative and the other atom slightly positive.
- polar molecule** A molecule (such as water) with opposite charges on opposite sides.
- polarity** A lack of symmetry. Structural differences in opposite ends of an organism or structure, such as the root end and shoot end of a plant.
- pollen grains** The structures that contain the male gametophyte of seed plants.
- pollination** (pol'-uh-nāsh'un) The transfer of pollen to the part of a seed plant containing the ovules, a process that is a prerequisite for fertilization.
- poly-A tail** The modified end of the 3' end of an mRNA molecule consisting of the addition of some 50 to 250 adenine nucleotides.
- polyandry** (pol'-e-an'drē) A polygamous mating system involving one female and many **males**.
- polygamous** A type of relationship in which an individual of one sex mates with several of the other.
- polygenic inheritance** (pol'-e-jen'ik) An additive effect of two or more gene loci on a single phenotypic character.
- polygyny** (puh-līj'en-e) A polygamous mating system involving one male and many females.
- polymer** (pol'-uh-mer) A long molecule consisting of many similar or identical monomers linked together.
- polymerase chain reaction (PCR)** (puh-lim'-uh-ras) A technique for amplifying DNA in *vitro* by incubating with special primers, DNA polymerase molecules, and nucleotides.
- polymorphism** (pol'-e-mōr'fizm) The coexistence of two or more distinct forms in the same population.
- polynucleotide** (pol'-ē-nū'kle-6-tid) A polymer consisting of many nucleotide monomers; serves as a blueprint for proteins and, through the actions of proteins, for all cellular activities. The two types are DNA and RNA.
- polyp** (pol'-ip) The sessile variant of the cnidarian body plan. The alternate form is the medusa.
- polypeptide** (pol'-ē-pep'-tid) A polymer (chain) of many amino acids linked together by peptide bonds.
- polyphyletic** Pertaining to a grouping of species derived from two or more different ancestral forms.

Glossary

- polyplody** (pol'-é-ploy'-de) A chromosomal alteration in which the organism possesses more than two complete chromosome sets.
- polyribosome** (polysome) (pol'-é-ri'-bo-som) An aggregation of several ribosomes attached to one messenger RNA molecule.
- polysaccharide** (pol'-é-sak'-uh-rid) A polymer of up to over a thousand monosaccharides, formed by dehydration reactions.
- pans** Portion of the brain that participates in certain automatic, homeostatic functions, such as regulating the breathing centers in the medulla.
- population** A localized group of individuals that belong to the same biological species (that are capable of interbreeding and producing fertile offspring).
- population dynamics** The study of how complex interactions between biotic and abiotic factors influence variations in population size.
- population ecology** The study of populations in relation to the environment, including environmental influences on population density and distribution, age structure, and variations in population size.
- population genetics** The study of how populations change genetically over time.
- population viability analysis (PVA)** A method of predicting whether or not a population will persist.
- positional information** Signals to which genes regulating development respond, indicating a cell's location relative to other cells in an embryonic structure.
- positive feedback** A physiological control mechanism in which a change in some variable triggers mechanisms that amplify the change.
- positive pressure breathing** A breathing system in which air is forced into the lungs.
- posterior** Pertaining to the rear or tail end, of a bilaterally symmetrical animal.
- posterior pituitary** Also called the neurohypophysis; an extension of the hypothalamus composed of nervous tissue that secretes oxytocin and antidiuretic hormone made in the hypotalamus; a temporary storage site for these hormones.
- postsynaptic cell** The target cell at a synapse.
- postzygotic barrier** (post'-zi-got'-ik) Any of several species-isolating mechanisms that prevent hybrids produced by two different species from developing into viable, fertile adults.
- potential energy** The energy stored by matter as a result of its location or spatial arrangement.
- precautionary principle** A guiding principle in making decisions about the environment, cautioning to consider carefully the potential consequences of actions.
- predation** An interaction between species in which one species, the predator, eats the other, the prey.
- pregnancy** The condition of carrying one or more embryos in the uterus.
- prophase band** Microtubules in the cortex (outer cytoplasm) of a cell that are concentrated into a ring.
- prepuce** (pre'-pyüs) A fold of skin covering the head of the clitoris and penis.
- pressure potential** (^p) A component of water potential that consists of the physical pressure on a solution, which can be positive, zero, or negative.
- presynaptic cell** The transmitting cell at a synapse.
- prezygotic barrier** (pre'-z'l-got'-ik) A reproductive barrier that impedes mating between species or hinders fertilization of ova if interspecific mating is attempted.
- primary cell wall** A relatively thin and flexible layer first secreted by a young plant cell.
- primary consumer** An herbivore; an organism in the trophic level of an ecosystem that eats plants or algae.
- primary electron acceptor** A specialized molecule sharing the reaction center with the pair of reaction-center chlorophyll *a* molecules; it accepts an electron from one of these two chlorophylls.
- primary growth** Growth produced by apical meristems, lengthening stems and roots.
- primary immune response** The initial acquired immune response to an antigen, which appears after a lag of about 10 to 17 days.
- primary oocyte** (6-uh-ST) A diploid cell, in prophase I of meiosis, that can be hormonally triggered to develop into an ovum.
- primary plant body** The tissues produced by apical meristems, which lengthen stems and roots.
- primary producer** An autotroph, usually a photosynthetic organism. Collectively, autotrophs make up the trophic level of an ecosystem that ultimately supports all other levels.
- primary production** The amount of light energy converted to chemical energy (organic compounds) by autotrophs in an ecosystem during a given time period.
- primary structure** The level of protein structure referring to the specific sequence of amino acids.
- primary succession** A type of ecological succession that occurs in a virtually lifeless area, where there were originally no organisms and where soil has not yet formed.
- primary transcript** An initial RNA transcript; also called pre-mRNA when transcribed from a protein-coding gene.
- primary visual cortex** The destination in the occipital lobe of the cerebrum for most of the axons from the lateral geniculate nuclei.
- primase** An enzyme that joins RNA nucleotides to make the primer.
- primer** A polynucleotide with a free 3' end, bound by complementary base pairing to the template strand, that is elongated during DNA replication.
- primitive streak** A groove on the surface of an early avian embryo along the future long axis of the body.
- prion** An infectious form of protein that may increase in number by converting related proteins to more prions.
- product** An ending material in a chemical reaction.
- production efficiency** The fraction of energy stored in food that is not used for respiration.
- progesterone** (pro'-jes-tin) One of a family of steroid hormones, including progesterone, that prepare the uterus for pregnancy.
- progymnosperms** Extinct seedless vascular plants that may be ancestral to seed plants.
- prokaryotic cell** (pro'-kar'-e-ot'-ik) A type of cell lacking a membrane-enclosed nucleus and membrane-enclosed organelles; found only in the domains Bacteria and Archaea.
- prolactin (PRL)** A hormone produced and secreted by the anterior pituitary⁷ with a great diversity of effects in different vertebrate species. In mammals, it stimulates growth of and milk production by the mammary glands.
- proliferative phase** That portion of the uterine (menstrual) cycle when the endometrium regenerates and thickens.
- prometaphase** The second stage of mitosis, in which discrete chromosomes consisting of identical sister chromatids appear, the nuclear envelope fragments, and the spindle microtubules attach to the kinetochores of the chromosomes.
- promiscuous** A type of relationship in which mating occurs with no strong pair-bonds or lasting relationships.
- promoter** A specific nucleotide sequence in DNA that binds RNA polymerase and indicates where to start transcribing RNA.
- prophage** (pro'-faj) A phage genome that has been inserted into a specific site on the bacterial chromosome.
- prophase** The first stage of mitosis, in which the chromatin is condensing and the mitotic spindle begins to form, but the nucleolus and nucleus are still intact.
- prostaglandin (PG)** (pros'-tuh-glan'-din) One of a group of modified fatty acids secreted by virtually all tissues and performing a wide variety of functions as local regulators.
- prostate gland** (pros'-tat) A gland in human males that secretes an acid-neutralizing component of semen.
- proteasome** A giant protein complex that recognizes and destroys proteins tagged for elimination by the small protein ubiquitin.
- protein** (pro'-ten) A three-dimensional biological polymer constructed from a set of 20 different monomers called amino acids.
- protein kinase** An enzyme that transfers phosphate groups from ATP to a protein.

- protein phosphatase** An enzyme that removes phosphate groups from proteins, often functioning to reverse the effect of a protein kinase.
- proteoglycan** (*pro'-ie-o-gly-kun*) A glycoprotein in the extracellular matrix of animal cells, rich in carbohydrate.
- proteomics** The systematic study of the full protein sets (proteomes) encoded by genomes.
- protist** An informal term applied to any eukaryote that is not a plant, animal, or fungus. Most protists are unicellular, though some are colonial or multicellular.
- probiont** An aggregate of abiotically produced molecules surrounded by a membrane or membrane-like structure.
- proton** (*pro'-ton*) A subatomic particle with a single positive electrical charge, found in the nucleus of an atom.
- proton pump** An active transport mechanism in cell membranes that uses ATP to force hydrogen ions out of a cell, generating a membrane potential in the process.
- prototrichia** A mass of green, branched, one-cell-thick filaments produced by germinating moss spores.
- protonephridium** (*pro'-to-nuh-frid-e-um*) An excretory system, such as the flame-bulb system of flatworms, consisting of a network of closed tubules having external openings called nephriopores and lacking internal openings.
- proto-motive force** The potential energy stored in the form of an electrochemical gradient, generated by the pumping of hydrogen ions across biological membranes during chemiosmosis.
- proto-oncogene** (*pro'-to-on'-ko-jeh*) A normal cellular gene corresponding to an oncogene; a gene with a potential to cause cancer but that requires some alteration to become an oncogene.
- protoplast** The contents of a plant cell exclusive of the cell wall.
- protoplasm fusion** The fusing of two protoplasts from different plant species that would otherwise be reproductively incompatible.
- protostome development** In animals, a developmental mode distinguished by the development of the mouth from the blastopore; often also characterized by schizocoelous development of the body cavity and by spiral cleavage.
- protozoan** (*pro'-lo-zo'-un*) A protist that feeds by ingesting food, an animal-like mode of nutrition.
- ptovirus** Viral DNA that inserts into a host genome.
- proximal tubule** In the vertebrate kidney, the portion of a nephron immediately downstream from Bowman's capsule that conveys and helps refine nitrate.
- proximate question** In animal behavior, an inquiry that focuses on the environmental stimuli, if any, that trigger a particular behavioral act, as well as the genetic, physiological, and anatomical mechanisms underlying it.
- PR protein** A protein involved in plant responses to pathogens (PR = pathogenesis-related).
- pseudocoelomate** (*sü'-do-sé'-lo-mat*) An animal whose body cavity is not completely lined by mesoderm.
- pseudogene** A DNA segment very similar to a real gene but which does not yield a functional product; a gene that has become inactivated in a particular species because of mutation.
- pseudopodium** (*su-dö-pö'-de-um*) (plural, pseudopodia) A cellular extension of amoeboid cells used in moving and feeding.
- pterophyte** An informal name for any member of the phylum Pterophyta, which includes ferns, horsetails, whisk ferns, and the genus *Tmesipteris*.
- pterosaur** Winged reptile that lived during the time of dinosaurs.
- pulmocutaneous circuit** The route of circulation that directs blood to the skin and lungs.
- pulmonary circuit** The branch of the circulatory system that supplies the lungs.
- pulse** The rhythmic stretching of the arteries caused by the pressure of blood forced through the arteries by contractions of the ventricles during systole.
- punctuated equilibrium** In evolutionary theory, long periods of apparent stasis (no change) interrupted by relatively brief periods of sudden change.
- Punnett square** A diagram used in the study of inheritance to show the results of random fertilization in genetic crosses.
- pupli** The opening in the iris, which admits light into the interior of the vertebrate eye. Muscles in the iris regulate its size.
- purine** (*pyü'-ren*) One of two types of nitrogenous bases found in nucleotides. Adenine (A) and guanine (G) are purines.
- pyloric sphincter** (*pT-lör'-ik sfink'-ter*) In the vertebrate digestive tract, a muscular ring that regulates the passage of food out of the stomach and into the small intestine.
- pyrimidine** (*püh-rim-uh-den*) One of two types of nitrogenous bases found in nucleotides. Cytosine (C), thymine ("T"), and uracil (U) are pyrimidines.
- quantitative character** A heritable feature that varies continuously over a range rather than in an either-or fashion.
- quaternary structure** (*kwof-er-när-e*) The particular shape of a complex, aggregate protein, defined by the characteristic three-dimensional arrangement of its constituent subunits, each a polypeptide.
- R plasmid** A bacterial plasmid bearing genes that confer resistance to certain antibiotics.
- radial cleavage** A type of embryonic development in deuterostomes in which the planes of cell division that transform the zygote into a ball of cells are either parallel or perpendicular to the polar axis, thereby aligning tiers of cells one above the other.
- radial glia** In an embryo, supporting cells that form tracks along which newly formed neurons migrate from the neural tube; can also act as stem cells that give rise to neurons and other glia.
- radial symmetry** Characterizing a body shaped like a pie or barrel, with many equal parts radiating outward like the spokes of a wheel; present in cnidarians and echinoderms; also can refer to flower structure.
- radiation** The emission of electromagnetic waves by all objects warmer than absolute zero.
- radicle** An embryonic root of a plant.
- radioactive isotope** An isotope (an atomic form of a chemical element) that is unstable; the nucleus decays spontaneously, giving off detectable particles and energy.
- radiolarian** A protist, usually marine, with a shell generally made of silica and pseudopodia that radiate from the central body.
- radiometric dating** A method paleontologists use for determining the ages of rocks and fossils on a scale of absolute time, based on the half-life of radioactive isotopes.
- radula** A straplike rasping organ used by many molluscs during feeding.
- ras gene** A gene that codes for Ras protein, a G protein that relays a growth signal from a growth factor receptor on the plasma membrane to a cascade of protein kinases that ultimately results in the stimulation of the cell cycle. Many Ras oncogenes have a point mutation that leads to a hyperactive version of the Ras protein that can lead to excessive cell division.
- ratite** (*rat*-it*) Member of the group of flightless birds.
- ray initials** Cells within the vascular cambium that produce xylem and phloem rays, radial files that consist mostly of parenchyma cells.
- ray-finned fish** Member of the class *Osteichthyes*.
- reactant** A starting material in a chemical reaction.
- reaction center** Complex of proteins associated with two special chlorophyll *a* molecules and a primary electron acceptor. Located centrally in a photosystem, this complex triggers the light reactions of photosynthesis. Excited by light energy, one of the chlorophylls donates an electron to the primary electron acceptor, which passes an electron to an electron transport chain.
- reading frame** The way a cell's mRNA-translating machinery groups the mRNA nucleotides into codons.
- receptacle** The base of a flower; the part of the stem that is the site of attachment of the floral organs.

Glossary

- reception In cellular communication, the target cell's detection (by binding to a receptor protein) of a signal molecule from outside the cell.
- receptor-mediated endocytosis (*en*-*do-si-to-*'sis) The movement of specific molecules into a cell by the inward budding of membranous vesicles containing proteins with receptor sites specific to two molecules being taken in; enables a cell to acquire bulk quantities of specific substances.
- receptor potential An initial response of a receptor cell to a stimulus, consisting of a change in voltage across the receptor membrane proportional to the stimulus strength. The intensity of the receptor potential determines the frequency of action potentials traveling to the nervous system.
- receptor tyrosine kinase A receptor protein in the plasma membrane that responds to the binding of a signal molecule by catalyzing the transfer of phosphate groups from ATP to tyrosines on the cytoplasmic side of the receptor. The phosphotyrosylated tyrosines activate other signal transduction proteins within the cell.
- recessive allele An allele whose phenotypic effect is not observed in a heterozygote.
- reciprocal altruism Altruistic behavior between unrelated individuals, whereby the current altruistic individual benefits the future when the current beneficiary reciprocates.
- recombinant An offspring whose phenotype differs from that of its parents; also called recombinant type.
- recombinant chromosome A chromosome created when crossing over combines the DNA from two parents into a single chromosome.
- recombinant DNA A DNA molecule, made *in vitro* with segments from different sources.
- recruitment The process of progressively increasing the tension of a muscle by activating more and more of the motor neurons controlling the muscle.
- rectum The terminal portion of the large intestine where the feces are stored until they are eliminated.
- red alga A photosynthetic marine protist that contains the accessory pigment phycoerythrin. Most are multicellular.
- red blood cell A blood cell containing hemoglobin, which transports O₂; also called an erythrocyte.
- redox reaction (*re-doks*) A chemical reaction involving the transfer of one or more electrons from one reactant to another; also called oxidation-reduction reaction.
- reducing agent The electron donor in a redox reaction.
- reduction The addition of electrons to a substance involved in a redox reaction.
- reductionism Reducing complex system? 10 simpler components that are more manageable to study.
- redundancy model The concept, put forth by Henry Gleason and Brian Walker, that most of the species in a community are not tightly coupled with, one another (that is, the web of life is very loose). According to this model, an increase or decrease in one species in a community has little effect on other species, which operate independently reflex An automatic reaction to a stimulus, mediated by the spinal cord or lower brain, refractory period (*re-frak-tor-e*) The short time immediately after an action potential in which the neuron cannot respond to another stimulus, owing to an increase in potassium permeability.
- regeneration The growth of body parts from pieces of an organism.
- regulator A characterization of an animal in regard to environmental variables. A regulator uses mechanisms of homeostasis to moderate internal changes in the face of external fluctuations.
- regulatory gene A gene that codes for a protein, such as a repressor, that controls the transcription of another gene or group of genes.
- relative abundance Differences in the abundance of different species // *ithir.* a community
- relative fitness The contribution of one genotype to the next Generators compared to that of alternative genotypes for the same locus.
- renal artery The blood vessel bringing blood to the kidney.
- renal cortex The outer portion of the vertebrate kidney.
- renal medulla The inner portion of the vertebrate kidney, beneath the renal cortex.
- renal pelvis Funnel-shaped chamber that receives processed filtrate from the vertebrate kidney's collecting ducts and is drained by the ureter.
- renal vein The blood vessel draining the kidney.
- renin-angiotensin-aldosterone system (RAAS) A part of a complex feedback circuit that helps regulate blood pressure and blood volume.
- repeated reproduction A life history in which adults produce large numbers of offspring over many years; also known as iteroparity
- repetitive DNA Nucleotide sequences, usually noncoding, that are present in many copies in a eukaryotic genome. The repeated units may be short and arranged tandemly (in series) or long and dispersed in the genome.
- replicational fork A Y-shaped region on a replicating DNA molecule where new strands are growing.
- repressor A protein that suppresses the transcription of a gene.
- reproductive isolation The existence of biological factors (barriers) that impede members of two species from producing viable, fertile hybrids.
- reproductive table An age-specific summary of the reproductive rates in a population.
- reptile Member of the clade of amniotes that includes tuatara, lizards, snakes, turtles, crocodilians, and birds.
- residual volume The amount of air that remains in the lungs after forcefully exhaling, resources partitioning The division of environmental resources by coexisting species such that the niche of each species differs by one or more significant factors from the niches of all coexisting species.
- respiratory medium The source of oxygen. It is typically air for terrestrial animals and water for aquatic organisms.
- respiratory pigment A protein that transports most of the oxygen in blood.
- respiratory surface The part of an animal where gases are exchanged with the environment.
- response In cellular communication, the change in a specific cellular activity brought about by a transduced signal from outside the cell.
- resting potential The membrane potential characteristic of a nonconducting, excitable cell, with the inside of the cell more negative than the outside.
- restoration ecology A goal-directed science that applies ecological principles in an effort to return degraded ecosystems to conditions as similar as possible to their natural, predegraded state.
- restriction enzyme A degradative enzyme that recognizes and cuts up DNA (including that of certain phases) that is foreign to a bacterium.
- restriction fragment DNA segment resulting from cutting of DNA by a restriction enzyme.
- restriction fragment length polymorphisms (RFLPs) Differences in DNA sequence on homologous chromosomes that can result in different patterns of restriction fragment lengths (DNA segments resulting from treatment with restriction enzymes); useful as genetic markers for making linkage maps.
- restriction site A specific sequence on a DNA strand that is recognized as a "cut site" by a restriction enzyme.
- reticular fiber A very thin and branched fiber made of collagen. Reticular fibers form a tightly woven fabric that is continuous with the collagenous fibers of the extracellular matrix.
- reticular formation A system of neurons, containing over 90 separate nuclei, that passes through the core of the brainstem.
- retina (*ret-uh-nuh*) The innermost layer of the vertebrate eye, containing photo-receptor cells (rods and cones) and neurons; transmits images formed by the lens to the brain via the optic nerve.
- retinal The light-absorbing pigment in rods and cones of the vertebrate eye.
- retrotransposon *A rjaissuu-aok:* element that moves within a genome by means of an RNA intermediate, a transcript of the retrotransposon DNA.

- retrovirus (ret'-tro-vT-rus)** An RNA virus that reproduces by transcribing its RNA into DNA and then inserting the DNA into a cellular chromosome; an important class of cancer-causing viruses.
- reverse transcriptase (tran-skrip'-tas)** An enzyme encoded by some certain viruses (retroviruses) that uses RNA as a template for DNA synthesis.
- Rh factor A** protein antigen on the surface of red blood cells designated Rh-positive. If an Rh-negative mother is exposed to blood from an Rh-positive fetus, she produces anti-Rh antibodies of the IgG class.
- rhizoid Lorii** tubular single cell or filament of cells that anchors bryophytes to die ground.
- Rhizoïdes** are *nc* composed of tissues, lack specialized conducting cells, and do not play a primary role in water and mineral absorption.
- rhodopsin** A visual pigment consisting of retinal and opsin. When rhodopsin absorbs light, the retinal changes shape and dissociates from the opsin, after which it is converted back to its original form.
- rhythm method** A form of contraception that relies on refraining from sexual intercourse when conception is most likely to occur; also called natural family planning.
- ribonucleic acid (RNA) (ri'-bo-nu-kla'-ik)** A type of nucleic acid consisting of nucleotide monomers with a ribose sugar and the nitrogenous bases adenine (A), cytosine i.O, guanine (G), and uracil *i: usually single-stranded; functions in protein synthesis and as the genome of some viruses.
- ribose** The sugar component of RNA.
- ribosomal RNA (rRNA) (T-buh-so'-mul)** The most abundant type of RNA, which together with proteins forms the structure of ribosomes. Ribosomes coordinate the sequential coupling of tRNA molecules to mRNA codons.
- ribosome** A cell organelle constructed in the nucleolus and functioning as the site of protein synthesis in the cytoplasm; consists of rRNA and protein molecules, which make up two subunits.
- ribozyme (ri'-bo-zim)** An enzyme-like RNA molecule that catalyzes reactions during RNA splicing.
- river A flowing body of water.**
- rivet model** The concept, put forth by Paul and Anne Ehrlich, that many or most of the species in a community are associated tightly with other species in a web of life. According to this model, an increase or decrease in one species in a community affects many other species.
- RNA interference (RNAi)** A technique to silence the expression of selected genes in nonmammalian organisms. The method uses synthetic double-stranded RNA molecules matching the sequence *oi* a particular gene to trigger the breakdown of the gene's messenger RNA.
- RNA polymerase** An enzyme that links together the growing chain of ribonucleotides during transcription.
- RNA processing** Modification of RNA before it leaves the nucleus, a process unique to eukaryotes.
- RNA splicing** The removal of noncoding portions (introns) of the RNA molecule after initial synthesis.
- rod cell** One of two kinds of photoreceptors in the vertebrate retina: sensitive to black and white and enables night vision.
- root** An organ in vascular plants that anchors the plant and enables it to absorb water and nutrients from the soil.
- root cap** A cone of cells at the tip of a plant root that protects the apical meristem.
- root hair** A tiny extension of a root epidermal c.A. growing just behind the root tip and increasing surface area for absorption of water and minerals.
- root pressure** The upward push of \ lem -ap in the vascular tissue of roots.
- root system** All of a plant's roots that anchor it in the soil, absorb and transport minerals and water, and store food.
- rosette** cellulose-synthesizing complex Rose-shaped array of proteins that synthesize the cellulose microfibrils of the cell walls of charophyceans and land plants.
- rough ER** That portion of the endoplasmic reticulum studded with ribosomes.
- round window** The point of contact between the stapes and the cochlea. It is where the vibrations of the stapes create a traveling series of pressure waves in the fluid of the cochlea.
- r-selection** The concept that in certain (r-selected) populations, a high reproductive rate is the chief determinant of life history.
- rubisco** Ribulose carboxylase, the enzyme that catalyzes the first step of the Calvin cycle (the addition of CO₂ to RuBP, or ribulose bisphosphate).
- ruminant** An animal, such as a cow or a sheep, with an elaborate, multicompartmentalized stomach specialized for an herbivorous diet.
- S phase** The synthesis phase of the cell cycle; the portion of interphase during which DNA is replicated.
- sac fungus** Member of the phylum Ascomycota. Sac fungi range in size and complexity from unicellular yeasts to minute leafspot fungi to elaborate cup fungi and morels. About half of the sac fungi live with algae or cyanobacteria in the mutualistic associations called lichens.
- saccule** A chamber in the vestibule behind the oval window that participates in the sense of balance.
- salicylic acid** A plant hormone that may be partially responsible for activating systemic acquired resistance to pathogens.
- salivary amylase** A salivary gland enzyme that hydrolyzes starch and glycogen.
- salivary glands** Exocrine glands associated with the oral cavity. The secretions of salivary glands contain substances to lubricate food, adhere together chewed pieces into a bolus, and begin the process of chemical digestion.
- salt** A compound resulting from the formation of an ionic bond; also called an ionic compound.
- saltatory conduction (sol"-sub-tor'-E)** Rapid transmission of a nerve impulse along an axon, resulting from the action potential jumping from one node of Ranvier to another, skipping the myelin-sheathed regions of membrane.
- sapwood** Outer layers of secondary xylem that still transport xylem sap.
- sarcomere (sar'-ko-mer)** The fundamental, repeating unit of striated muscle, delimited by the Z lines.
- sarcoplasmic reticulum (SR)** A specialized endoplasmic reticulum that regulates di calcium concentration in the cytosol.
- saturated fatty acid** A fatty acid in which all carbons in the hydrocarbon tail are connected by single bonds, thus maximizing the number of hydrogen atoms that can attach to the carbon skeleton.
- savanna (suu-win -ub)** A tropical grassland biome with scattered individual trees, large herbivores, and three distinct seasons based primarily on rainfall, maintained by occasional fires and drought.
- scaffolding protein** A type of large relay protein to which several other relay proteins are simultaneously attached to increase the efficiency of signal transduction.
- scanning electron microscope (SEM) A** microscope that uses an electron beam to scan the surface of a sample to study details of its topography.
- schizocoelous** Pattern of formation of the body cavity common in protostome development, in which initially solid masses of mesoderm split, forming the body cavity.
- schizophrenia** Severe mental disturbance characterized by psychotic episodes in which patients lose the ability to distinguish reality from hallucination.
- Schwann cell** A type of glial cell that forms insulating myelin sheaths around the axons of neurons in the peripheral nervous system.
- scion (sT-un)** The twig grafted onto the stock when making a graft.
- sclera (sklar'-uh)** A tough, white outer layer of connective tissue that forms the globe of the vertebrate eye.
- scleireid (sklar'-e-id)** A short, irregular sclerenchyma cell in nutshells and seed coats and scattered through the parenchyma of some plants.
- sclerenchyma cell (skluh-ren'-ke-muh)** A rigid, supportive plant cell type usually lacking protoplasts and possessing thick secondary walls strengthened by lignin at maturity.

- reception In cellular communication, the target redundancy model The concept, put forth by reptile Member of the clade of amniotes that scrotum A pouch of skin outside the abdomen that houses a testis; functions in cooling sperm, thereby keeping them viable.
- scutellum (skoo-tel'-uhm) A specialized type of cotyledon found in the grass family.
- seascape Several different, primarily aquatic ecosystems linked by exchanges of energy, materials, and organisms.
- second law of thermodynamics The principle whereby(ever) energy transfer or transformation increases the entropy of the universe. Ordered forms of energy are at least partly converted to heat, and in spontaneous reactions, the free energy of the system also decreases.
- second messenger A small, nonprotein, water-soluble molecule or ion, such as calcium ion or cyclic AMP, that relays a signal to a cell's interior in response to a signal received by a signal receptor protein.
- secondary cell wall A strong and durable matrix often deposited in several laminated layers for plant cell protection and support.
- secondary consumer A member of the trophic level of an ecosystem consisting of carnivores that eat herbivores.
- secondary endosymbiosis A process in eukaryotic evolution in which a heterotrophic eukaryotic cell engulfed a photosynthetic eukaryotic cell, which survived in a symbiotic relationship inside the heterotrophic cell.
- secondary growth Growth produced by lateral meristems, thickening the roots and shoots of woody plants.
- secondary immune response The acquired immune response elicited on second or subsequent exposures to a particular antigen. The secondary immune response is more rapid, of greater magnitude, and of longer duration than the primary immune response.
- secondary oocyte A haploid cell resulting from meiosis I in oogenesis, which will become an ovum after meiosis II.
- secondary plant body The tissues produced by the vascular cambium and cork cambium, which thicken the stems and roots of woody plants.
- secondary production The amount of chemical energy in consumers' food that is converted to their own new biomass during a given time period.
- secondary structure The localized, repetitive coiling or folding of the polypeptide backbone of a protein due to hydrogen bond formation between peptide linkages.
- secondary succession A type of succession that occurs where an existing community has been cleared by some disturbance that leaves the soil intact.
- secretion (1) The discharge of molecules synthesized by a cell. (2) The discharge of wastes from the body fluid into the filtrate.
- secretory phase That portion of the uterine (menstrual) cycle when the endometrium continues to thicken, becomes more vascularized, and develops glands that secrete a fluid rich in glycogen.
- sedimentary rock (sed'-uh-men-tuh-re) Rock formed from sand and mud that once settled in layers on the bottom of seas, lakes, and marshes. Sedimentary rocks are often rich in fossils.
- seed An adaptation for terrestrial plants consisting of an embryo packaged along with a store of food within a resistant coat.
- seed coat A tough outer covering of a seed, formed from the outer coat of an ovule. In a flowering plant, the seed coat encloses and protects the embryo and endosperm.
- seedless vascular plants The informal collective name for the phyla Lycopodiophyta (club mosses and their relatives) and Pteridophyta (ferns and their relatives).
- segmentation gene A gene of the embryo that directs the actual formation of segments after the embryo's axes are defined.
- selective permeability A property of biological membranes that allows some substances to cross more easily than others.
- selective reabsorption The selective uptake of solutes from a filtrate of blood, coelomic fluid, or hemulymph in the excretory organs of animals.
- self-incompatibility The ability of a seed plant to reject its own pollen and sometimes the pollen of closely related individuals.
- semelparity A life history in which adults have but a single reproductive opportunity to produce large numbers of offspring, such as the life history of the Pacific salmon: also known as big-bang reproduction.
- semen (se'-mun) The fluid that is ejaculated by the male during orgasm; contains sperm and secretions from several glands of the male reproductive tract.
- semicircular canals A three-part chamber of the inner ear that functions in maintaining equilibrium.
- semiconservative model Type of DNA replication in which the replicated double helix consists of one old strand, derived from the old molecule, and one newly made strand.
- semilunar valve A valve located at the two exits of the heart, where the aorta leaves the left ventricle and the pulmonary artery leaves the right ventricle.
- seminal vesicle (sem'-uh-nul ves'-uh-kul) A gland in males that secretes a fluid component of semen that lubricates and nourishes sperm.
- seminiferous tubule (sem'-uh-nif'-uh-rus) A highly coiled tube in the testis in which sperm are produced.
- sensation An impulse sent to the brain from activated receptors and sensory neurons.
- sensitive period A limited phase in an individual animal's development when learning of particular behaviors can take place.
- sensory adaptation The tendency⁷ of sensory neurons to become less sensitive when they are stimulated repeatedly.
- sensory neuron A nerve cell that receives information from the internal and external environments and transmits the signals to the central nervous system.
- sensory reception The detection of the energy of a stimulus by sensory cells.
- sensory receptor A cellular system that collects information about the physical world outside the body and inside the organism.
- sensory transduction The conversion of stimulus energy to a change in the membrane potential of a sensory receptor.
- sepal (se'-pul) A modified leaf in angiosperms that helps enclose and protect a flower bud before it opens.
- septum (plural, septa) One of the cross-walls that divide a fungal hypha into cells. Septa generally have pores large enough to allow ribosomes, mitochondria, and even nuclei to flow from cell to cell.
- sequential hermaphroditism A reproductive pattern in which an individual reverses its sex during its lifetime.
- serial endosymbiosis A model of the origin of eukaryotes consisting of a sequence of endosymbiotic events in which mitochondria, chloroplasts, and perhaps other cellular structures were derived from small prokaryotes that had been engulfed by larger cells.
- serotonin A biogenic amine synthesized from the amino acid tryptophan.
- seta (se'-tuh) The elongated stalk of a bryophyte sporophyte, such as in a moss.
- sex chromosome One of the pair of chromosomes responsible for determining the sex of an individual.
- sex-linked gene A gene located on a sex chromosome.
- sexual dimorphism (dih-mor'-fizm) A special case of polymorphism based on the distinction between the secondary sex characteristics of males and females.
- sexual reproduction A type of reproduction in which two parents give rise to offspring that have unique combinations of genes inherited from the gametes of the two parents.
- sexual selection Natural selection for mating success.
- shared derived character An evolutionary novelty that evolved within a particular clade.
- shared primitive character A character displayed in species outside a particular taxon.
- shoot system The aerial portion of a plant body, consisting of stems, leaves, and (in angiosperms) flowers.
- short-day plant A plant that flowers (usually in late summer, fall, or winter) only when the light period is shorter than a critical length.
- short-term memory The ability to hold information, anticipations, or goals for a time and then release them if they become irrelevant.

- sickle-cell disease** A human genetic disease caused by a recessive allele that results in the substitution of a single amino acid in the hemoglobin protein, characterized by deformed red blood cells that can lead to numerous symptoms.
- sieve plate** An end wall in a sieve-tube member, which facilitates the flow of phloem sap in angiosperm sieve tubes.
- sieve-tube member** A living cell that conducts sugars and other organic nutrients in the phloem of angiosperms. They form chains called sieve tubes.
- sign stimulus** An external sensory stimulus that triggers a fixed, action pattern.
- signal** A behavior that causes a change in behavior in another animal.
- signal peptide** A stretch of amino acids on a polypeptide that targets the protein to a specific destination in a eukaryotic cell.
- signal-recognition particle (SRP)** A protein-RNA complex that recognizes a signal peptide as it emerges from the ribosome.
- signal transduction pathway** A mechanism linking a mechanical or chemical stimulus to a specific cellular response.
- simple fruit** A fruit derived from a single carpel or several fused carpels.
- simple epithelium** An epithelium consisting of a single layer of cells that all touch the basal lamina.
- single nucleotide polymorphisms (SNPs)** One base-pair variation in the genome sequence.
- single-lens eye** The camera-like eye found in some jellies, polychaetes, spiders, and many molluscs.
- single-strand binding protein** During DNA replication, molecules that line up along the unpaired DNA strands, holding them apart while the DNA strands serve as templates for the synthesis of complementary strands of DNA.
- sinoatrial (SA) node** A region of the heart composed of specialized muscle tissue that sets the rate and timing at which all cardiac muscle cells contract; the pacemaker.
- sinus** Any of the spaces surrounding the organs of the body in animals with open circulatory systems.
- sister chromatids** Replicated forms of a chromosome joined together by the centromere and eventually separated during mitosis or meiosis II.
- skeletal muscle (striated muscle)** Muscle generally responsible for the voluntary movements of the body
- sliding-filament model** The theory explaining how muscle contracts, based on change within a sarcomere, the basic unit of muscle organization, stating that thin (actin) filaments slide across thick (myosin) filaments, shortening the sarcomere. The shortening of all sarcomeres in a myofibril shortens the entire myofibril.
- slow block to polyspermy** The formation of the fertilization envelope and other changes in the egg's surface that prevent fusion of the egg with more than one sperm.
- slow muscle fibers** Muscle cells that can sustain long contractions.
- small intestine** The longest section of the alimentary canal; the principal site of the enzymatic hydrolysis of food macromolecules and the absorption of nutrients.
- smooth ER** That portion of the endoplasmic reticulum that is free of ribosomes.
- smooth muscle** A type of muscle lacking the striations of skeletal and cardiac muscle because of the uniform distribution of myosin filaments in the cell; responsible for involuntary body activities.
- snowball Earth hypothesis** The hypothesis that glaciers covered the planet's landmasses from pole to pole 750–570 million years ago, confining life to very limited areas.
- social learning** Modification of behavior through the observation of other individuals.
- sociobiology** The study of social behavior based on evolutionary theory.
- sodium-potassium pump** A special transport protein in the plasma membrane of animal cells that transports sodium out of the cell and potassium into the cell against their concentration gradients.
- solute (sol'-üit)** A substance that is dissolved in a solution.
- solute potential (H^a)** A component of water potential that is proportional to the number of dissolved solute molecules in a solution and measures the effect of solutes on the direction of water movement; also called osmotic potential; it can be either zero or negative.
- solution** A liquid that is a homogeneous mixture of two or more substances.
- solvent** The dissolving agent of a solution. Water is the most versatile solvent known.
- somatic cell (so-mat'-ik)** Any cell in a multicellular organism except a sperm or egg cell.
- somatic nervous system** The branch of the motor division of the vertebrate peripheral nervous system composed of motor neurons that carry signals to skeletal muscles in response to external stimuli.
- somites** Paired blocks of mesoderm just lateral to the notochord of a vertebrate embryo.
- soredia** In lichens, small clusters of fungal hyphae with embedded algae.
- sorus (plural, sori)** A cluster of sporangia on a fern sporophyll. Sori may be arranged in various patterns, such as parallel lines or dots, that are useful in fern identification.
- Southern blotting** A hybridization technique that enables researchers to determine the presence of certain nucleotide sequences in a sample of DNA.
- spatial learning** Modification of behavior based on experience of the spatial structure of the environment.
- spatial summation** A phenomenon of neural integration in which the membrane potential of the postsynaptic cell is determined by the combined effect of EPSPs or IPSPs produced nearly simultaneously by different synapses.
- speciation (spe"-se-a-shun)** The origin of new species in evolution.
- species** A group whose members possess similar anatomical characteristics and have the ability to interbreed.
- species-area curve** The biodiversity pattern, first noted by Alexander von Humboldt, that illustrates that the larger the geographic area of a community, the greater the number of species.
- species diversity** The number and relative abundance of species in a biological community.
- species richness** The number of species in a biological community.
- species selection** A theory maintaining that species living the longest and generating the greatest number of species determine the direction of major evolutionary trends.
- specific epithet** The second part of a binomial, referring to one species within a genus.
- specific heat** The amount of heat that must be absorbed or lost for 1 g of a substance to change its temperature by 1°C.
- spectrophotometer** An instrument that measures the proportions of light of different wavelengths absorbed and transmitted by a pigment solution.
- sperm** The male gamete.
- spermatheca (sper"-muh-the'-kuh)** A sac in the female reproductive system where sperm are stored.
- spERMATogenesis** The continuous and prolific production of mature sperm cells in the testis.
- spERMATOGONIA** Stem cells that give rise to sperm.
- sphincter (sfink'-ter)** A ringlike valve consisting of modified muscles in a muscular tube, such as a digestive tract; closes off the tube like a drawstring.
- spinal nerve** In the vertebrate peripheral nervous system, a nerve that carries signals to or from the spinal cord.
- spiral cleavage** A type of embryonic development in protostomes, in which the planes of cell division that transform the zygote into a ball of cells occur obliquely to the polar axis, resulting in cells of each tier sitting in the grooves between cells of adjacent tiers.
- spiral valve** A corkscrew-shaped ridge that increases surface area and prolongs the passage of food along the short digestive tract.
- spliceosome (spli'-se-o-som)** A complex assembly that interacts with the ends of an RNA intron in splicing RNA, releasing the intron and joining the two adjacent exons.
- spongocoel (spon'-j6-sel)** The central cavity of a sponge.
- spongy mesophyll** Loosely arranged photosynthetic cells located below the palisade mesophyll cells in a leaf.

Glossary

sporangium (plural, *sporangia*) A capsule in fungi and plants in which meiosis occurs and haploid spores develop.

spore In the life cycle of a plant or alga undergoing alternation of generations, a meiotically produced haploid cell that divides mitotically generating a multicellular individual, the gametophyte, without fusing with another cell.

sporocyte A diploid cell, also known as a spore mother cell, that undergoes meiosis and generates haploid spores.

sporophyll A leaf specialized for reproduction.

sporophyte (spór'-o-fit) In organisms undergoing alternation of generations, the multicellular diploid form that results from a union of gametes and that meiotically produces haploid spores that grow into the gametophyte generation.

sporopollenin (spór'-uh-pol'-uh-nin) A durable polymer that covers exposed zygotes of charophycean algae and forms walls of plant spores, preventing them from drying out.

sporozoite (spór'-uh-zo'-it) A tiny infectious cell that represents a stage in the apicomplexan life cycle.

squamous The flat, tile-like shape of a type of epithelial cell.

stabilizing selection Natural selection that favors intermediate variants by acting against extreme phenotypes.

stamen (sta'men) The pollen-producing reproductive organ of a flower, consisting of an anther and filament.

standard metabolic rate (SMR) The metabolic rate of a resting, fasting, and nonstressed ectotherm.

stapes The third of the three middle ear bones.

starch A storage polysaccharide in plants consisting entirely of glucose.

statocyst (stat'-uh-sist) A type of mechanoreceptor that functions in equilibrium in invertebrates through the use of statoliths, which stimulate hair cells in relation to gravity. **statolith** (1) In plants, a specialized plastid that contains dense starch grains and may play a role in detecting gravity. (2) In invertebrates, a grain or other dense granule that settles in response to gravity and is found in sensory organs that function in equilibrium.

stele The vascular tissue of a stem or root.

stem A vascular plant organ consisting of an alternating system of nodes and internodes that support the leaves and reproductive structures.

stem cell Any relatively unspecialized cell that can divide during a single division into one identical daughter cell and one more specialized daughter cell, which can undergo further differentiation.

stenohaline Referring to organisms that cannot tolerate substantial changes in external osmolarity.

steroid A type of lipid characterized by a carbon skeleton consisting of four rings with various functional groups attached.

sticky end A Single-Stranded end of a double-stranded DNA restriction fragment.

stigma (plural, *stigmata*) The sticky part of a flower's carpel, which traps pollen grains.

stipe A stemlike structure of a seaweed.

stock The plant that provides the root system when making a graft.

stoma (sto'muh) (plural, *stomata*) A microscopic pore surrounded by guard cells in the epidermis of leaves and stems that allows gas exchange between the environment and the interior of the plant.

stomach An organ of the digestive system that stores food and performs preliminary steps of digestion.

stratified epithelium An epithelium consisting of more than one layer of cells in which some but not all cells touch the basal lamina.

stream A flowing body of water that is generally small, cold, and clear.

stress-induced proteins Molecules, including heat-shock proteins, that are produced within cells in response to exposure to marked increases in temperature and to other forms of severe stress, such as toxins, rapid pH changes, and viral infections.

stretch-gated ion channel Protein pore in a cell's plasma membrane that opens when the membrane is mechanically deformed, allowing the passage of certain ions.

striated muscle See skeletal muscle.

strobili The technical term for clusters of sporophylls known commonly as cones, found in most gymnosperms and some seedless vascular plants.

stroke The death of nervous tissue in the brain, usually resulting from rupture or blockage of arteries in the head.

stroke volume The amount of blood pumped by the left ventricle in each contraction.

stroma (stro'muh) The fluid of the chloroplast surrounding the thylakoid membrane; involved in the synthesis of organic molecules from carbon dioxide and water.

stromatolite Rocklike structure composed of layers of prokaryotes and sediment.

structural formula A type of molecular notation in which the constituent atoms are joined by lines representing covalent bonds.

structural isomer One of several organic compounds that have the same molecular formula but differ in the covalent arrangements of their atoms.

style The stalk of a flower's carpel, with the ovary at the base and the stigma at the top. **substance P** A neuropeptide that is a key excitatory signal that mediates our perception of pain.

substrate The reactant on which an enzyme works.

substrate feeder An organism that lives in or on its food source, eating its way through the food.

substrate-level phosphorylation The

formation of ATP by directly transferring a phosphate group to ADP from an intermediate substrate in catabolism.

sugar sink A plant organ that is a net consumer or storer of sugar. Growing roots, shoot tips, stems, and fruit are sugar sinks supplied by phloem.

sugar source A plant organ in which sugar is being produced by either photosynthesis or the breakdown of starch. Mature leaves are the primary sugar sources of plants.

sulphydryl group A functional group consisting of a sulfur atom bonded to a hydrogen atom. (—SH).

suprachiasmatic nuclei (SCN) A pair of structures in the hypothalamus of mammals that functions as a biological clock.

surface tension A measure of how difficult it is to stretch or break the surface of a liquid.

Water has a high surface tension because of the hydrogen bonding of surface molecules.

survivorship curve A plot of the number of members of a cohort that are still alive at each age; one way to represent age-specific mortality.

suspension feeder An aquatic animal, such as a clam or a baleen whale, that sifts small food particles from the water.

sustainable agriculture Long-term productive farming methods that are environmentally safe.

sustainable development The long-term prosperity of human societies and the ecosystems that support them.

swim bladder In aquatic osteichthyans, an air sac that enables the animal to control its buoyancy in the water.

symbiont (sim'b-uhnt) The smaller participant in a symbiotic relationship, living in or on the host.

symbiosis An ecological relationship between organisms of two different species that live together in direct contact.

sympathetic division One of three divisions of the autonomic nervous system of vertebrates; generally increases energy expenditure and prepares the body for action.

sympatric speciation (sim-pat'rik) A mode of speciation occurring as a result of a radical change in the genome of a subpopulation, reproductively isolating the subpopulation from the parent population.

symplast In plants, the continuum of cytoplasm connected by plasmodesmata between cells.

synapse (sin'aps) The locus where one neuron communicates with another neuron in a neural pathway; a narrow gap between a synaptic terminal of an axon and a signal-receiving portion (dendrite or cell body) of

- another neuron or effector cell. Neurotransmitter molecules released by synaptic terminals diffuse across the synapse, relaying messages to the dendrite or effector.
- synapsid** Member of an amniote clade distinguished by a single hole on each side of the skull, including the mammals.
- synapsis** The pairing of replicated homologous chromosomes during prophase I of meiosis.
- synaptic cleft** (sin-ap'-tik) A narrow gap separating the synaptic knob of a transmitting neuron from a receiving neuron or an effector cell.
- synaptic terminal** A bulb at the end of an axon in which neurotransmitter molecules are stored and released.
- synaptic vesicle** Membranous sac containing neurotransmitter molecules at the tip of the presynaptic axon.
- system** A more complex organization formed from a combination of components.
- systematics** The analytical study of the diversity and relationships of organisms, both present-day and extinct.
- systemic acquired resistance (SAR)** A defensive response in infected plants that helps protect healthy tissue from pathogenic invasion.
- systemic circuit** The branch of the circulatory system that supplies all body organs and then returns oxygen-poor blood to the right atrium via the veins.
- systemic circulation** Movement of blood through the systemic circuit.
- systems biology** An approach to studying biology that aims to model the dynamic behavior of whole biological systems.
- systole** (sis'-to-le) The stage of the heart cycle in which the heart muscle contracts and the chambers pump blood.
- systolic pressure** Blood pressure in the arteries during contraction of the ventricles.
- T cell receptor** The antigen receptor on T cells; a membrane-bound molecule consisting of one α chain and one β chain linked by a disulfide bridge and containing one antigen-binding site.
- T lymphocyte (T cell)** A type of lymphocyte, including the helper T cells and cytotoxic T cells, that develops to maturity in the thymus. After encountering antigen, T cells are responsible for cell-mediated immunity.
- taproot system** A root system common to eudicots, consisting of one large, vertical root (the taproot) that produces many smaller lateral, or branch, roots.
- taste buds** Collections of modified epithelial cells that are scattered in several areas of the tongue and mouth and are receptors for taste in humans.
- TATA box** A promoter DNA sequence crucial in forming the transcription initiation complex, *taxis* (tak'-sis) Movement toward or away from a stimulus.
- taxon (plural, taxa)** The named taxonomic unit at any given level of classification.
- taxonomy** (tak-son'-uh-me) Ordered division of organisms into categories based on a set of characteristics used to assess similarities and differences, leading to a classification scheme; the branch of biology concerned with naming and classifying the diverse forms of life.
- Tay-Sachs disease** A human genetic disease caused by a recessive allele for a dysfunctional enzyme, leading to accumulation of certain lipids in the brain. Seizures, blindness, and degeneration of motor and mental performance usually become manifest a few months after birth.
- technology** The application of scientific knowledge for a specific purpose.
- telomerase** An enzyme that catalyzes the lengthening of telomeres. The enzyme includes a molecule of RNA that serves as a template for new telomere segments.
- telomere** (tel'-uh-méir) The protective structure at each end of a eukaryotic chromosome. Specifically, the tandemly repetitive DNA at the end of the chromosome's DNA molecule. See also repetitive DNA.
- telophase** The fifth and final stage of mitosis, in which daughter nuclei are forming and cytokinesis has typically begun.
- temperate broadleaf forest** A biome located throughout midlatitude regions where there is sufficient moisture to support the growth of large, broadleaf deciduous trees.
- temperate grassland** A terrestrial biome dominated by grasses and forbs.
- temperate phage** A phage that is capable of reproducing by either the lytic or lysogenic cycle.
- temperature** A measure of the intensity of heat in degrees, reflecting the average kinetic energy of the molecules.
- template strand** The DNA strand that provides the template for ordering the sequence of nucleotides in an RNA transcript.
- temporal summation** A phenomenon of neural integration in which the membrane potential of the postsynaptic cell in a chemical synapse is determined by the combined effect of EPSPs or IPSPs produced in rapid succession.
- tendon** A type of fibrous connective tissue that attaches muscle to bone.
- terminal bud** Embryonic tissue at the tip of a shoot, made up of developing leaves and a compact series of nodes and internodes.
- terminator** In prokaryotes, a special sequence of nucleotides in DNA that marks the end of a gene. It signals RNA polymerase to release the newly made RNA molecule, which then departs from the gene.
- territoriality** A behavior in which an animal defends a bounded physical space against encroachment by other individuals, usually of its own species. Territory defense may involve direct aggression or indirect mechanisms such as scent marking or singing.
- tertiary consumer** A member of the trophic level of an ecosystem consisting of carnivores that eat mainly other carnivores.
- tertiary structure** (ter'-she-ar-e) Irregular contortions of a protein molecule due to interactions of side chains involved in hydrophobic interactions, ionic bonds, hydrogen bonds, and disulfide bridges.
- test** The hardened shell of some protists, including forams and radiolarians, or the rigid endoskeleton of a sea urchin or sand dollar.
- testcross** Breeding of an organism of unknown genotype with a homozygous recessive individual to determine the unknown genotype. The ratio of phenotypes in the offspring determines the unknown genotype.
- testis (plural, testes)** The male reproductive organ, or gonad, in which sperm and reproductive hormones are produced.
- testosterone** The most abundant androgen hormone in the male body.
- tetanus** (tet'-uh-nus) The maximal, sustained contraction of a skeletal muscle, caused by a very fast frequency of action potentials elicited by continual stimulation.
- tetrad** A paired set of homologous chromosomes, each composed of two sister chromatids.
- Tetrad** Form during prophase I of meiosis.
- tetrapod** A vertebrate with two pairs of limbs, including mammals, amphibians, and birds and other reptiles.
- thalamus** (tha'zuh-mus) One of two integrating centers of the vertebrate forebrain. Neurons with cell bodies in the thalamus relay neural input to specific areas in the cerebral cortex and regulate what information goes to the cerebral cortex.
- thallus (plural, thalli)** A seaweed body that is plantlike but lacks true roots, stems, and leaves.
- theory** An explanation that is broad in scope, generates new hypotheses, and is supported by a large body of evidence.
- thermal energy** See heat.
- thermocline** A narrow stratum of rapid temperature change in the ocean and in many temperate-zone lakes.
- thermodynamics** (ther'-mo-di-nam'-iks)
- (1) The study of energy transformations that occur in a collection of matter. See First law of thermodynamics and second law of thermodynamics.
 - (2) A phenomenon in which external DNA is taken up by a cell and functions there.
- thermoreceptor** An interoceptor stimulated by either heat or cold.
- thermoregulation** The maintenance of internal body temperature within a tolerable range.
- theropod** A member of an ancient group of dinosaurs that were bipedal carnivores.
- thick filament** A filament composed of staggered arrays of myosin molecules; a component of myofibrils in muscle fibers.

Glossary

thigmomorphogenesis A response in plants to chronic mechanical stimulation, resulting from increased ethylene production. An example is thickening stems in response to strong winds.

thigmotropism (thig'-mo-tro'-pizm) A directional growth of a plant in response to touch.

thin filament The smaller of the two myofilaments consisting of two strands of actin and two strands of regulatory protein coiled around one another.

thoracic cavity The body cavity in mammals that houses the lungs and heart. It is surrounded in part by ribs and separated from the lower abdominal cavity by the diaphragm. **threatened species** A species that is considered likely to become endangered in the foreseeable future.

three-domain system A system of taxonomic classification based on three "superkingdoms": Bacteria, Archaea, and Eukarya.

threshold The potential an excitable cell membrane must reach for an action potential to be initiated.

thrombus A clump of platelets and fibrin that blocks the flow of blood through a blood vessel.

thylakoid (thi'-luh-koyd) A flattened membrane sac inside the chloroplast, used to convert light energy to chemical energy.

thymus (thi'-mus) A small organ in the thoracic cavity of vertebrates where maturation of T cells is completed.

thyroid gland An endocrine gland, located on the ventral surface of the trachea, that secretes two iodine-containing hormones, triiodothyronine (T_3) and thyroxine (T_4), and calcitonin.

thyroid-stimulating hormone (TSH) A tropic hormone produced and secreted by the anterior pituitary that regulates the release of thyroid hormones.

thyroxine (T_4) One of two iodine-containing hormones that are secreted by the thyroid gland and help regulate metabolism, development, and maturation in vertebrates.

T plasmid A plasmid of a tumor-inducing bacterium that integrates a segment of its DNA into the host chromosome of a plant; frequently used as a carrier for genetic engineering in plants.

tidal volume The volume of air an animal inhales and exhales with each breath.

tight junction A type of intercellular junction in animal cells that prevents the leakage of material between cells.

tissue An integrated group of cells with a common function, structure, or both.

tissue system One or more tissues organized into a functional unit connecting the organs of a plant.

tonicity The ability of a solution to cause a cell within it to gain or lose water.

tonoplast A membrane that encloses the central vacuole in a plant cell separating the cytosol from the vacuolar contents, called cell sap; also known as the vacuolar membrane.

top-down model A model of community organization in which predation controls community organization because predators control herbivores, which in turn control plants, which in turn control nutrient levels; also called the trophic cascade model.

topoisomerase A protein that functions in DNA replication, helping to relieve strain in the double helix ahead of the replication fork.

topsoil A mixture of particles derived from rock, living organisms, and humus.

torpor In animals, a physiological state that conserves energy by slowing down metabolism.

torsion A characteristic of gastropods in which the visceral mass rotates during development.

totipotent Describing a cell that can give rise to all parts of an organism.

trace element An element indispensable for life but required in extremely minute amounts.

trachea (trä'-ké-uh) The windpipe; that portion of the respiratory tube that has C-shaped cartilaginous rings and passes from the larynx to two bronchi.

tracheal system A gas exchange system of branched, chitin-lined tubes that infiltrate the body and carry oxygen directly to cells in insects.

tracheid (trä'-ke-id) A long, tapered water-conducting cell that is dead at maturity and is found in the xylem of all vascular plants.

trait Any detectable variation in a genetic character.

trims Arrangement of two noncarbon atoms, each bound to one of the carbons in a carbon-carbon double bond, where the two noncarbon atoms are on opposite sides relative to the double bond.

transcription The synthesis of RNA on a DNA template.

transcription factor A regulatory protein that binds to DNA and stimulates transcription of specific genes.

transcription initiation complex The completed assembly of transcription factors and RNA polymerase bound to the promoter.

transcription unit A region of a DNA molecule

that is transcribed into an RNA molecule.

transduction (1) A DNA transfer process in which phages carry bacterial genes from one host cell to another. (2) In cellular communication, the conversion of a signal from outside the cell to a form that can bring about a specific cellular response.

transfer cell A companion cell with numerous ingrowths of its wall, increasing the cells surface area and enhancing the transfer of solutes between apoplast and symplast.

transfer RNA (tRNA) An RNA molecule that functions as an interpreter between nucleic

acid and protein language by picking up specific amino acids and recognizing the appropriate codons in the mRNA.

transformation (1) The conversion of a normal animal cell to a cancerous cell. (2) A change in genotype and phenotype due to the assimilation of external DNA by a cell.

transgenic Pertaining to an individual plant or animal whose genome contains a gene introduced from another organism, either from the same or a different species.

translation The synthesis of a polypeptide using the genetic information encoded in an mRNA molecule. There is a change of "language" from nucleotides to amino acids.

translocation (1) An aberration in chromosome structure resulting from attachment of a chromosomal fragment to a nonhomologous chromosome. (2) During protein synthesis, the third stage in the elongation cycle when the RNA carrying the growing polypeptide moves from the A site to the P site on the ribosome. (3) The transport of organic nutrients in the phloem of vascular plants.

transmission The conduction of impulses to the central nervous system.

transmission electron microscope (TEM) A microscope that passes an electron beam through very thin sections; primarily used to study the internal ultrastructure of cells.

transpiration The evaporative loss of water from a plant.

transport epithelium One or more layers of specialized epithelial cells that regulate solute movements.

transport protein A transmembrane protein that helps a certain substance or class of closely related substances to cross the membrane.

transport vesicle A tiny membranous sac in a cell's cytoplasm carrying molecules produced by the cell.

transposable element A segment of DNA that can move within the genome of a cell by means of a DNA or RNA intermediate; also called a transposon element.

transposon A transposable element that moves within a genome by means of a DNA intermediate.

transverse (T) tubules Infoldings of the plasma membrane of skeletal muscle cells.

triacylglycerol Three fatty acids linked to one glycerol molecule.

triiodothyronine (T_3) (tri'-i'-o'-do-thi'-ro-nen)

One of two iodine-containing hormones that are secreted by the thyroid gland and help regulate metabolism, development, and maturation in vertebrates.

trilobite An extinct arthropod with pronounced segmentation and appendages that varied little from segment to segment.

trimester In human development, one of three 3-month-long periods of pregnancy.

triple response A plant growth maneuver in response to mechanical stress, involving

- slowing of stem elongation, a thickening of the stem, and a curvature that causes the stem to start growing horizontally.**
- triplet code** A set of three-nucleotide-long words that specify the amino acids for polypeptide chains.
- triploblastic** Possessing three germ layers: the endoderm, mesoderm, and ectoderm. Most eumetazoans are **triploblastic**.
- trisomic** Referring to a cell that has three copies of a particular chromosome, instead of the normal two.
- trochophore larva** Distinctive larval stage observed in certain invertebrates, including some annelids and molluscs.
- trophic efficiency** The percentage of production transferred from one trophic level to the next.
- trophic structure** The different feeding relationships in an ecosystem, which determine the route of energy flow and the pattern of chemical cycling.
- trophoblast** The outer epithelium of the blastocyst, which forms the fetal part of the placenta.
- tropical rainforest** A terrestrial biome characterized by high levels of precipitation and warm temperatures year-round.
- troponin hormone** A hormone that has another endocrine gland as a target.
- tropics** Latitudes between 23.5° north and south.
- tropism** A growth response that results in the curvature of whole plant organs toward or away from stimuli owing to differential rates of cell elongation.
- tropomyosin** The regulatory protein that blocks the myosin-binding sites on the actin molecules.
- troponin complex** The regulatory proteins that control the position of tropomyosin on the thin filament.
- true-breeding** Referring to plants that produce offspring of the same variety when they self-pollinate.
- tubal ligation** A means of sterilization in which a woman's two oviducts (Fallopian tubes) are tied closed to prevent eggs from reaching the uterus. A segment of each oviduct is removed.
- tube foot** One of numerous extensions of an echinoderms water vascular system. Tube feet function in locomotion, feeding, and gas exchange.
- tumor-suppressor gene** A gene whose protein products inhibit cell division, thereby preventing uncontrolled cell growth (cancer).
- tundra** A biome at the extreme limits of plant growth. At the northernmost limits, it is called arctic tundra, and at high altitudes, where plant forms are limited to low shrubby or matlike vegetation, it is called alpine tundra.
- tunicate** Member of the subphylum Urochordata, sessile marine chordates that lack a backbone.
- turgid** (ter'-jid) Very firm. A walled cell becomes turgid if it has a greater solute concentration than its surroundings, resulting in **entry** of water.
- turgor pressure** The force directed against a cell wall after the influx of water and the swelling of a walled cell due to osmosis.
- turnover** The mixing of waters as a result of changing water-temperature profiles in a lake.
- turnover time** The time required to replace the standing crop of a population or group of populations (for example, of phytoplankton), calculated as the ratio of standing crop biomass to production.
- tympanic membrane** Another name for the eardrum.
- tyrosine kinase** An enzyme that catalyzes the transfer of phosphate groups from ATP to the amino acid tyrosine on a substrate protein.
- ultimate question** In animal behavior, an inquiry that focuses on the evolutionary significance of a behavioral act.
- ultrametric tree** A phylogenetic tree in which the lengths of the branches reflect measurements of geologic time.
- undernourishment** A diet that is chronically deficient in calories.
- uniformitarianism** Charles Lyell's idea that geologic processes have not changed throughout Earth's history.
- unsaturated fatty acid** A fatty acid possessing one or more double bonds between the carbons in the hydrocarbon tail. Such bonding reduces the number of hydrogen atoms attached to the carbon skeleton.
- urea** A soluble nitrogenous waste excreted by mammals, most adult amphibians, sharks, and some marine bony fishes and turtles; produced in the liver by a metabolic cycle that combines ammonia with carbon dioxide.
- ureter** A duct leading from the kidney to the urinary bladder.
- urethra** A tube that releases urine from the body near the vagina in females and through the penis in males; also serves in males as the exit tube for the reproductive system.
- uric acid** An insoluble precipitate of nitrogenous waste excreted by land snails, insects, and many reptiles, including birds.
- urinary bladder** The pouch where urine is stored prior to elimination.
- uterine cycle** The changes that occur in the uterus during the reproductive cycle of the human female; also called the menstrual cycle.
- uterus** A female organ where eggs are fertilized and/or development of the young occurs.
- utricle** A chamber behind the oval window that opens into the three semicircular canals.
- vaccination** See immunization.
- vaccine** A harmless variant or derivative of a pathogen that stimulates a host's immune system to mount defenses against the pathogen.
- vacuolar membrane** A membrane that encloses the central vacuole in a plant cell, separating the cytosol from the vacuolar contents, called cell sap; also known as the tonoplast.
- vagina** Part of the female reproductive system between the uterus and the outside opening; the birth canal in mammals; also accommodates the male penis and receives sperm during copulation.
- valence** The bonding capacity of an atom, generally equal to the number of unpaired electrons in the atom's outermost shell.
- valence electron** An electron in the outermost electron shell.
- valence shell** The outermost energy shell of an atom, containing the valence electrons involved in the chemical reactions of that atom.
- van der Waals interactions** Weak attractions between molecules or parts of molecules that are brought about by localized charge fluctuations.
- variation** Differences between members of the same species.
- vas deferens** The tube in the male reproductive system in which sperm travel from the epididymis to the urethra.
- vasa recta** The capillary system that serves the loop of Henle.
- vascular bundle** (vas'-kyu-lər) A strand of vascular tissues (both xylem and phloem) in a stem or leaf.
- vascular cambium** A cylinder of meristematic tissue in woody plants that *iv*; *Jcn* layers of secondary vascular tissue called secondary xylem (wood) and secondary phloem.
- vascular cylinder** The central cylinder of vascular tissue in a root.
- vascular plant** A plant with vascular tissue. Vascular plants include all living species except mosses, liverworts, and hornworts.
- vascular tissue** Plant tissue consisting of cells joined into tubes that transport water and nutrients throughout the plant body.
- vascular tissue system** A system formed by xylem and phloem throughout a vascular plant, serving as a transport system for water and nutrients, respectively.
- vasectomy** The cutting of each vas deferens to prevent sperm from entering the urethra.
- vasocongestion** The filling of a tissue with blood, caused by increased blood flow through the arteries of that tissue.
- vasoconsanction** A decrease in the diameter of superficial blood vessels triggered by nerve signals that contract the muscles of the vessel walls.
- vasodilation** An increase in the diameter of superficial blood vessels triggered by nerve signals that relax the muscles of the vessel walls.
- vegetal pole** The portion of the egg where most yolk is concentrated; opposite of animal pole.
- vegetative reproduction** Cloning of plants by asexual means.
- vein** (1) In animals, a vessel that returns blood to the heart. (2) In plants, a vascular bundle in a leaf.
- ventilation** Any method of increasing contact between the respiratory medium and the respiratory surface.

- ventral** Pertaining to the underside, or bottom, of a bilaterally symmetrical animal.
- ventricle** (ven'-truh-kul) (1) A heart chamber that pumps blood out of a heart. (2) A space in the vertebrate brain, filled with cerebrospinal fluid.
- venule** (ven'-yool) A vessel that conveys blood between a capillary bed and a vein.
- vernation** The use of cold treatment to induce a plant to flower.
- vertebrate** A chordate animal with a backbone: the mammals, reptiles (including birds), amphibians, sharks and rays, ray-finned fishes, and lobe-fins.
- vesicle** A sac made of membrane made of cells.
- vessel element** A short, wide, walled-concaving cell found in the xylem of most angiosperms and a few nonflowering vascular plants.
- Dead at maturity, vessel elements are aligned end to end to form micropipes called vessels.
- vessels** Continuous water-conducting micropipes found in most angiosperms and a few nonflowering vascular plants.
- vestibule** The cavity enclosed by the labia minora; the space into which the vagina and urethral opening empty.
- vestigial organ** A structure of marginal, if any, importance to an organism. Vestigial organs are historical remnants of structures that had important functions in ancestors.
- villus** (plural, villi) (1) A fingerlike projection of the inner surface of the small intestine. (2) A fingerlike projection of the chorion of the mammalian placenta. Large numbers of villi increase the surface areas of these organs.
- viral envelope** A membrane that cloaks the capsid that in turn encloses a viral genome.
- viroid** (vīrōid) A plant pathogen composed of molecules of naked circular RNA only several hundred nucleotides long.
- virulent** A term describing a pathogen against which a plant has little specific defense.
- virulent phage** A phage that reproduces only by a lytic cycle.
- visceral mass** One of the three main parts of a mollusc, containing most of the internal organs.
- visible light** That portion of the electromagnetic spectrum detected as various colors by the human eye, ranging in wavelength from about 380 nm to about 750 nm.
- vital capacity** The maximum volume of air that a respiratory system can inhale and exhale.
- vitamin** An organic molecule required in the diet in very small amounts. Vitamins serve primarily as coenzymes or parts of coenzymes.
- vitamin D** One of the fat-soluble vitamins. The active form functions as a hormone, acting in concert with parathyroid hormone in bone and promoting the uptake of calcium from food within the intestines.
- vitreous humor** The jellylike material that fills the posterior cavity of the vertebrate eye.
- viviparous** (vī-pär'ē-əs) Referring to a type of development in which the young are born alive after having been nourished in the uterus by blood from the placenta.
- vocal cord** One of a pair of thin, elastic bands in the larynx. Air rushing past the tensed vocal cords makes them vibrate, producing sounds.
- voltage-gated ion channel** A specialized ion channel that opens or closes in response to changes in membrane potential.
- vulva** Collective term for the female external genitalia.
- water potential** The physical property predicting the direction in which water will flow, governed by solute concentration and applied pressure.
- water vascular system** A network of hydraulic canals unique to echinoderms that branches into extensions called tube feet, which function in locomotion, feeding, and gas exchange.
- wavelength** The distance between crests of waves, such as those of the electromagnetic spectrum.
- wetland** An ecosystem intermediate between an aquatic one and a terrestrial one. Wetland soil is saturated with water permanently or periodically.
- white blood cell** A blood cell that functions in defending the body against infections and cancer cells; also called a leukocyte.
- white matter** Tracts of axons within the CNS.
- wild type** An individual with the normal (most common) phenotype.
- wilting** The drooping of leaves and stems as a result of plant cells becoming flaccid.
- wobble** A violation of the base-pairing rules in that the third nucleotide (5' end) of a tRNA anticodon can form hydrogen bonds with more than one kind of base in the third position (3' end) of a codon.
- xerophyte** A plant adapted to an arid climate.
- X-ray crystallography** A technique that depends on the diffraction of an X-ray beam by the individual atoms of a molecule to study the three-dimensional structure of the molecule.
- xylem** (zīl'əm) Vascular plant tissue consisting mainly of tubular dead cells that conduct most of the water and minerals upward from roots to the rest of the plant.
- yeast** Single-celled fungi that inhabit liquid or moist habitats and reproduce asexually by simple cell division or by the pinching off of small buds off a parent cell.
- yeast artificial chromosome (YAC)** A vector that combines the essentials of a eukaryotic chromosome—an origin for DNA replication, a centromere, and two telomeres—with foreign DNA.
- yolk** Nutrients stored in an egg.
- yolk plug** Large food-laden endodermal cells surrounded by the blastopore of an amphibian gastrula.
- yolk sac** One of four extraembryonic membranes that support embryonic development; the first site of blood cells and circulatory system function.
- Z lines** The borders of a sarcomere.
- zero population growth (ZPG)** A period of stability in population size, when the per capita birth rate and death rate are equal.
- zonula pellucida** The extracellular matrix of a mammalian egg.
- zone of cell division** The zone of primary growth in roots consisting of the root apical meristem and its derivatives. New root cells are produced in this region.
- zone of elongation** The zone of primary growth in roots where new cells elongate, sometimes up to ten times their original length.
- zone of maturation** The zone of primary growth in roots where cells complete their differentiation and become functionally mature.
- zone of polarizing activity (ZPA)** A limb-bud organizer region consisting of a block of mesoderm located where the posterior side of the bud is attached to the body.
- zoned reserve** An extensive region of land that includes one or more areas undisturbed by humans surrounded by lands that have been changed by human activity and are used for economic gain.
- zoospores** Flagellated spores occurring in chytrid fungi.
- zygomycete** Member of the fungal phylum Zygomycota, characterized by forming a sturdy structure called a zygosporangium during sexual reproduction.
- zygosporangium** In zygomycete fungi, a sturdy multicellular structure in which karyogamy and meiosis occur.
- zygote** The diploid product of the union of haploid gametes in conception; a fertilized
